Hence, Viviani's curve is truly spherical.

Exercise 1.7.11. Show that the following curve is spherical.

$$(a\cos^2(t),\, a\sin(t)\cos(t),\, a\sin(t))$$

In Exercise 1.3.15, curves of constant precession were discussed. The recreate procedures above may be used to create curves of constant precession by choosing $\kappa(s) = -a\sin(bs)$ and $\tau(s) = a\cos(bs)$ for constants $a > 0$ and b. However, in [Sco95], an explicit parametrization for such curves is derived. Furthermore, it is shown that any such curve lies on a hyperboloid of one sheet (which we shall consider several times in this book) with the formula

$$x^2 + y^2 - \frac{b^2}{a^2}\,z^2 = \frac{4b^2}{a^4}.$$

The explicit parametrization is given by

$$\begin{aligned}
x(s) &= \frac{c+b}{2c(c-b)}\,\sin([c-b]s) - \frac{c-b}{2c(c+b)}\,\sin([c+b]s)\\
y(s) &= -\frac{c+b}{2c(c-b)}\,\cos([c-b]s) + \frac{c-b}{2c(c+b)}\,\cos([c+b]s)\\
z(s) &= \frac{a}{bc}\,\sin(bs)
\end{aligned}$$

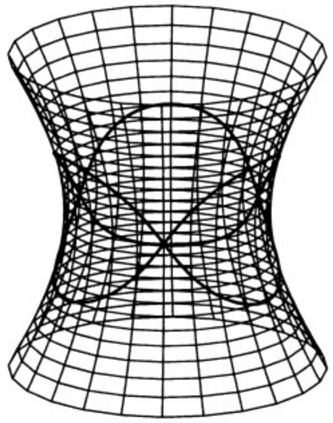

Figure 1.40. Constant precession curve with $a = 4$ and $b = 3$

where $c = \sqrt{a^2 + b^2}$. The following procedure graphs curves of constant precession on the associated hyperboloids.

```
> constprec:=proc(a,b)
local c,alpha,a1,a2,hyp,pl1,pl2;
c:=sqrt(a^2+b^2);
a1:=c+b;
a2:=c-b;
alpha:=[a1/(2*c*a2)*sin(a2*s)-a2/(2*c*a1)*sin(a1*s),
-a1/(2*c*a2)*cos(a2*s)+a2/(2*c*a1)*cos(a1*s),
a/(b*c)*sin(b*s)];
hyp:=[2*b/a^2*cosh(r)*cos(q),2*b/a^2*cosh(r)*sin(q),
2/a*sinh(r)];
pl1:=tubeplot(alpha,s=0..2*Pi,radius=0.01,color=black,
numpoints=200);
pl2:=plot3d(hyp,r=-1..1,q=0..2*Pi);
display({pl1,pl2},scaling=constrained,style=wireframe,
shading=XY);
end:
```

Let's take a curve of constant precession with $a = 4$ and $b = 3$. See Figure 1.40.

```
> constprec(4,3);
```

Exercise 1.7.12. Graph the curves of constant precession with $a = 15$, $b = 8$ and with $a = \sqrt{6}$, $b = \sqrt{2}$. Can you make a conjecture about when curves of constant precession are closed curves? See [Sco95].

Exercise 1.7.13. Graph the unit tangent vector $T(s)$ (i.e., the *tantrix* or *tangent indicatrix*) for curves of constant precession with $a = 15$, $b = 8$ and with $a = \sqrt{6}$, $b = \sqrt{2}$. Use "display" to graph $T(s)$ on the unit sphere. Can you make a conjecture about the number of cusps of such curves? For a discussion of tangent indicatrices of spherical curves, see [Sol96].

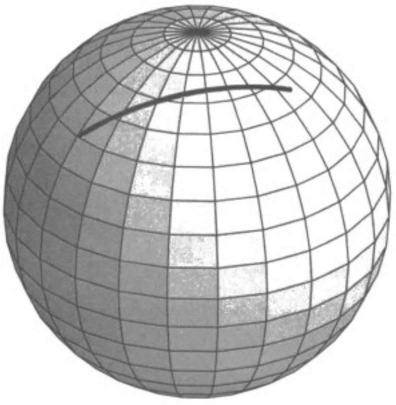

Figure 1.41. New York to Moscow

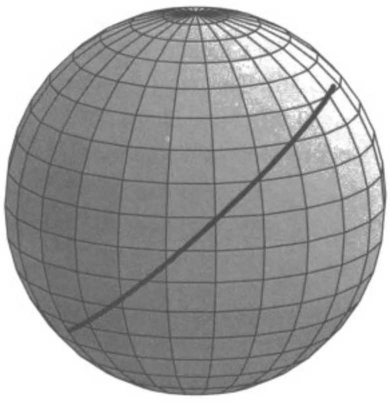

Figure 1.42 Cleveland to Sydney

Exercise 1.7.14. The following procedure draws the great circle arc between two points A and B on Earth and gives the distance between the points (assuming the radius of the Earth to be 3970 miles). A and B are given by longitude and latitude coordinates. For example A=[100,25] means that the point A has longitude 100 degrees and latitude 25 degrees. We take positive longitude to be east of Greenwich, England and negative longitude to be west of it. We also assume that the Earth is a sphere with parametrization (see Chapter 2) ($R\cos(u)\cos(v)$, $R\sin(u)\cos(v)$, $R\sin(v)$), R being the radius of the Earth.

Explain every line of the procedure. This should be a good test of the vector calculus used in this chapter.

CHAPTER I

THE properties of circles discussed in this chapter are those which have the habit of appearing in other branches of mathematics.

1. The nine-point circle

This circle is the first really exciting one to appear in any course on elementary geometry. It is a circle which is found to pass through nine points intimately connected with a given triangle ABC. Three proofs are given. Each has its own peculiar merits.

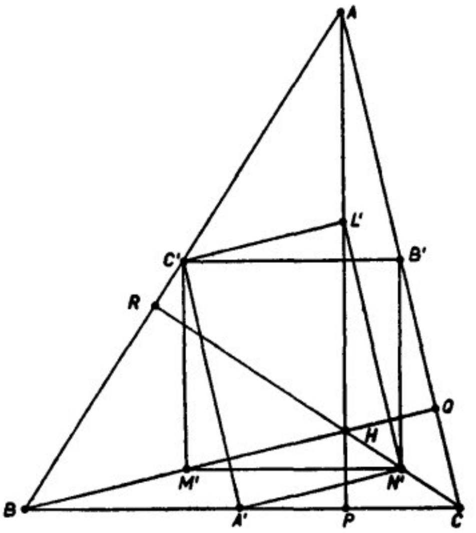

FIG. 1

(i) H is the orthocentre of triangle ABC, the intersection of the altitudes AP, BQ, CR. The midpoints of BC, CA and AB are A', B' and C' respectively. L', M', N' are the midpoints of HA, HB, HC. We show that a circle passes through the nine points A', B', C', L', M', N', P, Q, R. We use the theorem that the line joining the midpoints of two sides of a triangle is parallel to the third side.

Both $B'C'$ and $N'M'$ are $\parallel$ to BC, and both $B'N'$ and $C'M'$ are $\parallel$ to AH. Hence $B'C'M'N'$ is a rectangle. Similarly $C'A'N'L'$ is a rectangle.

Hence $A'L'$, $B'M'$ and $C'N'$ are three diameters of one circle. Since $A'P$ and $L'P$ are $\perp$, this circle passes through P. Similarly it passes through Q and R.

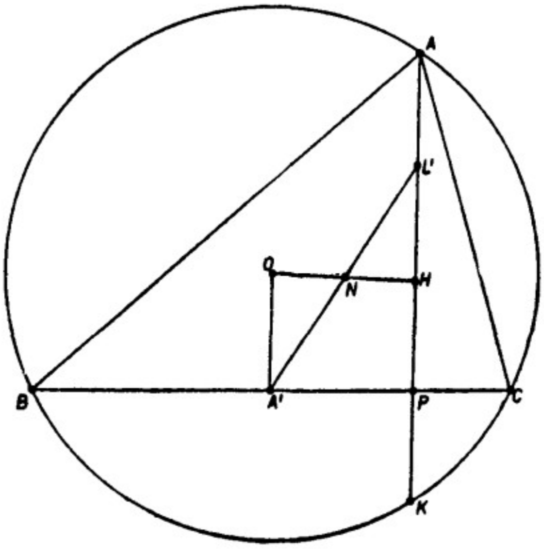

FIG. 2

(ii) Let O be the circumcentre of ABC and R the circumradius. We know that $AH = 2OA'$. Since L' bisects AH, $L'H = OA'$, and therefore OH and $L'A'$ bisect each other, in N, say.

Now $NL' = NA' = NP$ (since $\angle APB = 90°$). We also know that $HP = PK$, and since $ON = NH$, we have

$$NP = \tfrac{1}{2}OK = \tfrac{1}{2}R.$$

Therefore the circle centre N and radius $\frac{1}{2}R$ passes through P, A', L'. Similarly it passes through Q, B', M' and R, C', N'.

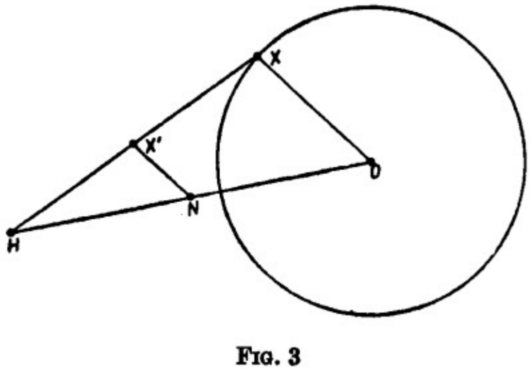

FIG. 3

(iii) The third proof uses a lemma from the theory of similar figures. If X is a point on a given circle of centre O and radius R, and H is any given fixed point, the locus of X', the midpoint of HX, is a circle centre N, where N bisects HO, and radius $\frac{1}{2}R$. The proof is clear.

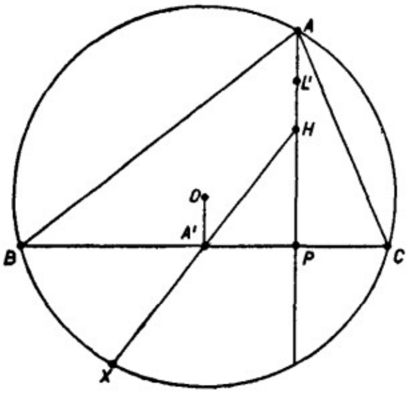

FIG. 4

Applying this lemma to the case of the circumcircle of ABC, H being the orthocentre, we see that a circle centre N and radius $\frac{1}{2}R$ passes through P, Q, R, L', M', N'. We must now show that this circle also passes through A', B', C'. It is sufficient to show that if HX contains A', then HX is bisected at A'.

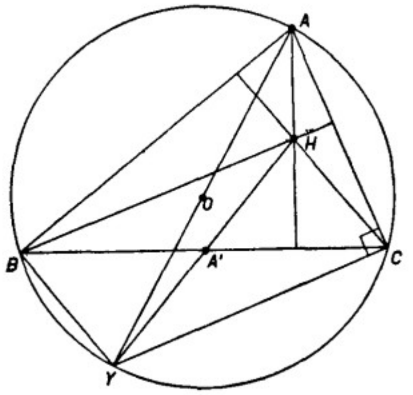

FIG. 5

Let AO meet the circumcircle in Y. Then $\angle ACY = 90°$, so that $YC \parallel BH$. Since also $\angle ABY = 90°$, $YB \parallel CH$. Therefore $YBHC$ is a parallelogram, and the diagonals YH and BC

bisect each other. Hence Y is the same point as X in the previous diagram, and the theorem is proved.

The methods used above are elementary, and at least one of the three proofs will be familiar to most readers of this book. In chapter II we shall need to assume some theorems in inversion and coaxal systems of circles. As fashions in mathematical teaching change, it cannot be assumed that all readers will be familiar with these theories, and a brief (but adequate) outline of each will now be given.

2. Inversion

This is a one-to-one transformation of the points of the plane by means of a given circle, which we shall call Σ, of radius k and centre O. To obtain the transform X' of any given point X, or the *inverse* of X in the circle Σ, we join X to O, and find X' on OX such that $OX.OX' = k^2$. The point O itself is excluded from the points of the plane which may be transformed. It is clear that

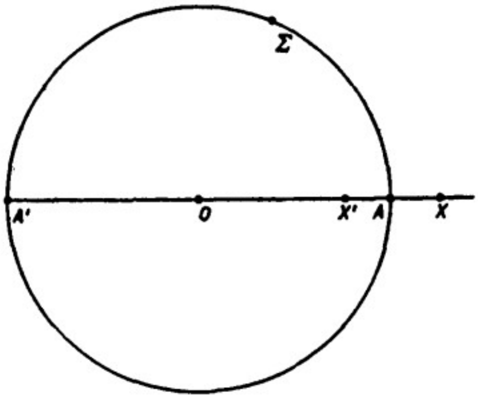

FIG. 6

(i) X is the inverse of X';
(ii) points on Σ transform into themselves;
(iii) if A, A' are the ends of the diameter of Σ through X, then X, X' are harmonic conjugates with respect to A, A'.

All circles through X and X' cut Σ orthogonally, since the square of the tangent from O to such a circle $= OX.OX' = k^2$.

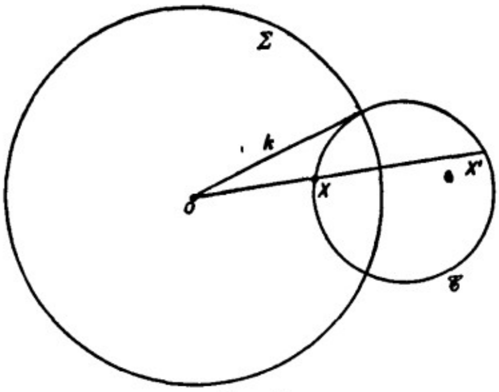

FIG. 7

As a corollary to this remark, we see that if $\mathscr{C}$ is any circle orthogonal to Σ, all points on $\mathscr{C}$ invert into points on $\mathscr{C}$, for $OX.OX' = k^2$. It is sometimes necessary to consider the process of inversion when Σ, the circle of inversion, is a line. If we keep A fixed, and let A' move off to infinity, we see that X' moves towards the geometrical image of X in the resulting line.

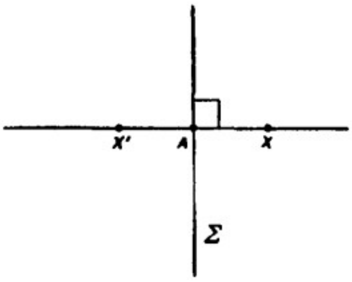

FIG. 8

For future application we now give a construction, using only a

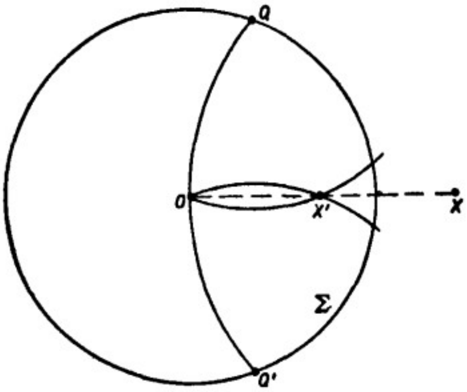

FIG. 9

pair of compasses, by which we can find the inverse of a point X in a circle Σ of given centre O. Let the circle centre X and radius XO cut Σ in Q and Q', and let O and X' be the intersections of the two circles with centres Q and Q' and radii QO and $Q'O$ respectively. Then X' is the inverse of X in Σ.

For QOX and $X'OQ$ are isosceles triangles with a common base angle. They are therefore similar, and $OX : OQ = OQ : OX'$. Hence $OX . OX' = OQ^2$.

This construction lies at the basis of the discussion on *compass geometry* in §11.

We are interested in the locus of inverse points X' as X describes a given curve $\mathscr{C}$. This locus is called the *inverse of the curve* $\mathscr{C}$ with respect to Σ. When $\mathscr{C}$ is a circle orthogonal to Σ, we have seen that the inverse is $\mathscr{C}$ itself. The general theorem is:

The inverse of a circle is a straight line or a circle.

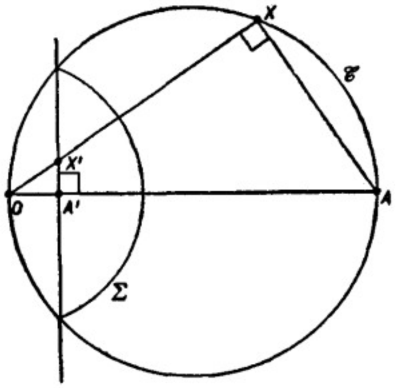

FIG. 10

(i) The centre of inversion O is on $\mathscr{C}$:

Let OA be the diameter of $\mathscr{C}$ through O, and let A' be the inverse of A. Then $OA . OA' = k^2$. If X is any point on $\mathscr{C}$, and X' its inverse,

$$OX . OX' = k^2 = OA . OA'.$$

Hence A, X, X', A' are concyclic points, and since $\angle AXO = 90°$, $\angle X'A'A = 90°$. Therefore X' describes the line through $A' \perp$ to OA.

We note that this line is $\|$ to the tangent to $\mathscr{C}$ at O. It naturally passes through the intersections of $\mathscr{C}$ and Σ, since points on Σ invert into themselves.

Corollary. The inverse of a straight line is a circle through the centre of inversion.

(ii) The centre of inversion O is not on $\mathscr{C}$. Let C be the centre of $\mathscr{C}$. Since

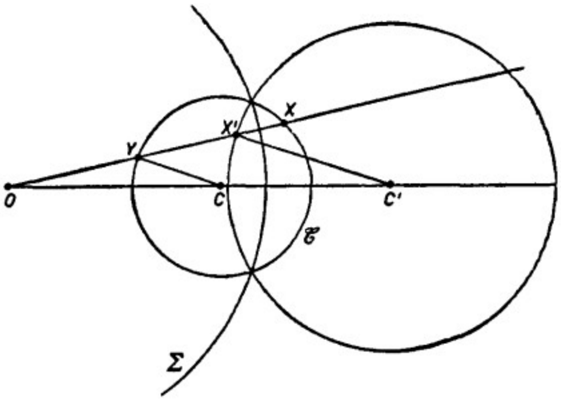

FIG. 11

$$OX.OX' = k^2,$$

and
$$OX.OY = t^2,$$

where t is the tangent[†] from O to $\mathscr{C}$, by division we have

$$\frac{OX'}{OY} = \frac{k^2}{t^2}.$$

Since this ratio is constant, it follows that if C' is a point on OC such that $C'X' \parallel CY$, then C' is a fixed point, and $C'X'$ is constant. Hence X' moves on a circle centre C'.

Note that C' is not necessarily the inverse of C. We shall soon find what point the centre of $\mathscr{C}$ does invert into.

We need only one further theorem from the theory of inversion:

The angle of intersection of two circles is unaltered by inversion.

In fact a more general theorem is true, but this one will suffice for our subsequent needs.

[†] We shall see later that t^2 may be negative. Then O is inside $\mathscr{C}$.

(i) If both circles $\mathscr{C}$ and $\mathscr{D}$ pass through the centre O of inversion, they transform into straight lines parallel to the tangents to $\mathscr{C}$ and $\mathscr{D}$ at O, so that the theorem is evident.

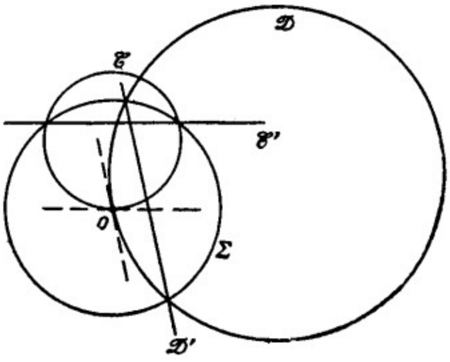

FIG. 12

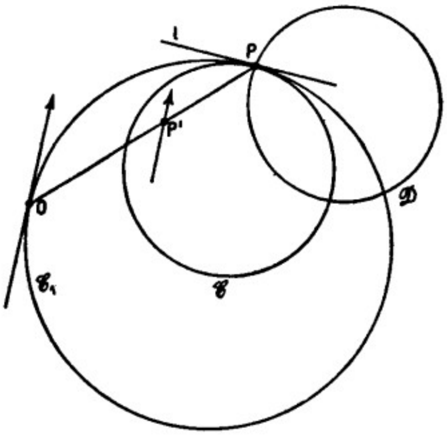

FIG. 13

(ii) If at least one of the circles $\mathscr{C}$, $\mathscr{D}$ does not pass through O, let P be a point of intersection of the two circles, and let l, m be the tangents at P to $\mathscr{C}$, $\mathscr{D}$ respectively. We may draw a circle $\mathscr{C}_1$ through O which touches l at P, and a circle $\mathscr{D}_1$ through O which touches m at P. Then the angle between $\mathscr{C}_1$ and $\mathscr{D}_1$ is the same as that between $\mathscr{C}$ and $\mathscr{D}$.

Now if P' is the inverse of P, the tangent at P' to the inverse of $\mathscr{C}$ is the inverse of $\mathscr{C}_1$. Hence the angle between the circles inverse to $\mathscr{C}$ and to $\mathscr{D}$ is equal to the angle between $\mathscr{C}_1$ and $\mathscr{D}_1$ (by (i) above), and this is equal to the angle between $\mathscr{C}$ and $\mathscr{D}$.

With the help of this theorem we can now find the inverse of the centre of a circle $\mathscr{C}$. All lines through the centre C cut $\mathscr{C}$ orthogonally. These lines invert into circles through the centre of inversion O and the inverse of C. Since all circles through O and the inverse of C cut the inverse of $\mathscr{C}$ orthogonally, the inverse of C must be *the inverse of O in the inverse of* $\mathscr{C}$.

If O lies on $\mathscr{C}$, so that the inverse of $\mathscr{C}$ is a straight line, the centre of $\mathscr{C}$ inverts into the geometrical image of O in this line.

We now give some applications of the theory of inversion.

3. Feuerbach's theorem

The nine-point circle of a triangle touches the incircle and excircles of the triangle.

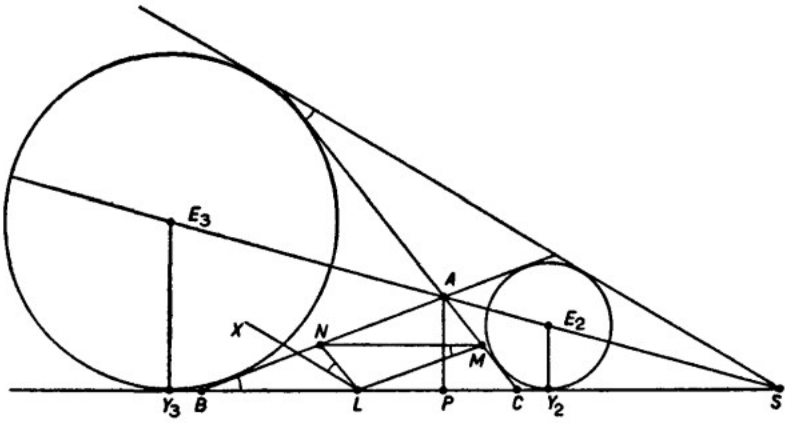

FIG. 14

We consider the excircles opposite B and C. Let their centres be E_2 and E_3, and their points of contact with BC Y_2 and Y_3. The points A, S divide E_2E_3 internally and externally in the same ratio, that of the radii of the two excircles. Dropping perpendiculars on BC, it follows that P and S also divide Y_2Y_3 internally and externally in the same ratio. That is, P and S are harmonic conjugates with respect to Y_2 and Y_3.

Let L, M, N be midpoints of BC, CA, AB. We note that $BY_2 = \frac{1}{2}(BC + CA + AB) = CY_3$, so that L is also the midpoint of Y_2Y_3. From the harmonic relation just proved we see that

$$LP \, . \, LS = LY_2{}^2 = LY_3{}^2.$$

Now let LX be the tangent at L to the circle LMN, where X is on the same side of BC as N. Then

$$\angle XLN = \angle NML = \angle ABC.$$

Hence the angle between LX and $CA = \angle ABC$. It follows that LX is $\parallel$ to the fourth common tangent of the two excircles, the common tangent through S other than BC.

Now since $LP.LS = LY_2^2 = LY_3^2$, the nine-point circle LMN is the inverse of this fourth common tangent with respect to the circle centre L and radius LY_2. For this nine-point circle contains P, and inverts into the line through S parallel to the tangent to the circle at L.

Also since the circle of inversion cuts both excircles orthogonally, each excircle inverts into itself. We have seen that the inverse of the nine-point circle touches these excircles. It follows that the nine-point circle touches the excircles centres E_2, E_3. In precisely the same way we can show that the nine-point circle touches the incircle and the excircle opposite A.

4. Extension of Ptolemy's theorem

If A, B, C, D are any four points in a plane, then

$$AB.CD + AD.BC > AC.BD,$$

unless A, B, C, D lie, in the order $ABCD$, on a circle or a straight line. In the latter case, the inequality becomes an equality.

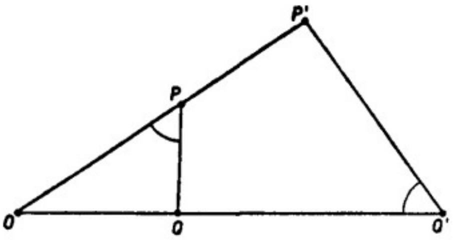

FIG. 15

This is proved by noting the influence of inversion on the length of a segment. If the points P, Q invert into the points P', Q', with O as centre of inversion, then OPQ and $OQ'P'$ are similar triangles. Hence

$$\frac{P'Q'}{PQ} = \frac{OP'}{OQ} = \frac{OP.OP'}{OP.OQ} = \frac{k^2}{OP.OQ},$$

so that

$$P'Q' = \frac{k^2\,PQ}{OP.OQ}.$$

Now, given the four points A, B, C, D, we invert with respect to A. Let B', C', D' be the respective inverses of B, C, D. Then $B'C' + C'D' > B'D'$ unless C' lies on the line $B'D'$ between B' and D′. In the latter case we have

$$B'C' + C'D' = B'D'.$$

The first inequality becomes

$$\frac{BC}{AB.AC} + \frac{CD}{AC.AD} > \frac{BD}{AB.AD},$$

or

$$AB.CD + AD.BC > AC.BD,$$

unless C' lies on the line $B'D'$ between B' and D', in which case A, B, C, D lie on a circle in the order $ABCD$, or on a straight line.

5. Fermat's problem

A, B, C are any three points in a plane. To find a point P such that $PA + PB + PC$ shall be least.

Let B and C be the acute angles of the triangle ABC. On BC, and away from A, describe an equilateral triangle BCD. Then by the extension of Ptolemy's theorem, unless P lies on the circle BCD so that the order of the points is $BPCD$, we have

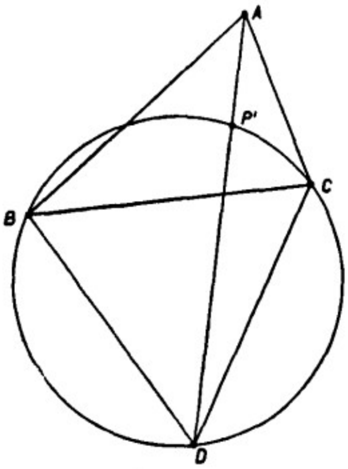

FIG. 16

$$BP.CD + PC.DB > PD.BC,$$

or

$$PB + PC > PD,$$

since $CD = DB = BC$. Therefore

$$PA + PB + PC > PA + PD.$$

Now, unless P lies on AD, we have $PA + PD > AD$. Hence, unless P is at P' (the other intersection of AD with the circle BCD), we have $PA + PB + PC > AD$.

But if P is at P', both the above inequalities become equalities; so that $P'A + P'B + P'C = AD$.

Hence $P'A + P'B + P'C < PA + PB + PC$.

Therefore P' is the required point.

If $\angle BAC = 120°$, $A = P'$, and A is the required point.

If $\angle BAC > 120°$, A is still the required point.

6. The centres of similitude of two circles

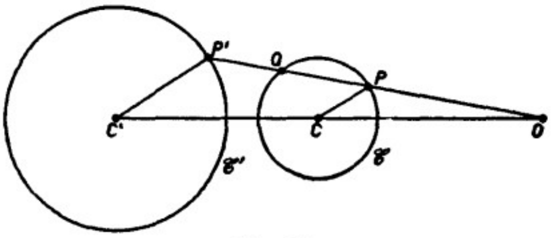

FIG. 17

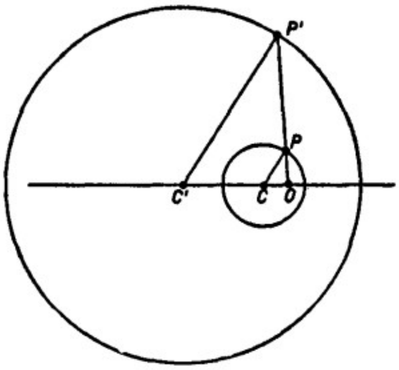

FIG. 18

These points have already appeared in some of our proofs. We now define them.

External centre of similitude. Let $\mathscr{C}$ and $\mathscr{C}'$ be two circles of unequal radii, with centres C and C'. Let CP and $C'P'$ be parallel radii drawn in the *same* sense. Then it is clear that $P'P$ cuts $C'C$ in a fixed point O, which divides $C'C$ externally in the ratio of the radii of the two circles. This is the external centre of similitude. If the ratio of the radii $= k$, then $OP' : OP = k$. We also have $OP . OQ =$ constant. Therefore

$$OP' . OQ = \text{constant}.$$

It follows that with centre of inversion O, and a suitable radius of inversion, $\mathscr{C}$ can be inverted into $\mathscr{C}'$.

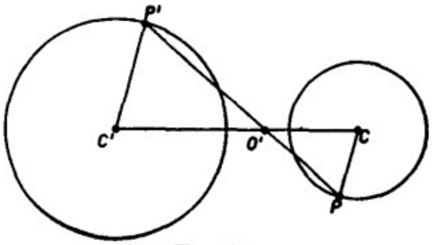

FIG. 19

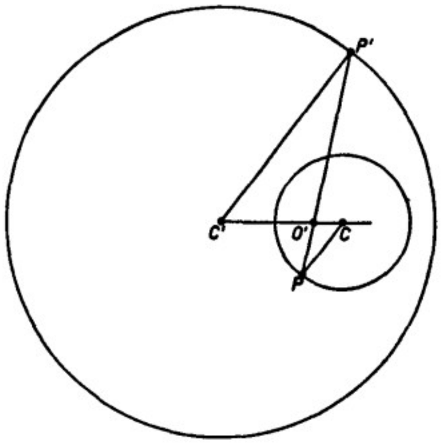

FIG. 20

Internal centre of similitude. Here the radii of the circles $\mathscr{C}$ and $\mathscr{C}'$ may be equal. CP and $C'P'$ are parallel radii in opposite senses. $P'P$ cuts $C'C$ in a fixed point O', the internal centre of similitude, which divides $C'C$ internally in the ratio of the radii.

Direct common tangents of $\mathscr{C}$ and $\mathscr{C}'$, if they exist, cut the line of centres in O, and transverse common tangents, if they exist, cut the line of centres in O'.

If $\mathscr{C}$ and $\mathscr{C}'$ are concentric, the common centre is both the internal and external centre of similitude.

If $\mathscr{C}$ and $\mathscr{C}'$ touch externally, that is, if they lie on opposite sides of the tangent at the point of contact, this point is the *internal* centre of similitude. If the circles touch internally, the point of contact is the *external* centre.

If we have three circles, no two of which have equal radii, and the centres of which form a triangle, the six centres of similitude

3- % 5 *

lie in threes on four straight lines. This is easily proved, using the theorem of Menelaus.

7. Coaxal systems of circles

These are best introduced by using the methods of coordinate geometry.

The equation of any line passing through the origin of coordinates in the (x,y)-plane may be written as

$$\lambda x + \mu y = 0.$$

These lines are said to form a *pencil* of lines, and the equation of the system depends *linearly* on two distinct lines of the pencil, given by $x = 0$ and $y = 0$.

Similarly, if $u \equiv ax + by + c = 0$ and $v \equiv a'x + b'y + c' = 0$ are any two distinct lines, the line

$$\lambda u + \mu v = 0$$

represents, for suitable λ, μ, any line through the intersection of $u = 0$ and $v = 0$.

When we consider two distinct circles $\mathscr{C}$ and $\mathscr{C}'$, given by the equations

$$C \equiv x^2 + y^2 + 2gx + 2fy + c = 0,$$
$$C' \equiv x^2 + y^2 + 2g'x + 2f'y + c' = 0,$$

the system $\lambda C + \mu C' = 0$, derived linearly from them, is a system of circles, since it may also be written as

$$x^2 + y^2 + \frac{2x(\lambda g + \mu g')}{\lambda + \mu} + \frac{2y(\lambda f + \mu f')}{\lambda + \mu} + \frac{\lambda c + \mu c'}{\lambda + \mu} = 0.$$

If (x',y') is a point of intersection of $\mathscr{C}$ and $\mathscr{C}'$,

$$C(x',y') = C'(x',y') = 0,$$

that is, the point satisfies the equations of both circles. Since also, for all values of λ, μ,

$$\lambda C(x',y') + \mu C'(x',y') = 0,$$

this same point lies on all circles of the system $\lambda C + \mu C' = 0$. Such a system of circles therefore passes through the points of intersection (if any) of $\mathscr{C}$ and $\mathscr{C}'$. The system may be described as a *pencil* of circles, but for reasons which will soon become clear, we give it the more normal title of a *coaxal system* of circles.

A geometrical meaning may be given to the ratio of the parameters $\lambda : \mu$. Let $P\,(x',y')$ be any point in the plane, and let any line through P cut $\mathscr{C}$ in Q and R. Then it is elementary that the product

$$PQ.PR = x'^2 + y'^2 + 2gx' + 2fy' + c.$$

- *Scripting the Seeds of a Sunflower* (p. 58)*:* Here you will learn how to perform simple drawing operations with CindyScript. You will also learn how to combine CindyScript with the geometry part of Cinderella.

3.1 Pappus's Theorem

Pappus's theorem is one of the most fundamental theorems in projective geometry. In a certain sense it is the smallest example of an incidence theorem. In this step-by-step example we will construct an instance of the theorem that can be selected and dragged.

3.1.1 Drawing Your First Point

When you start *Cinderella.2*, the first window that appears is a "Euclidean view." This window has a large toolbar that is the key to most of *Cinderella's* functionality. Below this toolbar is the drawing surface on which you perform operations by constructing and dragging the elements you need.

You may notice that in the toolbar one button is slightly darker. This indicates the current mode of *Cinderella*.

All mouse actions in the drawing surface refer to the selected mode. For drawing a single point you have to switch to the add a point (p. 74) mode by clicking it. Now *move the mouse over the drawing surface and click the left button.* A new point is added and labeled with a capital letter.

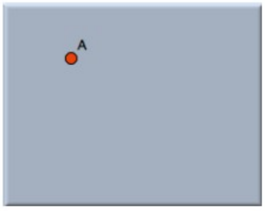

Figure 1: Your first point

Before you add a second point, continue reading. If you hold the left mouse button down while adding a point, you are able to move the point around. The definition of the point will be adapted to the geometric situation at the current location of the mouse pointer. (So far, there is not a lot of geometry in our drawing, but this will change soon.) *Move the mouse over the drawing surface, press the left button, and hold it. Now move the mouse.* You will notice that the new point sticks to the mouse pointer. Coordinates that indicate the current position are shown. When you approach an existing point (*try it*), the new point snaps to the old point. Only after you *release the button* is the new point added to the construction. If you release the mouse over an old point, no new point is added. *Play with these features and add a few new points.*

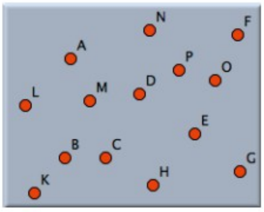

Figure 2: Many points

3.1.2 Undoing an Operation

Your screen may look a bit crowded now. There is an undo operation that inverts the actions you have performed. By pressing the undo button, you will cause the last point you added to disappear. *Click the undo button until exactly two points remain on the drawing surface*. You can use the undo button whenever you make a mistake. You can undo as many consecutive operations as you want.

3.1.3 Moving a Point

We want to continue with our construction of Pappus's theorem. You should first move the two remaining points A and B to approximately the positions shown in Figure 3.

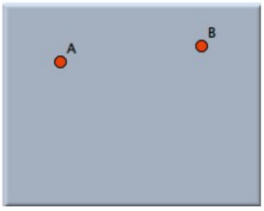

Figure 3: Move to this situation.

Most probably, your points are not already there. To move them, *select move mode* (p. 71) *by pressing the "move mode" button* *in the toolbar*. Now mouse actions in the drawing surface no longer add points; instead, you can select points and move them around. *Move the mouse pointer over the point you want to move. Press the left mouse button. Hold it and drag the mouse.* The point follows the mouse pointer. You will also notice that in this mode a point does not snap to other points. When you *release the mouse button*, the point is placed. In general, move mode allows free elements of a construction to be moved. The rest of the construction will change accordingly.

3.1.4 Adding a Line

We are now going to add a line from *A* to *B*. *Switch to add a line* (p. 76) *mode by pressing the button* . In this mode you can add a line between two points using a press–drag–release sequence with the mouse. *Move over point A. Press the left mouse button. Hold it and move the mouse over point B. Release the mouse.*

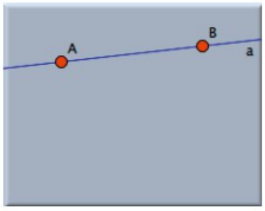

Figure 4: Add a line

This action should have created the desired line. You might have noticed a few things: When you pressed the mouse over point *A*, the point became highlighted. This means that you selected this point as the starting point of the line. While you drag the mouse, a second point is always present at the mouse position. When you release the mouse button, this second point will be added at the release point. When you approach another point, it will be highlighted, and the second point will snap to it. This is the action you used for attaching the line to point *B*.

If you did not notice these things or made a mistake, undo your operations and try again. Your final picture should look like Figure 4 before you proceed.

3.1.5 Adding More Lines

Now you are ready to add three more lines, in order to end up with Figure 5. You can do this with just three mouse operations. *First, move over point B and press–drag to the position of the not-yet-existing point C. Do another press–drag–release from C to D, and finally from D to E.*

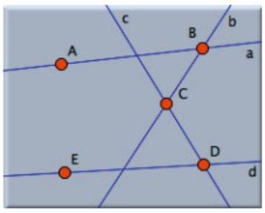

Figure 5: More lines

Observe that you have done all this without leaving "add a line" mode. You did some unnecessary work when you added the points *A* and *B* in add a point (p. 74) mode. You could have done this directly in add a line (p. 76) mode, since not only will the second point be created if necessary, but also the first one. The lines created so far were automatically labeled with the lowercase letters *a* to *d*.

3.1.6 Creating Points of Intersection

We will stay in add a line (p. 76) mode. Now we want to draw a line from point *E* to the intersection of the lines *a* and *c*. *Move the mouse over E. Press the button. Hold it and move to the intersection of a and c. Release the mouse.*

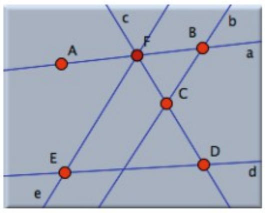

Figure 6: Adding an intersection

When you approached the intersection of the lines, they were highlighted and the endpoint of the new line snapped to the intersection. When you released the mouse, the new point was defined to be the intersection of the lines. If you move any one of the points *A* to *E*, the new line will follow the moves accordingly.

The new point *F* is drawn slightly darker. This means that it is not possible to move *F* freely in move mode. Thus, *F* is a "dependent" point. The other points in the construction are "free."

Two things are worth mentioning: With the same procedure you could also have added a "half-free" point that is bound to only one line. To do so, you need to release the mouse when you are over only one line. All these operations of creating intersections (dependent points), free, and half-free points work similarly in add a point (p. 74) mode. Many other modes, the interactive modes (p. 74), also come with this feature. Browse the reference guide of this manual for further information.

3.1.7 Finishing the Drawing

Now it should be easy for you to finish the drawing by adding four more lines to achieve the final configuration shown in Figure 7. *First add a line from A to the intersection of b and d. Then draw two lines from A to D and from B to E. Finally, draw a line from C to the intersection of e and f.*

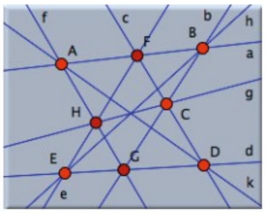

Figure 7: Pappus's theorem

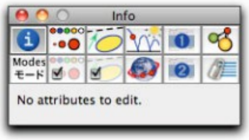
You have created a configuration of eight points and nine lines. If you look at the configuration, you will notice that if everything was done correctly, the lines g, h, and k meet in a point. That this will always be the case in such a construction is the content of Pappus's theorem. *Switch to move mode* (p. 71) *by clicking* *in the toolbar, and drag around the free points of the construction to convince yourself of the truth of this theorem.* This theorem was known to the ancient Greek geometers and is named for Pappus of Alexandria, who flourished in the fourth century C.E. Later, the theorem turned out to be of fundamental importance for the theory of *projective geometry*.

3.1.8 Selecting and Changing the Appearance of a Drawing

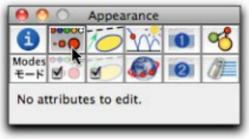
You may not like the appearance of a drawing. The lines may be too thin, and perhaps you want to emphasize the final conclusion of the theorem. This can be changed by using the inspector (p. 153) of *Cinderella.2*. For this *choose the menu item "Edit/Information"*. The following window will pop up:



No attributes to edit.

Figure 8: The inspector

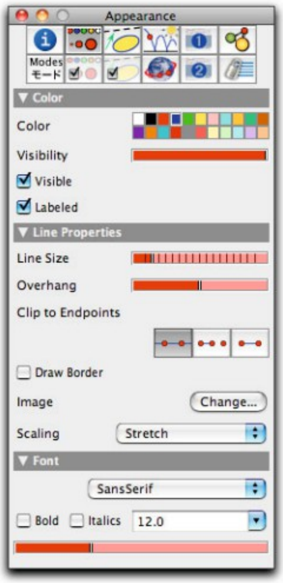
There are several tabs in the inspector that refer to different aspects of the construction and the selected objects. To change the appearance of objects, go to the appearance tab by *clicking the button* . If no elements are selected, the inspector shows that there are no attributes to edit.



No attributes to edit.

Figure 9: Selecting the appearance tab

As soon as an element is selected, the editable attributes of this elements are shown. *Now select all lines by clicking the button* *"Select all lines"*. The inspector window then looks as follows:



▼ Color

Color

Visibility

☑ Visible

☑ Labeled

▼ Line Properties

Line Size

Overhang

Clip to Endpoints

☐ Draw Border

Image Change...

Scaling Stretch

▼ Font

SansSerif

☐ Bold ☐ Italics 12.0

Figure 10: The appearance tab

Changes in the inspector are immediately applied to selected elements. If you now *move the slider "Line Size" in the inspector to its third tick*, all lines become thicker. After this, *switch to move mode* . Now, when you click over one or more elements, those elements will be selected. If you hold the shift key while you click, the selection state of the element will be toggled.

Click over line k, and then hold the shift key and click over lines h and g. The lines *g*, *h*, and *k* should be highlighted. *Click the red color box in the inspector's color palette.* The color of the three lines changes from blue to red. You can also change the size of these lines by moving the "Line Size" slider to its fourth tick. Finally, *deselect everything* by clicking the button .

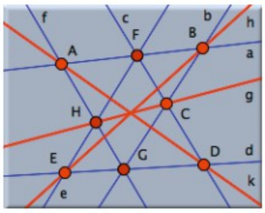


Figure 11: Changed appearance

3.1.9 Adding a Final Point and Proving a Theorem

Before continuing, open *Cinderella's* information window by choosing the menu item *Views/Information Window*. A console window pops up. *Cinderella.2* uses this console to report nontrivial facts about a configuration.

We will now create a final point at the intersection of the three red lines. This time we will add a point by *changing to intersection* (p. 92) *mode* . This mode expects you to mark two lines. A new point will be added at the intersection of these two lines. *Click two of the red lines, say g and h*. Their intersection point will be added.

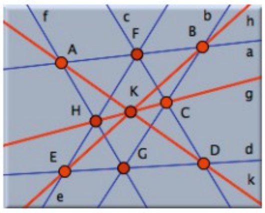

Figure 12: The point of intersection

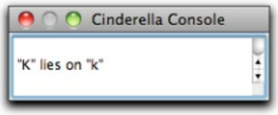
Note that the newly added point *K* will always be incident to line *k* because of Pappus's theorem. The information console reports this remarkable fact automatically.



```
"K" lies on "k"
```

Figure 13: A proven theorem

You may wonder how this "theorem proving" works. *Cinderella* does not use symbolic methods to create a formal proof, but a technique called "randomized theorem checking." First the conjecture, "it seems that line *k* always passes through point *K*," is generated. Then the configuration is moved into many different positions, and for each of these it is checked whether the conjecture holds. It may sound ridiculous, but generating enough (!) random (!) examples in which the theorem holds is at least as convincing as a computer-generated symbolic proof. *Cinderella* uses this method over and over to keep its own data structures clean and consistent.

3.1.10 Moving Points to Infinity

Let us explore the symmetry properties of Pappus's theorem. For a nicer picture, we want to get rid of the line labels and make the points and lines a bit smaller. *First select all lines using . Turn off the labeling by pressing the corresponding button in the inspector. Change the line size to "thin" (use the slider in the inspector). Then select all points using . Make them smaller using the "Point Size" slider in the* *inspector (observe that the inspector shows always information about the selected elements). Now choose the menu option "Views/Spherical View"*. What you get will not look very instructive at first glance.

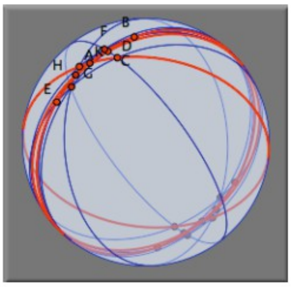


Figure 14: A spherical view

The spherical view shows a central projection of the plane to the surface of a ball. The projection point is the center of the sphere (see Figure 15). Every point is mapped to an antipodal pair of points, and each line is mapped to a great circle (a circle on the sphere dividing it into two equal hemispheres) of the ball.

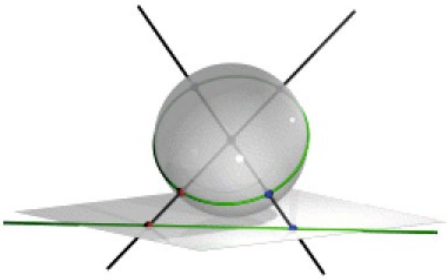

Figure 15: Projection from the plane to the ball

In spherical view there is a little red slider for controlling the distance of the ball to the original plane. Moving this slider corresponds to a kind of "zooming" operation on the sphere. Please *move the slider from its original position much more to the right.* Then the situation on the ball should become clearer. If you have adjusted the slider correctly, it should look somewhat like Figure 16. You should clearly recognize the original construction, now drawn on the surface of this ball.

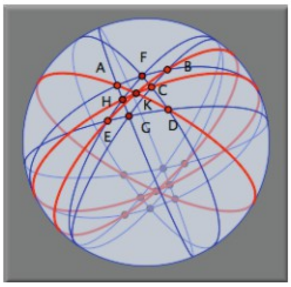

Figure 16: Pappus's theorem on a ball

The picture needs some explanation: For each point in the plane consider the line spanned by the point and the center of the ball. The intersection of this line with the surface of the ball gives the pair of antipodal points. For each line consider the plane spanned by the line and the center of the ball. The intersection of this plane and the surface of the ball is the great circle that represents the line in spherical view.

On the sphere there are points that have no correspondence in the Euclidean plane. If the ball touches the Euclidean plane at the "south pole," then the equator of the ball corresponds to the "points at infinity" in the usual Euclidean plane. In *Cinderella* it is possible to make manipulations in any currently open view. Therefore you can also move points in spherical view. The changes will be instantly reported to the Euclidean view. In particular, you can grab a point in spherical view and move it to what is really infinity in the Euclidean view.

We will do that now, in order to observe that our configuration has a nice threefold symmetry. *Select point A (in spherical view) and move it to the 11 o'clock position of the boundary.* This point is now really located "at infinity." Notice that in Euclidean view the lines passing through *A* became parallel, corresponding to the notion that "parallel lines meet at infinity." In a similar way, *move point E to the 7 o'clock position on the boundary and move point C to the 3 o'clock position.* Your spherical picture should then look like the ball in Figure 17. In Euclidean view you find three bundles of parallel lines, representing a kind of Euclidean specialization of Pappus's theorem. If you like, you can try to figure out the corresponding statement in terms of parallels and incidences.

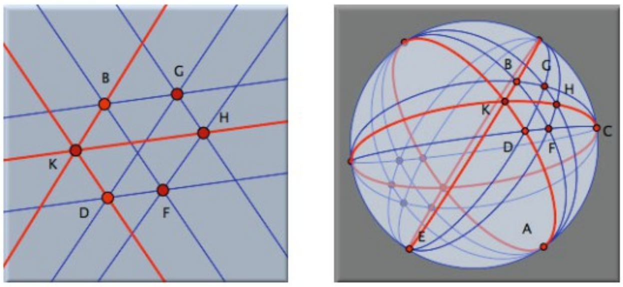

Figure 17: A threefold symmetry

It may happen that the drawing in Euclidean view is too big or too small. You can use the zooming tools to change this. There is a “Zoom-In” and a “Zoom-Out” tool below the Euclidean view. With a press–drag–release sequence you can mark the region to be zoomed in or out.

3.2 A Three-Bar Linkage

In the second tutorial we want to explore the dynamics of a little mechanical linkage. In particular, you will learn how to make bars of a fixed length. You will also learn how to produce a geometric locus of a point.

3.2.1 *Making a Bar*

After starting *Cinderella* or erasing a previous configuration, *switch to circle by radius* (p. 82) *mode by pressing the button* . This mode is used for working with circles whose radii remain constant when their centers move. *Move the mouse pointer over the view. Press the left mouse button. Hold the button while dragging the mouse. Release the mouse.* With these actions you have generated a circle. Switch to move mode (p. 71) to see how the circle behaves. When you select the center you can move the position of the circle, and the radius stays constant. You can also select the circle itself and move it. Then its center stays fixed and the radius of the circle changes.

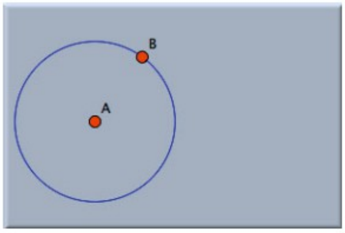

Figure 1: A first circle

We now want to add a point that is bound to the boundary of the circle. *Select add a point* (p. 74) *mode. Move the mouse over the view. With the button pressed, move the mouse pointer to the boundary of the circle. When the circle is highlighted, release the mouse.* You have now created a point that is on the boundary of the circle. You could alternatively have clicked the mouse over the circle boundary. However, that gives you a bit less control over whether you actually hit the circle. Your configuration should now look approximately like that in Figure 1.

Switch to move mode (p. 71) *to see how this new point behaves.* If you select it and drag the mouse, the point will never leave the circle; it attempts to remain as close to the mouse position as possible. When you move the center of the circle or change the circle's radius, the point also stays on the circle. The point furthermore keeps its relative angle to the center. *Choose the interactive add a segment* (p. 84) *mode by pressing the and draw a segment from the center to the point on the perimeter* (see Figure 2).

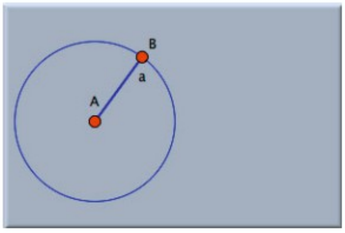

Figure 2: A bar

This line now behaves like a bar of fixed length, given by the radius of the circle. The only way to change its length is to change the radius of the circle.

3.2.2 Adding Two More Bars

We now want to add two more bars to complete the three-bar linkage that was presented in the introduction (p. 5). The linkage is a chain of three consecutive bars that is pinned down at each of its ends. *Switch to circle by radius* (p. 82) *mode again and add a second circle to the right of the first one. Do not let the two circles intersect.*

The radius of the second circle represents the length of the third bar in the row (we have not created the second one yet). Before finishing the construction we should analyze the situation. If point *C* in our construction is to be linked to point *B* of the construction by two bars of given lengths, then there is not much freedom for the point that is common to those two bars. In fact, there are exactly two possible positions for this point. They are the two intersections of two circles: one circle around *C*, already drawn, and another, yet to be drawn, circle around *B*.

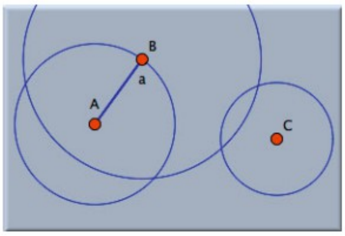

Figure 3: Two more circles

Therefore, as the next step, *draw a circle around point B in circle by radius* (p. 82) *mode. Make sure that its radius is large enough so the circle intersects the circle*

The *projective plane* consists of the points of the usual, Euclidean, plane together with one additional "infinite" point for every possible direction. The lines of the projective plane are the Euclidean lines together with one special "line at infinity." All infinite points lie on the line at infinity. The following nicely symmetric relations between points and lines hold:

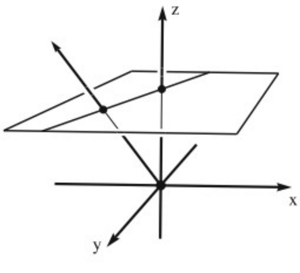
- Every two distinct points have a unique connecting line (their *join*).
- Every two distinct lines have a unique point of intersection (their *meet*).

The first person who formalized these rules, around 1822, was *Victor Poncelet*, a student of Monge, who today may be considered the "father of projective geometry." In projective geometry there is no need to consider parallels as something special. They still have a point of intersection; it just happens to lie at infinity. For a readable introduction to projective geometry we refer to the books of H. S. M. Coxeter on that topic [4, 3].

2.3 Homogeneous Coordinates

On a computer we unfortunately do not have geometric objects as primitive data types. A point or a line has to be represented by numbers: the coordinates. Usually, a point in the plane is described by its (x,y) coordinates. A line may be given by the three parameters (a,b,c) of its defining equation $ax+by+c=0$. However, when we want to do projective geometry, this turns out to be impractical. Each pair of coordinates (x,y) represents a finite point, and there is no representation for the points at infinity. A solution to this problem gradually became clear in the first half of the nineteenth century. It started with Möbius's *barycentric coordinates*, via the refined setup of *homogeneous coordinates* given by Plücker, and finally led to Grassmann's setup of *multilinear algebra*.

The way out of the dilemma is as follows. For every point we use three instead of two coordinates, thereby introducing a third dimension. Consider the following scenario: The plane is embedded parallel to the *xy*-plane of three-space at a height of $z = 1$, so it does not pass through the origin (0, 0, 0).



Embedding the plane in space

Every point (x, y) is represented by its three-dimensional coordinates $(x, y, 1)$. These coordinates are the *homogeneous coordinates* of the point. What happens with the rest of the points in the three-dimensional space? Almost all of them will be interpreted as points in the original plane: we identify all three-dimensional points that differ by a nonzero multiple. For instance, (4, 6, 2) and (2, 3, 1) describe the same point. In general, a point with spatial coordinates (x, y, z) is identified with the point $(x/z, y/z, 1)$ of the original plane. This process is called dehomogenization. In a way, every point of the original plane corresponds to the line spanned by this point and the origin in three-space.

However, there are points in three-space that do not correspond to points in the original plane. The points of the form $(x, y, 0)$ cannot be dehomogenized in the above way, since we would have to divide by zero. These points correspond precisely to the "points at infinity" of projective geometry. To see this, we study the behavior of a point that gradually moves to infinity in the original plane.

Assume that the moving point has coordinates (r, r). As r becomes larger and larger, this point gradually approaches a point at infinity in the 45° direction. Looking at its homogeneous coordinates, we see that they have the form $(r, r, 1) \sim (1, 1, 1/r)$. As r increases, the contribution of the first two coordinates dominates the last coordinate more and more. In the limiting case of r equals "infinity," the homogeneous coordinates are given by (1, 1, 0), an infinite point. You can also try to imagine the line through this point and the three-dimensional origin. As the point approaches infinity, this line becomes more and more horizontal, until, in the limiting case, it is contained entirely in the xy-plane.

A similar representation can be given for lines. For the line $ax + by + c = 0$ we take the parameters (a, b, c) as the homogeneous coordinates of the line. As in the case of points, we identify nonzero multiples of such coordinates, since they do not alter the solution space of the corresponding equation. There is one set of parameters, (0, 0, 1), that does not correspond to a finite line. This is the line at infinity. The vector (a, b, c) of a line is orthogonal to the plane spanned by the corresponding line and the origin of three-space. In particular, the vector (0, 0, 1) is orthogonal to the xy-plane, the "line at infinity."

In fact, the algebraic notion of homogeneous coordinates provides a complete symmetry between points and lines. Each point or line is represented by three homogeneous coordinates. A point (x, y, z) lies on a line (a, b, c) if and only if the scalar product $ax + by + cz$ is zero, which is simply rewriting the equation of the line. Geometrically, this means that the two corresponding vectors are orthogonal in three-space.

2.4 Complex Numbers

It is not only geometry that has been extended throughout the centuries. A similar process happened to numbers. Probably the first numerical concept considered by mankind was that of the positive integers: 1, 2, 3, ... From that beginning, it was reasonable to extend the number system gradually to encompass more powerful concepts. The *negative numbers*, the *rational numbers*, and the *real numbers* had to be invented to achieve a useful and self-contained system. The observation that there must be numbers that cannot be represented as quotients of two integers is of a geometric nature and dates back to approximately 600 B.C.E. It was observed by the Pythagoreans that there is no rational number measuring the length of a diagonal of a square with sides of length one. Through application of the Pythagorean theorem, this task is equivalent to finding a number x such that $x^2 = 2$. This discovery led to a deep crisis in the foundations of ancient geometry.

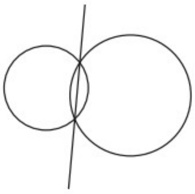
However, the story of extending the number system does not stop at that point. One of the extensions, with perhaps the most drastic consequences, was the introduction of *complex numbers*. It was *Geronimo Cardano* in his 1545 work *Ars Magna* who was first to explicitly propose such an extension of the real numbers. He was led to his conclusions by the study of solutions of polynomials of degree three. Based on the work of other contemporary mathematicians, he discovered that a complete systematic representation of these solutions can be given only with the help of hitherto unknown values involving square roots of negative numbers.

A complex number is a number of the form $a + ib$, where the symbol i satisfies the equation $i^2 = -1$, and a and b are real numbers. Clearly, the number i cannot be a real number, since the square of a real number can never be negative. The system of complex numbers is, like the real numbers, closed under the four basic arithmetic operations of addition, subtraction, multiplication, and division (excluding, of course, division by zero). In other words, the sum and the product of two complex numbers, as well as their difference and quotient, can again be written in the form $a + ib$ for suitable parameters a and b. However, unlike the real numbers, the system of complex numbers is also closed under the operation of finding solutions of polynomials. For instance, consider the polynomial

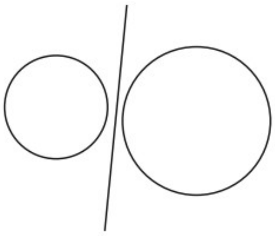
$$x^2 - 6x + 13 = 0$$

As you can easily check, it has no real solutions, but the complex numbers $3 + 2i$ and $3 - 2i$ do solve this equation. In fact, the following beautiful result is true: *Every polynomial equation with arbitrary real or complex coefficients has all its solutions again in the field of complex numbers.*

In a sense, the discovery of complex numbers is the starting point for most modern mathematics. Many mathematical theories find their broadest, most elegant, and most economical setting when they are formulated over the complex numbers. This happens also with geometry. Consider the situation of two circles. Depending on their position, they can have two, one, or no points of intersection.



Circles can intersect...



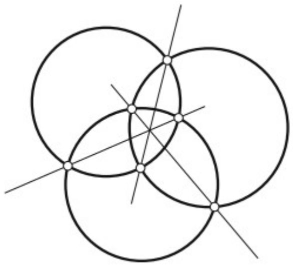
...or not.

Finding the coordinates of the points of intersection amounts to solving a quadratic equation. Over the real numbers, this equation might have no solution. In this case, the circles do not intersect. Over the complex numbers, however, a solution always exists. So in the case of visually nonintersecting circles, we say that the intersections still exist, but that they have complex coordinates, and therefore we cannot see them in the real plane.

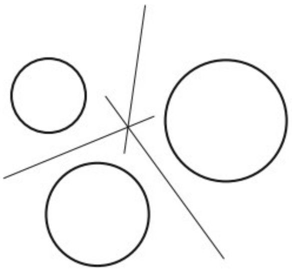
Cinderella's mathematical kernel is implemented entirely over the complex numbers. So when intersections visually vanish, *Cinderella* does not have to deal with special cases, and it can still continue calculating. The solutions just have complex coordinates.

What happens if two complex points are connected by a line? In general, this line will also have complex coordinates. However, if the points are so-called *complex conjugates*, which means that they differ only by the sign of their complex part, then their join is again real. Since the solutions of a quadratic equation with real coefficients are always complex conjugates, it follows that the intersection points of two circles are always complex conjugates. This is the reason why the line joining them is a real line, no matter where in the plane the circles are located, even if the intersection points are complex and therefore invisible. *Cinderella* will correctly calculate and draw this line, independent of the position of the circles. It may take a while to get used to the fact that intermediate results can disappear while some constructions depending on them remain visible. However, this is exactly what you should expect. Consider the case in which the circles have the same radius. The line is then the *perpendicular bisector* of the segment joining the two midpoints. If you include the complex situations, you are not compelled to consider so many special cases.

Another example of a theorem in which intermediate steps disappear is the following statement about three circles. Construct the line joining the two points of intersection of each pair of circles. The three chords that you obtain in this way meet in a point, no matter whether the circles intersect or not.



Intermediate points can be complex...



...but theorems remain true.

So in *Cinderella* each point and each line is represented by *complex homogeneous coordinates*. This means that altogether, any point or line has a six-dimensional(!) internal representation in the mathematical kernel. This may sound crazy, but it is the most natural thing to do.

2.5 Measurements and Complex Numbers

If we were satisfied with projective incidence theory, then the system presented so far would be fairly complete. However, we want to be able to measure distances and angles, too. Measurements are in a sense the most fundamental geometrical operations. Unfortunately, at first glance, projective geometry does not appear to be capable of measuring, since under perspective transformations distances can change. Actually, for a long time mathematicians considered projective geometry a "nice toy" for doing incidence geometry, but not appropriate for the real stuff: measuring.

History proved them wrong. With the right setup, projective geometry is *the* universal system for doing measurements. This system unifies and explains different kinds of measurements. For example, it explains the relationship between Euclidean and hyperbolic geometry. However, it took a long time to finally find the algebraic setting in which Projective Geometry develops its full power. The key objects are called "Cayley-Klein geometries" in modern terms. It is an elegant and consistent mathematical approach to measurements that combines projective geometry and complex numbers.

2.5.1 Euclidean and Non-Euclidean Geometry

One part of this development started with the discovery of non-Euclidean geometries. Our everyday geometry is, with relatively great accuracy, described by Euclid's five postulates. He used these postulates to axiomatize geometry. This happened almost 2000 years ago. The last postulate, the so-called parallel axiom, plays a special role in the development of geometry. A way to formulate it is this: *"Whenever there is a line l in the plane and a point P not on l, then there is exactly one line through P that does not meet l."*

Euclid was very cautious about using the parallel postulate. Large parts of Euclid's elaborations, for instance the complete theory of congruence of triangles, were done without the explicit need for this axiom. Today we are relatively sure that Euclid himself believed that this axiom was a consequence of the other four axioms. But he could not prove this. After Euclid, many other mathematicians tried to do so, and some of them even presented proofs. But all these proofs were incorrect.

In the sixteenth to eighteenth centuries, mathematicians also found many equivalent formulations for the parallel postulate. One of the most prominent formulations is "The interior angles in a triangle sum up to 180°." If this statement could be derived from Euclid's first four axioms, then this would prove the dependence of the parallel postulate.

Proving that an axiom is dependent can be done by assuming its contrary and drawing conclusions until a contradiction is shown. Many people tried this, among them *C.F. Gauss*, *J. Bolyai*, and *N. Lobachevski*. They drew conclusion after conclusion, but to their surprise, instead of arriving at a contradiction, they found themselves developing a beautiful geometric system: *hyperbolic geometry*. There Euclid's parallel postulate is modified in the following way: *"Whenever there is a line l in the plane and a point P not on l, then there will be more than one line through P that does not meet l."* A consequence of this assumption is that the angle sum in a triangle

since $\nabla^{\mathbb{R}^{n+1}} = \nabla + (\nabla^{\mathbb{R}^{n+1}})^N$ and, at $t = 0$, we are on M. Also, for $t = 0$, U and the ∂_i are orthogonal and the coordinates are normal, so

$$\begin{aligned}\frac{d}{dt}\left(\frac{\sqrt{g_t}}{\sqrt{g}}\right)\bigg|_{t=0} &= \sum_{i=1}^{k} -\langle U, \left(\nabla^{\mathbb{R}^{n+1}}_{\partial_i}\partial_i\right)^N\rangle \\ &= -\langle U, \sum_{i=1}^{k}\left(\nabla^{\mathbb{R}^{n+1}}_{\partial_i}\partial_i\right)^N\rangle \\ &= -\langle U, H\rangle\end{aligned}$$

where H is the mean curvature vector field of M in $\mathbb{R}^{n+1}$. After integration, we have the

Theorem 8.4.12. *The derivative of the area functional at zero is given by*

$$\frac{dA(t)}{dt}\bigg|_{t=0} = \int_M -\langle U, H\rangle\, dA$$

where H is the mean curvature vector field and U is the normal variational direction.

If M (i.e., $t = 0$) is a critical point for all variations, then we must have $H = 0$. This follows because any nonzero part of H would produce a nonzero $\langle U, H\rangle$ for some U and this then could be localized by a bump function to produce a nonzero integral, contradicting the assumption that M is a critical point of $A(t)$. Thus, we have the higher-dimensional version of Theorem 4.3.4,

Corollary 8.4.13. *If M is least area, then the mean curvature vector field is zero.*

8.5 Curvatures

In Section 3.4 we developed a formula for Gauss curvature which depended only on the metric. This led of course to Gauss's Theorem Egregium. If we look closely at how the formula was derived, we see that we used the fact that $\mathbf{x}_{uuv} - \mathbf{x}_{uvu} = 0$. Written in our "covariant" notation (and noting that the covariant derivative with respect to a parameter curve is simply partial differentiation), we have

$$\nabla^{\mathbb{R}^{n+1}}_{\mathbf{x}_v}\nabla^{\mathbb{R}^{n+1}}_{\mathbf{x}_u}\mathbf{x}_u - \nabla^{\mathbb{R}^{n+1}}_{\mathbf{x}_u}\nabla^{\mathbb{R}^{n+1}}_{\mathbf{x}_v}\mathbf{x}_u = 0.$$

Furthermore, the derivation also reveals that we made essential use of the basis descriptions of U_u and U_v, where U is the unit normal of the surface. In fact, it was these terms which provided the $(ln - m^2)/EG = K$ in the formula. Now, however, we must use M^k's covariant derivative ∇ without the benefit of a unit normal. Therefore, we should not expect the corresponding quantity

$$\nabla_{\partial_j}\nabla_{\partial_i}\partial_s - \nabla_{\partial_i}\nabla_{\partial_j}\partial_s$$

to be zero. Indeed, analogous to the derivation of the two-dimensional formula (but without the ingredients U_u and U_v), we may tentatively define a vector field $R(\partial_i, \partial_j)\partial_s = \sum_l R^l_{ijs}\partial_l$ by

$$R(\partial_i, \partial_j)\partial_s = \nabla_{\partial_j}\nabla_{\partial_i}\partial_s - \nabla_{\partial_i}\nabla_{\partial_j}\partial_s.$$

The object $R(\cdot, \cdot)$ will be called the Riemann curvature, *but the formula on the right-hand side does not yet describe it in general*. We want R to possess certain qualities. Namely, we want R to be bilinear with respect to smooth functions. By this we mean that $R(fX,Y)=fR(X,Y)$, $R(X+Z,Y)=R(X,Y)+R(Z,Y)$, $R(X,fY)=fR(X,Y)$ and $R(X,Y+Z)=R(X,Y)+R(X,Z)$ for any smooth function $f\colon M\to\mathbb{R}$. But, as the reader is asked to check in the following exercise, as yet, this is *not the case*! Moreover, we want $R(\cdot,\cdot)$ to be a linear map on vector fields as well.

Exercise 8.5.1. Use the properties of covariant derivatives to show that

$$R(\boldsymbol{\partial}_i,\boldsymbol{\partial}_j)f\boldsymbol{\partial}_s = fR(\boldsymbol{\partial}_i,\boldsymbol{\partial}_j)\boldsymbol{\partial}_s. \tag{1}$$

$$\begin{aligned} R(f\boldsymbol{\partial}_i,\boldsymbol{\partial}_j)\boldsymbol{\partial}_s &= \boldsymbol{\partial}_j f\nabla_{\boldsymbol{\partial}_i}\boldsymbol{\partial}_s + fR(\boldsymbol{\partial}_i,\boldsymbol{\partial}_j)\boldsymbol{\partial}_s \\ &= -\nabla_{[f\boldsymbol{\partial}_i,\boldsymbol{\partial}_j]}\boldsymbol{\partial}_s + fR(\boldsymbol{\partial}_i,\boldsymbol{\partial}_j)\boldsymbol{\partial}_s. \end{aligned} \tag{2}$$

where the last line follows from Proposition 8.3.2 (ii) and Exercise 8.3.4 (4). Hence, R is not linear in the first (or second) variable.

The last formula of the exercise gives a hint as to how to redefine R so as to achieve bilinearity. Namely, for tangent vector fields X, Y and Z, we have

Definition 8.5.2. The *Riemann curvature* is defined to be

$$R(X,Y)Z = \nabla_{[X,Y]}Z + \nabla_Y\nabla_X Z - \nabla_X\nabla_Y Z.$$

Exercise 8.5.3. Show that

$$\begin{aligned} R(\boldsymbol{\partial}_i,\boldsymbol{\partial}_j)\boldsymbol{\partial}_s &= \sum_l R^l_{ijs}\boldsymbol{\partial}_l \\ &= \sum_l \left(\frac{\partial\Gamma^l_{is}}{\partial u^j} - \frac{\partial\Gamma^l_{js}}{\partial u^i} + \sum_m \Gamma^m_{is}\Gamma^l_{jm} - \Gamma^m_{js}\Gamma^l_{im}\right)\boldsymbol{\partial}_l. \end{aligned}$$

Since, as we showed previously, all Christoffel symbols vanish in $\mathbb{R}^{n+1}$, the expression above says that the Riemann curvature of $\mathbb{R}^{n+1}$ is zero everywhere. We say that $\mathbb{R}^{n+1}$ is *flat*. Further, show that

$$\begin{aligned} R_{ijsr} &\overset{\text{def}}{=} \sum_l R^l_{ijs}g_{lr} \\ &= \sum_l \left(\frac{\partial\Gamma^l_{is}}{\partial u^j} - \frac{\partial\Gamma^l_{js}}{\partial u^i} + \sum_m \Gamma^m_{is}\Gamma^l_{jm} - \Gamma^m_{js}\Gamma^l_{im}\right)g_{lr} \end{aligned}$$

and calculate R_{1212} for a two-dimensional patch $\mathbf{x}(u^1,u^2)=\mathbf{x}(u,v)$ with $g_{11}=E, g_{12}=g_{21}=0$ and $g_{22}=G$. Show that

$$R_{1212} = EG\left[\frac{E_uG_u}{4E^2G} - \frac{1}{E}\left(\frac{E_v}{2G}\right)_v - \frac{E_vG_v}{4EG^2} + \frac{E_vE_v}{4E^2G} - \frac{1}{E}\left(\frac{G_u}{2G}\right)_u - \frac{G_uG_u}{4EG^2}\right]$$

and compare this with the formula above Exercise 3.4.5 to see that

$$K = \frac{R_{1212}}{g}$$

where K is Gauss curvature and $g = \det(g_{ij}) = EG$. Thus the Riemann curvature generalizes the Gauss curvature.

Exercise 8.5.4. Suppose $M^n \subset \mathbb{R}^{n+1}$ is a hypersurface with unit normal U and shape operator S. Show that, for tangent vector fields X, Y and Z,

$$R(X, Y)Z = \langle S(X), Z\rangle\, S(Y) - \langle S(Y), Z\rangle\, S(X).$$

Hints: (1) write

$$R(X, Y) = \left(\nabla^{\mathbb{R}^{n+1}}_{[X,Y]} - \mathcal{S}_{[X,Y]}\right) + \left(\nabla^{\mathbb{R}^{n+1}}_{Y} - \mathcal{S}_Y\right)\left(\nabla^{\mathbb{R}^{n+1}}_{X} - \mathcal{S}_X\right) - \left(\nabla^{\mathbb{R}^{n+1}}_{X} - \mathcal{S}_X\right)\left(\nabla^{\mathbb{R}^{n+1}}_{Y} - \mathcal{S}_Y\right)$$

where $\mathcal{S}_Y(Z) = \langle S(Y), Z\rangle$. (2) Use the facts that $\nabla^{\mathbb{R}^{n+1}}_{[X,Y]} + \nabla^{\mathbb{R}^{n+1}}_{Y}\nabla^{\mathbb{R}^{n+1}}_{X} - \nabla^{\mathbb{R}^{n+1}}_{X}\nabla^{\mathbb{R}^{n+1}}_{Y} = 0$ (since $\mathbb{R}^{n+1}$ is flat) and $\langle \nabla^{\mathbb{R}^{n+1}}_{Y} U, U\rangle = 1/2\, Y\langle U, U\rangle = 0$ (since $\langle U, U\rangle = 1$ is constant).

It is clear that Riemann curvature is a complicated object to deal with. We can gain some intuition about it however by considering vector fields in pairs. First, let us introduce the notation

$$R(X, Y, Z, W) \overset{\text{def}}{=} \langle R(X, Y)Z, W\rangle.$$

Then we define the *sectional curvature* of the two-dimensional subspace of T_pM spanned by $X(p)$ and $Y(p)$ to be

$$K(X, Y) = \frac{R(X, Y, X, Y)}{\langle X, X\rangle\langle Y, Y\rangle - \langle X, Y\rangle^2}.$$

As the notation suggests, the sectional curvature is a Gauss curvature of a two-dimensional submanifold of M through p with tangent plane $\langle X, Y\rangle$. This generalizes Exercise 8.5.3, where $K = R_{1212}/g = R(\partial_1, \partial_2, \partial_1, \partial_2)/g$. Although we will not prove it, it is a fact that *the sectional curvature actually determines the Riemann curvature*. Of course the reverse is true by definition. Also note that if X and Y are orthonormal, then $K(X, Y) = R(X, Y, X, Y)$.

Example 8.5.5 (Sectional Curvature of the Sphere S^n of Radius R). In Example 8.3.8 we saw that the shape operator of S^n (of radius R) is given by $S(X) = -X/R$, where R is the radius of the sphere. From the formula of Exercise 8.5.4, we obtain

$$\begin{aligned} R(X, Y)Z &= \langle S(X), Z\rangle\, S(Y) - \langle S(Y), Z\rangle\, S(X) \\ &= \frac{1}{R^2}(\langle X, Z\rangle Y - \langle Y, Z\rangle X). \end{aligned}$$

The sectional curvature has an even more perspicacious appearance — especially when we take X and Y to be orthonormal. For then we have

$$\begin{aligned} K(X, Y) &= R(X, Y, X, Y) \\ &= \frac{1}{R^2}\langle \langle X, X\rangle Y - \langle Y, X\rangle X, Y\rangle \\ &= \frac{1}{R^2} \end{aligned}$$

since $\langle Y, X\rangle = 0 = \langle X, Y\rangle$ and $\langle X, X\rangle = 1 = \langle Y, Y\rangle$. Thus $K = 1/R^2$ is the *constant* sectional curvature of S^n; that is, completely analogous to the constant Gauss curvature of S^2.

Exercise 8.5.6. Show that the Riemann curvature obeys the following symmetry relations:

(1) $R(X, Y, Z, W) = -R(Y, X, Z, W)$;

(2) $R(X, Y, Z, W) = -R(X, Y, W, Z)$;

(3) $R(X, Y, Z, W) = R(Z, W, X, Y)$.

Hints: (1) $\langle \nabla_Y \nabla_X V, V\rangle = Y\langle \nabla_X V, V\rangle - \langle \nabla_X V, \nabla_Y V\rangle$ and (2) $\langle \nabla_{[X,Y]} V, V\rangle = 1/2\,[X, Y]\langle V, V\rangle$, both by (iv) of Proposition 8.3.2. For part (3), use the first Bianchi identity below.

Exercise 8.5.7. Prove the first Bianchi identity:

$$R(X, Y, Z, W) + R(Y, Z, X, W) + R(Z, X, Y, W) = 0.$$

Hints: W is superfluous, so drop it from the notation. Write out the definitions of the terms and group them to make use of the identity $\nabla_X Y - \nabla_Y X = [X, Y]$ etc. Then group the terms according to the respective Lie brackets which arise and apply the identity again to end up with only brackets in the formula. Apply the Jacobi identity (Exercise 8.3.4 (3)).

There is a *second Bianchi identity* which will prove very convenient a bit later. This identity involves covariant derivatives of the Riemann curvature, so we must understand how these are defined. The covariant derivative of R is given by

$$\begin{aligned}\nabla R(X, Y, Z, W, V) &= \nabla_V R(X, Y, Z, W)\\ &= V[R(X, Y, Z, W)] - R(\nabla_V X, Y, Z, W) - R(X, \nabla_V Y, Z, W)\\ &\quad - R(X, Y, \nabla_V Z, W) - R(X, Y, Z, \nabla_V W).\end{aligned}$$

Proposition 8.5.8 (The second Bianchi identity).

$$\nabla R(X, Y, Z, W, V) + \nabla R(X, Y, W, V, Z) + \nabla R(X, Y, V, Z, W) = 0.$$

Proof. Choose normal coordinates (see Theorem 8.4.10) about a point $p \in M$ and test the identity at this arbitrary point. Let X, Y, Z, W and V be in the orthonormal coordinate basis with $\nabla_X Y(p) = 0$ etc. Also note that brackets of these vector fields vanish as well by $[X, Y] = \nabla_X Y - \nabla_Y X = 0 - 0 = 0$. Then

$$\begin{aligned}\nabla R(X, Y, Z, W, V) &= \nabla_V R(X, Y, Z, W)\\ &= \nabla_V R(Z, W, X, Y)\\ &= V[R(Z, W, X, Y)] \qquad \text{since } \nabla_V(\cdot) = 0\\ &= \langle \nabla_V R(Z, W)X, Y\rangle\end{aligned}$$

by Proposition 8.3.2 (iv) and $\nabla_V Y = 0$. Similarly, $\nabla R(X, Y, W, V, Z) = \langle \nabla_Z R(W, V)X, Y\rangle$ and $\nabla R(X, Y, V, Z, W) = \langle \nabla_W R(V, Z)X, Y\rangle$. Hence, X and Y are superfluous, so we remove them from the notation. Then

$$\begin{aligned}\nabla_V R(Z, W) + \nabla_Z R(W, V) + \nabla_W R(V, Z) = {}&(\nabla_V\nabla_W - \nabla_W\nabla_V)\nabla_Z\\ &+ (\nabla_Z\nabla_V - \nabla_V\nabla_Z)\nabla_W + (\nabla_W\nabla_Z - \nabla_Z\nabla_W)\nabla_V\end{aligned}$$

and, evaluating on X, we get $(\nabla_V R(Z, W) + \nabla_Z R(W, V) + \nabla_W R(V, Z))(X) = R(W, V, \nabla_Z X) + R(V, Z, \nabla_W X) + R(Z, W, \nabla_V X)$ since brackets are zero. But then, since $\nabla_Z X = 0$ etc., we have

$$(\nabla_V R(Z, W) + \nabla_Z R(W, V) + \nabla_W R(V, Z))(X) = 0.$$

Hence, the result is proved. □

While the Bianchi identities may seem rather esoteric, they *do* simplify various calculations considerably as we will see below.

Higher-dimensional differential geometry offers us both the challenge of understanding nonvisualizable geometric phenomena and the opportunity to create new tools with which to study such phenomena. Some of these new tools are new types of curvatures which, in two dimensions, become the Gauss curvature. We have already seen that sectional curvature can tell us information somewhat obscured by the Riemann curvature. Sectional curvature, however, cannot be the final answer since, as we mentioned previously, it determines Riemann curvature. Instead, there is a general method called *contraction* which is available to us in higher dimensions and which allows us to isolate more tractable portions of the Riemann curvature. In order to do this, we will generalize the notion of a *frame field* which was used in Chapter 6. If $\mathcal{E}_1, \dots, \mathcal{E}_k$ are vector fields defined on a neighborhood of a point $p \in M^k$ with

$$\langle \mathcal{E}_i, \mathcal{E}_j\rangle = \delta_i^j$$

at every point in the neighborhood, then the collection $\{\mathcal{E}_1, \dots, \mathcal{E}_k\}$ is called a *frame* about p. One way to obtain a frame is to choose normal coordinates around p (Theorem 8.4.10) and then parallel translate the corresponding vector fields along geodesics passing through p. By Exercise 8.4.8, parallel translation is an isometry, so the orthonormality of the frame is preserved as it is translated to other points in the normal coordinate patch. The one bothersome thing about using a frame is that we lose many of the coordinate formulas we obtained earlier. Nevertheless, we shall see that the advantages of a frame outweigh the disadvantages, so we assume that we have a frame about p in what follows.

Definition 8.5.9. The *Ricci curvature* is defined to be

$$\operatorname{Ric}(X, Y) = \sum_{i=1}^{k} \langle R(X, \mathcal{E}_i)Y, \mathcal{E}_i\rangle$$

where X and Y are tangent vector fields on M^k. The *scalar curvature* is defined to be

$$\begin{aligned}\kappa &= \sum_{j=1}^{k} \operatorname{Ric}(\mathcal{E}_j, \mathcal{E}_j)\\ &= \sum_{i,j=1}^{k} \langle R(\mathcal{E}_j, \mathcal{E}_i)\mathcal{E}_j, \mathcal{E}_i\rangle.\end{aligned}$$

The first thing we should note is that these definitions are independent of the frame field we choose. The reason is this. Any two frames are related at a point by an orthogonal matrix; that is, a matrix A with $A^t = A^{-1}$. This is equivalent to saying that the rows of A form an orthonormal set of vectors. This, together with the symmetry relations of Exercise 8.5.6 suffice to prove the invariance of the definition. Rather than give a proof of this in general, we will simply concentrate on the $k = 2$ case. So, suppose that $\{\mathcal{F}_j\}$ is another frame field which is related to $\{\mathcal{E}_i\}$ by a 2×2 orthogonal matrix $A = (a_{st})$ as follows:

$$\mathcal{E}_i = a_{1i}\mathcal{F}_1 + a_{2i}\mathcal{F}_2.$$

Now we can just compute using the fact that the rows of A are orthonormal. That is, $a_{11}a_{21} + a_{12}a_{22} = 0$, $a_{11}^2 + a_{12}^2 = 1$ and $a_{21}^2 + a_{22}^2 = 1$.

$$\begin{aligned}\operatorname{Ric}(X, Y) &= \langle R(X, \mathcal{E}_1)Y, \mathcal{E}_1\rangle + \langle R(X, \mathcal{E}_2)Y, \mathcal{E}_2\rangle\\ &= \langle R(X, a_{11}\mathcal{F}_1 + a_{21}\mathcal{F}_2)Y, a_{11}\mathcal{F}_1 + a_{21}\mathcal{F}_2\rangle\\ &\qquad + \langle R(X, a_{12}\mathcal{F}_1 + a_{22}\mathcal{F}_2)Y, a_{12}\mathcal{F}_1 + a_{22}\mathcal{F}_2\rangle\\ &= a_{11}^2\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_1\rangle + a_{11}a_{21}\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_2\rangle\\ &\quad + a_{21}a_{11}\langle R(X, \mathcal{F}_2)Y, \mathcal{F}_1\rangle + a_{21}^2\langle R(X, \mathcal{F}_2)Y, \mathcal{F}_2\rangle\\ &\quad + a_{12}^2\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_1\rangle + a_{12}a_{22}\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_2\rangle\\ &\quad + a_{22}a_{12}\langle R(X, \mathcal{F}_2)Y, \mathcal{F}_1\rangle + a_{22}^2\langle R(X, \mathcal{F}_2)Y, \mathcal{F}_2\rangle\\ &= a_{11}^2\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_1\rangle + 2a_{11}a_{21}\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_2\rangle + a_{21}^2\langle R(X, \mathcal{F}_2)Y, \mathcal{F}_2\rangle\\ &\quad + a_{12}^2\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_1\rangle + 2a_{12}a_{22}\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_2\rangle + a_{22}^2\langle R(X, \mathcal{F}_2)Y, \mathcal{F}_2\rangle\end{aligned}$$

using the symmetry relations of Exercise 8.5.6. Then

$$\begin{aligned}\operatorname{Ric}(X, Y) &= (a_{11}^2 + a_{12}^2)\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_1\rangle\\ &\qquad + 2(a_{11}a_{21} + a_{12}a_{22})\langle R(X, \mathcal{F}_1)Y, \mathcal{F}_2\rangle + (a_{21}^2 + a_{22}^2)\langle R(X, \mathcal{F}_2)Y, \mathcal{F}_2\rangle\\ &= \langle R(X, \mathcal{F}_1)Y, \mathcal{F}_1\rangle + \langle R(X, \mathcal{F}_2)Y, \mathcal{F}_2\rangle\end{aligned}$$

by the equalities $a_{11}a_{21} + a_{12}a_{22} = 0$, $a_{11}^2 + a_{12}^2 = 1$ and $a_{21}^2 + a_{22}^2 = 1$. Hence, the Ricci curvature is well defined.

The second thing to note is that both Ricci and scalar curvatures come about through a "trace-like" process. Of course, to take the trace of a matrix $A = (a_{ij})$, we form

$$\operatorname{tr} A = \sum_i a_{ii} = \sum_i \langle A(\mathcal{E}_i), \mathcal{E}_i\rangle$$

for an orthonormal basis $\{\mathcal{E}_1, \dots, \mathcal{E}_k\}$. Here, for Ric, we take two slots of the Riemann curvature and sum over the same elements of the frame. Similarly, and even more closely analogous to trace, to form κ, we sum over the only available slots in Ric. This process of summing over two slots with the same frame elements is called *contraction* and is sometimes denoted $\mathcal{C}$. Thus, $\mathcal{C}_{24}R = \mathrm{Ric}$ and $\mathcal{C}_{12}\,\mathrm{Ric} = \kappa$ since, in the first case, we sum over the second and fourth slots and, in the second case, we sum over the first and second slots. We note here that some authors order the subscripts on R_{ijlr} differently, so contraction subscripts may have to be adjusted to correspond to ours. As the reader might expect, there is a more formal and precise notion of "contraction", but we shall have no need of it here.

Example 8.5.10 (Contraction of the Metric).
(i) For a k-manifold M^k, let us compute the (only available) contraction of the metric $\langle \cdot, \cdot \rangle$. For a frame as above, since $\langle \mathcal{E}_i, \mathcal{E}_i \rangle = \delta_i^j$,

$$\begin{aligned} \mathcal{C}(\langle \cdot, \cdot \rangle) &= \sum_{i=1}^{k} \langle \mathcal{E}_i, \mathcal{E}_i \rangle \\ &= k \\ &= \dim M^k. \end{aligned}$$

(ii) Contraction can also be done by coordinates. Without going into details, for coordinates $u^1, \dots, u^k$ and basis tangent vector fields $\boldsymbol{\partial}_1, \dots, \boldsymbol{\partial}_k$ with $\langle R(\boldsymbol{\partial}_i, \boldsymbol{\partial}_j)\boldsymbol{\partial}_s, \boldsymbol{\partial}_r \rangle = R_{ijsr}$, let

$$R_{is} = \sum_{j,r} R_{ijsr} g^{jr}.$$

These are then the components of Ricci curvature. Thus, by Exercise 8.5.3,

$$\begin{aligned} R_{is} &= \sum_{j,r} \sum_{l} \left(\frac{\partial \Gamma_{is}^{l}}{\partial u^j} - \frac{\partial \Gamma_{js}^{l}}{\partial u^i} + \sum_m \Gamma_{is}^{m} \Gamma_{jm}^{l} - \Gamma_{js}^{m} \Gamma_{im}^{l} \right) g_{lr} g^{jr} \\ &= \sum_{j,l} \left(\frac{\partial \Gamma_{is}^{l}}{\partial u^j} - \frac{\partial \Gamma_{js}^{l}}{\partial u^i} + \sum_m \Gamma_{is}^{m} \Gamma_{jm}^{l} - \Gamma_{js}^{m} \Gamma_{im}^{l} \right) \sum_r g_{lr} g^{jr} \\ &= \sum_{l} \left(\frac{\partial \Gamma_{is}^{l}}{\partial u^l} - \frac{\partial \Gamma_{ls}^{l}}{\partial u^i} + \sum_m \Gamma_{is}^{m} \Gamma_{lm}^{l} - \Gamma_{ls}^{m} \Gamma_{im}^{l} \right) \end{aligned}$$

since $\sum_r g_{lr} g^{jr} = \delta_j^l$.

In order to see the power of these curvatures, we offer the following theorems without proof. For a proof of the the first, see [GHL90] for example.

Theorem 8.5.11 (Myers's Theorem). *Let M^k be a complete k-manifold and suppose that the Ricci curvature on all of M^k is strictly bounded away from zero; that is,*

$$\mathrm{Ric}(X, X) \geq \frac{k-1}{r^2} > 0.$$

Then M^k is compact and the diameter of M^k is less than or equal to πr.

Compare this result with Bonnet's result, Theorem 6.8.16. Scalar curvature also has the power to constrain the type of a manifold. Compare the following result (due to Ros [Ros87]) to Alexandrov's result, Theorem 4.4.6.

Theorem 8.5.12. *A compact hypersurface $M^n \subset \mathbb{R}^{n+1}$ of constant scalar curvature is a sphere S^n with metric induced by that of $\mathbb{R}^{n+1}$.*

Exercise 8.5.13. For a surface defined by an orthogonal patch in $\mathbb{R}^3$, show that Ricci and scalar curvatures are given by

$$\operatorname{Ric}(X, Y) = K\,\langle X, Y\rangle \qquad \text{and} \qquad \kappa = 2K$$

where K is Gauss curvature. Hint: use Exercise 8.5.3. The orthogonal patch condition is, in fact, unnecessary, but Exercise 8.5.3 assumed it for simplicity.

Exercise 8.5.14. Show that the following formula holds relating the covariant derivative, the metric and the bracket.

$$2\langle X, \nabla_Z Y\rangle = Z\,\langle X, Y\rangle + Y\,\langle X, Z\rangle - X\,\langle Y, Z\rangle + \langle Y, [X, Z]\rangle + \langle Z, [X, Y]\rangle - \langle X, [Y, Z]\rangle.$$

Exercise 8.5.15. Here is a first small step toward getting away from the induced metric of $\mathbb{R}^{n+1}$. A metric $\widetilde{\langle \cdot, \cdot\rangle}$ is a *multiple* of another metric $\langle \cdot, \cdot\rangle$ if

$$\widetilde{\langle X, Y\rangle} = \lambda\,\langle X, Y\rangle$$

for all X and Y, where λ is a constant. If λ is allowed to be a smooth function on M, then the metrics are *conformal*. Denoting the covariant derivative and curvatures of the associated metric $\widetilde{\langle \cdot, \cdot\rangle}$ by $\widetilde{\nabla}$, $\tilde{R}$, $\widetilde{\operatorname{Ric}}$, $\tilde{\kappa}$, show that the following properties hold for a "multiple" metric.

(1) $\widetilde{\nabla}_X Y = \nabla_X Y$. (Use the formula from Exercise 8.5.14.)

(2) $\tilde{R}(X, Y, Z, W) = \lambda\, R(X, Y, Z, W)$. (Use (1).)

(3) $\tilde{K}(X, Y) = \dfrac{1}{\lambda}\, K(X, Y)$. (Use (2).)

(4) $\widetilde{\operatorname{Ric}}(X, Y) = \operatorname{Ric}(X, Y)$. (Use (2).)

(5) $\tilde{\kappa} = \dfrac{1}{\lambda}\,\kappa$. (Use (4).)

Exercise 8.5.16. Let $P^k = \{(u^1, \ldots, u^k) \in \mathbb{R}^k \mid u^k > 0\}$ be the "upper half space" analogous to the two-dimensional Poincaré plane. Define an analogous metric on P^k by

$$\langle \mathbf{v}, \mathbf{w}\rangle = \frac{\mathbf{v}\cdot\mathbf{w}}{(u^k)^2}.$$

In our present language, this means that

$$g_{ij} = \langle \mathbf{e}_i, \mathbf{e}_j\rangle = \frac{\mathbf{e}_i\cdot\mathbf{e}_j}{(u^k)^2} = \frac{\delta^i_j}{(u^k)^2}$$

where the $\mathbf{e}_i$ are the standard orthonormal $\mathbb{R}^k$ basis vectors. Hence, the metric is diagonal. The sectional curvature of P^k is known to be constant at -1. The following steps lead to a partial understanding of this result. For further and complete details, including formulas for general conformal metrics, see [dC92, Chapter 8.3].

(1) Show that the Christoffel symbols are

$$\begin{aligned}\Gamma^r_{ij} &= \frac{1}{2}\sum_l g^{lr}\left(\partial_i g_{jl} + \partial_j g_{li} - \partial_l g_{ij}\right)\\ &= \frac{1}{2} g^{rr}\left(\partial_i g_{jr} + \partial_j g_{ri} - \partial_r g_{ij}\right)\end{aligned}$$

and that the only non-zero ones are

$$\Gamma^j_{kj} = -\frac{1}{u^k} \quad \text{for } j \neq k, \qquad \Gamma^k_{ii} = \frac{1}{u^k} \quad \text{for } i \neq k, \qquad \Gamma^k_{kk} = -\frac{1}{u^k}.$$

(2) Now show that the components of Riemann curvature relevant to sectional curvature are

$$\begin{aligned}R_{ijij} &= \sum_l \left(\frac{\partial \Gamma^l_{ii}}{\partial u^j} - \frac{\partial \Gamma^l_{ji}}{\partial u^i} + \sum_m \Gamma^m_{ii}\Gamma^l_{jm} - \Gamma^m_{ji}\Gamma^l_{im}\right) g_{lj}\\ &= \left(\frac{\partial \Gamma^j_{ii}}{\partial u^j} - \frac{\partial \Gamma^j_{ji}}{\partial u^i} + \sum_m \Gamma^m_{ii}\Gamma^j_{jm} - \Gamma^m_{ji}\Gamma^j_{im}\right)\left(\frac{1}{(u^k)^2}\right)\end{aligned}$$

and the only non-zero components are $R_{kjkj} = R_{ikik} = R_{ijij} = -1/(u^k)^4$. Here we assume $k \neq j$ in R_{kjkj}, $i \neq k$ in R_{ikik} and $i \neq j$, $i \neq k$ and $j \neq k$ in R_{ijij}.

(3) Using the calculation of (2), show that the components of sectional curvature $K_{ij} = R_{ijij}/(g_{ii} \cdot g_{jj})$ for the cases above are constantly equal to -1. This exercise indicates how the conformal metrics of Chapter 5 may be generalized to higher dimensions.

Exercise* 8.5.17. A manifold M^k is said to have nonnegative sectional curvature if $K(X, Y) \geq 0$ for all X and Y. The Ricci curvature is said to be nonnegative when $\text{Ric}(X, X) \geq 0$ for all X. Show that nonnegative sectional curvature on M implies nonnegative Ricci curvature on M and, in turn, this implies nonnegative scalar curvature on M. Hint: First prove the formula

$$\text{Ric}(X, X) = \langle X, X\rangle \sum_{j=1}^{k-1} K(X, \mathcal{E}_j) = \langle X, X\rangle \sum_{j=1}^{k-1} K(\mathcal{E}_k, \mathcal{E}_j)$$

for a frame $\{\mathcal{E}_j\}$ spanning $X^\perp$, the space of vector fields orthogonal to X, and $\mathcal{E}_k = X/|X|$.

Exercise 8.5.18. Here is an exercise which at once goes beyond our definitions and tests them. A *Lie Group* G is a smooth manifold with a smooth associative multiplication $G \times G \to G$ having an identity e and inverses. Take G to be compact and connected. For example, the special orthogonal group $SO(n)$ is a compact connected Lie group. We may define certain vector fields on G by fixing a vector $X(e) \in T_eG$ and then taking $X(g) = g_*(X(e)) \in T_gG$. Here, g_* is the map induced on tangent vectors by the multiplication $(g, h) \mapsto g \cdot h$ for all $h \in G$. These types of vector fields are called *left invariant vector fields*. Lie groups are quite symmetric in the sense that the covariant derivative (which may be defined without reference to an ambient Euclidean space, but which has all the properties of Proposition 8.3.2) and curvature at the identity determine the covariant derivatives and curvatures at all other points of G. Furthermore, it is known that

$\nabla_X X = 0$ for X any left invariant vector field. Thus, curves whose tangent vectors belong to left invariant vector fields are geodesics. Also, for G as above, the following identity is known to hold: $\langle [X, Y], Z\rangle = -\langle Y, [X, Z]\rangle$ for left invariant vector fields X, Y and Z. Here, $\langle \cdot, \cdot \rangle$ is a metric which is first defined on T_eG and then transported around G by the Lie group multiplication.

Now, for a compact, connected Lie group G with left invariant vector fields X, Y and Z, show that

(1) $\nabla_X Y = \frac{1}{2}[X, Y]$. (Consider $\nabla_{X-Y}(X - Y)$ and use Proposition 8.3.2 (v).)

(2) $R(X, Y)Z = \frac{1}{4}[[X, Y], Z]$.
(Start with the definition of R, then use (1) to express R completely in terms of brackets. Finally, use the Jacobi identity for the bracket (Exercise 8.3.4 (3)).)

(3) If X and Y are orthonormal, then $K(X, Y) = \frac{1}{4}\left|[X, Y]\right|^2$.
Thus, sectional curvature, and hence, Ricci and scalar curvatures, are nonnegative for a compact, connected Lie group. (Use the definition of K, (1), Proposition 8.3.2 (iv) and the identity $\langle [X, Y], Z\rangle = -\langle Y, [X, Z]\rangle$ with $Z = Y$.)

The *Killing form* of a Lie group G is defined to be $b(X, Y) = \operatorname{tr}(\mathrm{ad}_X\, \mathrm{ad}_Y)$, where $\mathrm{ad}_Z(W) = [Z, W]$ is a linear transformation of the vector space of left invariant vector fields. It can be shown that b is symmetric, bilinear and invariant under all automorphisms of G. A compact Lie group with nondegenerate Killing form is said to be *semisimple*. The form b is nondegenerate if $b(V, W) = 0$ for all W implies $V = 0$. In this case b is a negative definite form (i.e., $b(V, V) < 0$ for all $V \neq 0$) and $-b$ is actually the (bi-invariant) metric $\langle \cdot, \cdot \rangle$ on G. That is, $\langle X, Y\rangle = -b(X, Y)$. For instance, $SO(n)$ is semisimple. Using (2) above and the definition of ad_Z, show that a semisimple Lie group with metric b has Ricci curvature

$$\mathrm{Ric}(X, Y) = -\frac{1}{4}\, b(X, Y).$$

To end this section, we wish to make several calculations using the definitions above to try to understand a tiny bit of modern physics. Einstein's general theory of relativity is based on a principle that energy and momentum distort the geometry of spacetime and, as a consequence, are responsible for various physical phenomena such as light "bending" around the Sun (along a spacetime geodesic) and the precession of the perihelion of Mercury. Although this principle is simple to state in our naive discussion, the precise form of the relationship is far from clear. If we are to believe in the relationship at all, then perhaps the simplest such formula is

$$G = c\,T$$

where G is some type of curvature (called the *Einstein curvature*) and T is a quantity (called the *stress-energy tensor*) which depends on the amount of energy-momentum in a particular region of spacetime. In particular, in a vacuum we have $T = 0$ — but interesting physics (such as the bending of light) can still occur. If G were Riemann curvature R, then the formula $G = c\,T$ together with the assumption $T = 0$ would imply the vanishing of Riemann curvature. But, as we have said earlier, $R = 0$ implies that a manifold is flat. Hence, spacetime would be forced to be flat and this would contradict the interesting geometrically induced physics observed. So, G cannot then be the Riemann curvature. The next logical choice to try is the Ricci curvature, so we take $G = \mathrm{Ric}$ provisionally. But we must ask, what else do we desire in a physical quantity? Certainly, the law of conservation of energy-momentum must be obeyed, so we obtain the vanishing of some sort of divergence of T. This means that we should also require G to be divergence free as well. Let us consider this now.

If $V = (V^1, V^2, V^3)$ is a vector field in $\mathbb{R}^3$ with coordinates x^1, x^2 and x^3, then we know

$$\operatorname{div} V = \frac{\partial V^1}{\partial x^1} + \frac{\partial V^2}{\partial x^2} + \frac{\partial V^3}{\partial x^3} = \sum_i \langle \nabla^{\mathbb{R}^3}_{\mathbf{e}_i} V, \mathbf{e}_i \rangle$$

where the $\mathbf{e}_i$ are the usual Euclidean orthonormal basis vectors.

Exercise 8.5.19. Verify the last equality

$$\frac{\partial V^1}{\partial x^1} + \frac{\partial V^2}{\partial x^2} + \frac{\partial V^3}{\partial x^3} = \sum_i \langle \nabla^{\mathbb{R}^3}_{\mathbf{e}_i} V, \mathbf{e}_i \rangle.$$

In the same way, on a manifold M^k, we can define the divergence of vector fields and bilinear quantities with two slots (i.e., 2-tensors) such as the metric $\langle \cdot, \cdot \rangle$ and Ric. Let $A(\cdot, \cdot)$ be such a quantity and define the *divergence of* A, $\operatorname{div} A(\cdot)$, to be a linear quantity with one slot (i.e., a 1-form; see Section 8.6),

$$\begin{aligned}\operatorname{div} A(X) &\overset{\text{def}}{=} \sum_i \nabla_{\mathcal{E}_i} A(\mathcal{E}_i, X)\\ &= \sum_i \mathcal{E}_i A(\mathcal{E}_i, X) - A(\nabla_{\mathcal{E}_i}\mathcal{E}_i, X) - A(\mathcal{E}_i, \nabla_{\mathcal{E}_i} X)\end{aligned}$$

where $\{\mathcal{E}_i\}_{i=1}^k$ is a frame and we use a definition for ∇A similar to that for ∇R in the second Bianchi identity Proposition 8.5.8. There are several things to note here. First, the divergence produces a "tensor" which is completely determined at each point by the values of its constituents at that point. Also, although we have used a frame to define the divergence, this is in fact only a convenient way to compute — the divergence may be defined without reference to a particular frame used for computation. With this in mind, consider

Example 8.5.20 (The Metric $\langle \cdot, \cdot \rangle$ has Zero Divergence).

To see this, take normal coordinates about an arbitrary point $p \in M$ and extend to a frame $\{\mathcal{E}_1, \ldots, \mathcal{E}_k\}$ by parallel translation along geodesics emanating from p. In particular, we have $\nabla_{\mathcal{E}_i}\mathcal{E}_j = 0$ at p. Now, because the divergence is determined by the values of the frame etc. at p, the same calculation as below may be made for a normal coordinate frame about every point in M. At p we have

$$\begin{aligned}\operatorname{div} \langle \cdot, \cdot \rangle(\mathcal{E}_i) &= \sum_j \nabla_{\mathcal{E}_j} \langle \mathcal{E}_j, \mathcal{E}_i \rangle\\ &= \sum_j \mathcal{E}_j \langle \mathcal{E}_j, \mathcal{E}_i \rangle - \langle \nabla_{\mathcal{E}_j}\mathcal{E}_j, \mathcal{E}_i \rangle - \langle \mathcal{E}_j, \nabla_{\mathcal{E}_j}\mathcal{E}_i \rangle\\ &= \sum_j \mathcal{E}_j \langle \mathcal{E}_j, \mathcal{E}_i \rangle - 0 - 0\end{aligned}$$

since we have normal coordinates at p. But the first term vanishes as well because $\langle \mathcal{E}_i, \mathcal{E}_j \rangle = \delta_i^j$ on the coordinate neighborhood and the $\mathcal{E}_j$-derivative of a constant is zero. Therefore,

$$\operatorname{div} \langle \cdot, \cdot \rangle(\mathcal{E}_i) = 0.$$

Since this is true for all $\mathcal{E}_i$ and the process is linear, then it holds for all vector fields as well.

Exercise* 8.5.21. For a smooth function $f : M \to \mathbb{R}$, show that

$$\operatorname{div}(f \langle \cdot, \cdot \rangle) = df$$

where df is the differential of f defined by $df(X) = X[f]$ for a vector field X. Thus, the divergence of conformal metrics (i.e., $f > 0$ at every p) depends on the conformality factor alone. Note that this makes sense in light of Example 8.5.10 since the divergence depends on the frame chosen. Verify that, for metric $f \langle \cdot, \cdot \rangle$, the frame $\{(1/\sqrt{f})\, \mathcal{E}_i\}$ gives $\operatorname{div}(f \langle \cdot, \cdot \rangle) = 0$.

We will now apply the divergence to Ricci curvature to find a remarkable relationship.

Theorem 8.5.22. *For Ricci curvature* Ric *and scalar curvature* κ*,*

$$d\kappa = 2 \operatorname{div}(\mathrm{Ric}).$$

Proof. Again choose a frame derived from parallel translation along geodesics of normal coordinates about an arbitrary point $p \in M$. Hence, at p, $\nabla_{\mathcal{E}_i} \mathcal{E}_j = 0$ for all i and j. Then

$$\begin{aligned}
2 \operatorname{div}(\mathrm{Ric})(\mathcal{E}_s) &= 2 \sum_j \nabla_{\mathcal{E}_j} \mathrm{Ric}(\mathcal{E}_j, \mathcal{E}_s) \\
&= 2 \sum_j \mathcal{E}_j \,\mathrm{Ric}(\mathcal{E}_j, \mathcal{E}_s) \\
&= 2 \sum_{i,j} \mathcal{E}_j \langle R(\mathcal{E}_j, \mathcal{E}_i)\mathcal{E}_s, \mathcal{E}_i \rangle \\
&= \sum_{i,j} \mathcal{E}_j \langle R(\mathcal{E}_j, \mathcal{E}_i)\mathcal{E}_s, \mathcal{E}_i \rangle + \sum_{i,j} \mathcal{E}_i \langle R(\mathcal{E}_i, \mathcal{E}_j)\mathcal{E}_s, \mathcal{E}_j \rangle
\end{aligned}$$

where the second term is obtained by switching i and j. Then, the symmetry relations for R imply

$$\begin{aligned}
2 \operatorname{div}(\mathrm{Ric})(\mathcal{E}_s) &= \sum_{i,j} \mathcal{E}_j \langle R(\mathcal{E}_j, \mathcal{E}_i)\mathcal{E}_s, \mathcal{E}_i \rangle + \sum_{i,j} \mathcal{E}_i \langle R(\mathcal{E}_j, \mathcal{E}_i)\mathcal{E}_j, \mathcal{E}_s \rangle \\
&= \sum_{i,j} \nabla R(\mathcal{E}_j, \mathcal{E}_i, \mathcal{E}_s, \mathcal{E}_i, \mathcal{E}_j) + \nabla R(\mathcal{E}_j, \mathcal{E}_i, \mathcal{E}_j, \mathcal{E}_s, \mathcal{E}_i) \\
&= -\sum_{i,j} \nabla R(\mathcal{E}_j, \mathcal{E}_i, \mathcal{E}_i, \mathcal{E}_j, \mathcal{E}_s)
\end{aligned}$$

by the second Bianchi identity. Then, interchanging the first two coordinates,

$$\begin{aligned}
2\operatorname{div}(\mathrm{Ric})(\mathcal{E}_s) &= \sum_{i,j} \nabla R(\mathcal{E}_i, \mathcal{E}_j, \mathcal{E}_i, \mathcal{E}_j, \mathcal{E}_s) \\
&= \sum_{i,j} \mathcal{E}_s R(\mathcal{E}_i, \mathcal{E}_j, \mathcal{E}_i, \mathcal{E}_j) \\
&= \mathcal{E}_s \sum_{i,j} R(\mathcal{E}_i, \mathcal{E}_j, \mathcal{E}_i, \mathcal{E}_j) \\
&= \mathcal{E}_s[\kappa] \\
&= d\kappa(\mathcal{E}_s).
\end{aligned}$$

Since this is true on a basis, it is true in general. ☐

Exercise* 8.5.23. The manifold $(M^k, \langle \cdot, \cdot \rangle)$ with metric $\langle \cdot, \cdot \rangle$ is an *Einstein manifold* if $\mathrm{Ric}(X, Y) = \lambda \langle X, Y \rangle$ for a fixed constant λ and all vector fields X and Y.

(1) Show that, if $\mathrm{Ric}(X, Y)(p) = \lambda(p) \langle X, Y \rangle(p)$ for a smooth function $\lambda \colon M^k \to \mathbb{R}$ with $k \geq 3$, then M^k is Einstein. Hints: (1) first compute κ and (2) then use Theorem 8.5.22.

(2) Show that a semisimple Lie group with Killing form metric $-b$ is an Einstein manifold. Hint: use the last part of Exercise 8.5.18.

Now, what has been the point of all this? The argument we presented earlier suggested that the Einstein and Ricci curvatures should be identified and that the Einstein curvature should be divergence free. But, as Theorem 8.5.22 shows, in general, the Ricci curvature has a nonzero divergence. So what is to be done to rescue the idea? By Exercise 8.5.21, we know

$$\operatorname{div}(\kappa \langle \cdot, \cdot \rangle) = d\kappa$$

so that $\operatorname{div}(\kappa \langle \cdot, \cdot \rangle) = 2\operatorname{div}(\mathrm{Ric})$ and, therefore,

$$\operatorname{div}\left(\mathrm{Ric} - \frac{1}{2}\kappa \langle \cdot, \cdot \rangle\right) = 0.$$

This calculation then says that, if we define the *Einstein curvature* to be $G = \mathrm{Ric} - \frac{1}{2}\kappa \langle \cdot, \cdot \rangle$, then we obtain a type of curvature which is divergence free. Also, we have

Theorem 8.5.24. *The Einstein and Ricci curvatures determine each other. In particular,* $G = 0$ *if and only if* $\mathrm{Ric} = 0$.

Proof. Denoting contraction by $\mathcal{C}$, we may write

$$\begin{aligned}
G &= \mathrm{Ric} - \frac{1}{2}\kappa \langle \cdot, \cdot \rangle \\
&= \mathrm{Ric} - \frac{1}{2}\mathcal{C}(\mathrm{Ric}) \langle \cdot, \cdot \rangle
\end{aligned}$$

since the contraction of the Ricci curvature is scalar curvature by the discussion preceding Example 8.5.10. Of course, Example 8.5.10 itself shows that $\mathcal{C}(\langle\cdot,\cdot\rangle) = \dim M$, so we also have

$$\begin{aligned} \mathcal{C}(G) &= \mathcal{C}(\mathrm{Ric}) - \frac{1}{2}\kappa\, \mathcal{C}(\langle\cdot,\cdot\rangle) \\ &= \kappa - \frac{1}{2}\kappa \dim M \\ &= \left(1 - \frac{\dim M}{2}\right)\kappa. \end{aligned}$$

Now, spacetime has four dimensions — time and $\mathbb{R}^3$ — so $\dim M = 4$. Hence, $\mathcal{C}(G) = -\kappa$ and

$$\begin{aligned} \mathrm{Ric} &= G + \frac{1}{2}\kappa\, \langle\cdot,\cdot\rangle \\ &= G - \frac{1}{2}\mathcal{C}(G)\, \langle\cdot,\cdot\rangle. \end{aligned}$$

Thus, Ric and G determine each other. □

Therefore, it seems that the Einstein curvature is a good choice for the Einstein field equation $G = 8\pi\, T$ (where the constant 8π is determined by taking the Newtonian limit). Indeed, in a vacuum, where $T = 0$, it is generally more convenient to solve the equations $\mathrm{Ric} = 0$ rather than $G = 0$, so the relationship with Ricci curvature is important. Perhaps we should mention what the word "solve" means here. What is known and what is unknown? Generally, we try to determine the geometric structure of spacetime from a hypothesis on the Ricci curvature and a knowledge of some facet of the relevant geometry. In Example 8.5.10 we showed that the Ricci curvature is given in terms of Christoffel symbols and their derivatives. These, in turn, are given in terms of derivatives of the metric. Hence, the expressions

$$R_{is} = 0$$

form a system of second-order partial differential equations *in the metric*. Therefore, when we solve this system, we are *determining the metric in that region of spacetime*. Since the metric determines everything, it can be safely said then that we understand the geometry of spacetime in that particular region.

Example 8.5.25 (The Schwarzschild Solution). The solution (i.e., the metric coefficients) for the vacuum field equations $R_{is} = 0$ outside a spherically symmetric body of mass M is given by

$$g_{00} = 1 - \frac{2M}{r},\ g_{11} = -\left(1 - \frac{2M}{r}\right)^{-1},\ g_{22} = -r^2,\ g_{33} = -r^2 \sin^2\phi,$$

where time t is usually given the index 0. This is the Schwarzschild solution discovered by Schwarzschild in 1916. Note that this metric is different from our usual ones in the sense that it is not positive definite. Spacetime is, in fact, based on the flat (Minkowski) metric of special relativity which has the form $g_{00} = 1$, $g_{11} = -1$, $g_{22} = -1$ and $g_{33} = -1$. These metrics are said to be *semi-Riemannian metrics* and much of the theory of ordinary Riemannian geometry carries over to these metrics as well.

since the contraction of the Ricci curvature is scalar curvature by the discussion preceding Example 8.5.10. Of course, Example 8.5.10 itself shows that $\mathcal{C}(\langle\cdot,\cdot\rangle) = \dim M$, so we also have

$$\begin{aligned}\mathcal{C}(G) &= \mathcal{C}(\mathrm{Ric}) - \frac{1}{2}\kappa\,\mathcal{C}(\langle\cdot,\cdot\rangle)\\ &= \kappa - \frac{1}{2}\kappa\dim M\\ &= \left(1 - \frac{\dim M}{2}\right)\kappa.\end{aligned}$$

Now, spacetime has four dimensions — time and $\mathbb{R}^3$ — so $\dim M = 4$. Hence, $\mathcal{C}(G) = -\kappa$ and

$$\begin{aligned}\mathrm{Ric} &= G + \frac{1}{2}\kappa\,\langle\cdot,\cdot\rangle\\ &= G - \frac{1}{2}\mathcal{C}(G)\,\langle\cdot,\cdot\rangle.\end{aligned}$$

Thus, Ric and G determine each other. ☐

Therefore, it seems that the Einstein curvature is a good choice for the Einstein field equation $G = 8\pi\, T$ (where the constant 8π is determined by taking the Newtonian limit). Indeed, in a vacuum, where $T = 0$, it is generally more convenient to solve the equations $\mathrm{Ric} = 0$ rather than $G = 0$, so the relationship with Ricci curvature is important. Perhaps we should mention what the word "solve" means here. What is known and what is unknown? Generally, we try to determine the geometric structure of spacetime from a hypothesis on the Ricci curvature and a knowledge of some facet of the relevant geometry. In Example 8.5.10 we showed that the Ricci curvature is given in terms of Christoffel symbols and their derivatives. These, in turn, are given in terms of derivatives of the metric. Hence, the expressions

$$R_{is} = 0$$

form a system of second-order partial differential equations *in the metric*. Therefore, when we solve this system, we are *determining the metric in that region of spacetime*. Since the metric determines everything, it can be safely said then that we understand the geometry of spacetime in that particular region.

Example 8.5.25 (The Schwarzschild Solution). The solution (i.e., the metric coefficients) for the vacuum field equations $R_{is} = 0$ outside a spherically symmetric body of mass M is given by

$$g_{00} = 1 - \frac{2M}{r},\ g_{11} = -\left(1 - \frac{2M}{r}\right)^{-1},\ g_{22} = -r^2,\ g_{33} = -r^2\sin^2\phi,$$

where time t is usually given the index 0. This is the Schwarzschild solution discovered by Schwarzschild in 1916. Note that this metric is different from our usual ones in the sense that it is not positive definite. Spacetime is, in fact, based on the flat (Minkowski) metric of special relativity which has the form $g_{00} = 1$, $g_{11} = -1$, $g_{22} = -1$ and $g_{33} = -1$. These metrics are said to be *semi-Riemannian metrics* and much of the theory of ordinary Riemannian geometry carries over to these metrics as well.

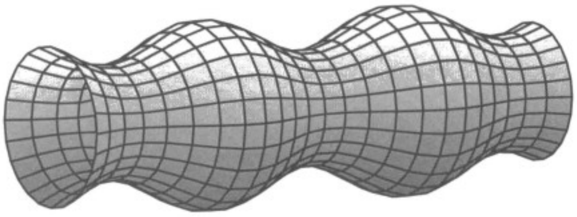

Figure 3.2. A surface of revolution

3.3 Surfaces of Revolution

We have already seen that many interesting examples of surfaces arise from revolving curves about an axis. These surfaces of revolution (see Figure 3.2) have patches of the form $\mathbf{x}(u, v) = (g(u), h(u)\cos v, h(u)\sin v)$. The curves on the surface which are circles formed by revolving a single point about the axis are called *parallels* (denoted π). The curves which look exactly like the original curve (but rotated out) are called *meridians* (denoted μ). Also, recall that $g(u)$ is the distance along the axis of revolution and $h(u)$ is the radius of a parallel. We have, $\mathbf{x}_u = (g', h'\cos v, h'\sin v)$, $\mathbf{x}_v = (0, -h\sin v, h\cos v)$ and $\mathbf{x}_u \times \mathbf{x}_v = (hh', -g'h\cos v, -g'h\sin v)$. Hence,

$$U = \frac{(h', -g'\cos v, -g'\sin v)}{\sqrt{g'^2 + h'^2}}.$$

Also, the second partial derivatives are $\mathbf{x}_{uu} = (g'', h''\cos v, h''\sin v)$, $\mathbf{x}_{uv} = (0, -h'\sin v, h'\cos v)$, and $\mathbf{x}_{vv} = (0, -h\cos v, -h\sin v)$. Hence,

$$E = g'^2 + h'^2, \qquad F = 0, \qquad G = h^2,$$
$$l = \frac{(g''h' - h''g')}{\sqrt{g'^2 + h'^2}}, \qquad m = 0, \qquad n = \frac{hg'}{\sqrt{g'^2 + h'^2}}.$$

Finally, the Gauss curvature is computed to be

$$K = \frac{g'(g''h' - h''g')}{h(g'^2 + h'^2)^2}.$$

Exercise 3.3.1. Verify the computations above.

If the original curve $\alpha(t) = (g(t), h(t), 0)$ has $g'(t) \neq 0$ for all t, then g is strictly increasing. Thus, it is one-to-one and has an inverse function g^{-1} which is differentiable as well. Such an inverse allows us to reparametrize the curve α. Define $f = h \circ g^{-1}$ and get

$$\begin{aligned}\overline{\alpha}(u) &= \alpha \circ g^{-1}(u) = (gg^{-1}(u), hg^{-1}(u), 0)\\ &= (u, f(u), 0).\end{aligned}$$

Thus, our calculations become somewhat easier. For instance, the formula for Gauss curvature becomes $K = -f''/f(1 + f'^2)^2$. To avoid confusion, we will still write $\alpha(u) = (u, h(u), 0)$ and $K = -h''/h(1 + h'^2)^2$.

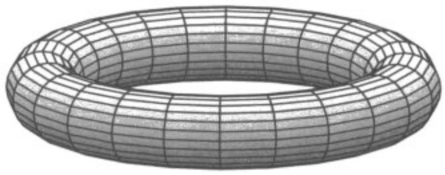

Figure 3.3. A torus

Example 3.3.2 (Torus Curvature).

$$\mathbf{x}(u,v) = (\underbrace{(R + r\cos u)}_{h(u)}\cos v,\ (R + r\cos u)\sin v,\ \underbrace{r\sin u}_{g(u)})$$

$$K = \frac{\cos u}{r(R + r\cos u)}.$$

Observe that, for $-\frac{\pi}{2} < u < \frac{\pi}{2}$, we have $\cos u > 0$. Hence $K > 0$ on the outer half of the torus. For $u = -\frac{\pi}{2}, \frac{\pi}{2}$ we have $\cos u = 0$, so $K = 0$ on the top and bottom of the torus. Finally, for $\frac{\pi}{2} < u < \frac{3\pi}{2}$ we have $\cos u < 0$ and $K < 0$ on the inner half of the torus. Note that the maximum K occurs at $u = 0$,

$$K(0) = \frac{1}{r(R + r)}$$

on the outermost circle, while the minimum K occurs at $u = \pi$,

$$K(\pi) = -\frac{1}{r(R - r)}$$

on the innermost circle.

Exercise 3.3.3. Verify the formula for K above.

Exercise∗ 3.3.4. For a surface of revolution parametrized as above, the v-parameter curves are parallels and the u-parameter curves are meridians. The normal curvatures in the directions of $\mathbf{x}_v$ and $\mathbf{x}_u$ are denoted k_π and k_μ respectively. Show that $k_\mu = l/E$ and $k_\pi = n/G$ by calculating the eigenvectors of S as $\mathbf{x}_u$ and $\mathbf{x}_v$ with eigenvalues l/E, n/G respectively. This shows directly that meridians and parallels are lines of curvature. Hint: $S(\mathbf{x}_u) = a\mathbf{x}_u + b\mathbf{x}_v$. Use $F = 0, m = 0$.

Exercise 3.3.5. For a general surface of revolution, show that

$$k_\mu = \frac{g''h' - g'h''}{(g'^2 + h'^2)^{3/2}}, \qquad k_\pi = \frac{g'}{h(g'^2 + h'^2)^{1/2}}$$

and obtain formulas for K and H. What is k_μ on a torus? What is the geometric reason for this?

Exercise 3.3.6. Revolve the catenary $y = c\cosh(\frac{x}{c})$ around the x-axis to obtain the *catenoid*. Show the following:

$$k_\mu = -\frac{1}{c\cosh^2\frac{u}{c}}, \qquad k_\pi = -k_\mu, \qquad K = -\frac{1}{c^2\cosh^4\frac{u}{c}}, \qquad H = 0.$$

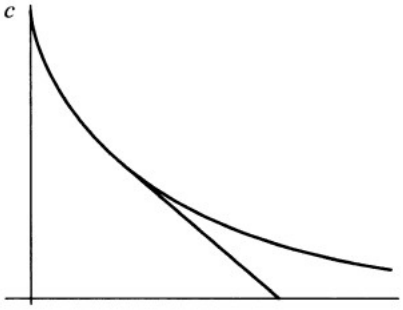

Figure 3.4. Tangent line segment of length c

Can you think of another surface of revolution which is minimal?

Exercise∗ 3.3.7. For the following surfaces of revolution, find K and describe where $K > 0$, $K < 0$, $K = 0$.

(a) Revolve $\alpha(u) = (u, e^{-u^2/2}, 0)$ about the x-axis.

(b) *Elliptical Torus.* Revolve the ellipse $\dfrac{(x-R)^2}{a^2} + \dfrac{y^2}{b^2} = 1$ about the y-axis.

Exercise 3.3.8. If a surface of revolution is generated by a *unit speed curve* $\alpha(u) = (g(u), h(u), 0)$, then show (a) $E = 1,\ F = 0,\ G = h^2$ and (b) $K = -h''/h$.

Example 3.3.9 (The Pseudosphere).
As another example of our computational techniques, we will consider a surface of revolution which is analogous to the sphere in the sense that it has *constant Gauss curvature*. This surface is called the *Pseudosphere* and it is defined by means of a condition on the generating curve. Namely, let α be a curve which begins at $(0, c)$ and traces a path so that its tangent line at any point reaches the x-axis after running a distance exactly equal to c. This means the curve α must decrease and flatten. The curve α is called a *tractrix* and is physically represented by the path a ship would follow when starting at $(0, c)$ and is being pulled by a tugboat which moves along the x-axis (see Figure 3.4).

Write $\alpha(u) = (u, h(u))$ and note $h' < 0$ and $g(u) = u$. Now, $\alpha'(u) = (1, h'(u))$ and a tangent line at $(u, h(u))$ has the equation

$$l(t) = \alpha(u) + t\alpha'(u).$$

The y-coordinate of $l(t)$ is then $h + th'$, so for $t = 0$ we are at $\alpha(u)$ and for $t = -h/h'$ we are on the x-axis. We want the length of this segment to be c, so we have

$$\begin{aligned} c &= |\alpha(u) - (\alpha(u) - \frac{h}{h'}\alpha'(u))| \\ &= \frac{h}{|h'|}|\alpha'(u)| \\ &= \frac{h}{|h'|}\sqrt{1 + h'^2}. \end{aligned}$$

Then $c^2 = \frac{h^2}{h'^2}(1 + h'^2) = \frac{h^2}{h'^2} + h^2$. Solving for h' and then taking another derivative, we get

$$h' = -\frac{h}{\sqrt{c^2 - h^2}} \qquad h'' = -\frac{h'c^2}{(c^2 - h^2)^{3/2}}.$$

Exercise 3.3.10. Show that, for the surface of revolution obtained by revolving α about the x-axis, we obtain (a) $k_\mu = h'/c$ (b) $k_\pi = -1/ch'$ and (c) $K = -1/c^2$.

Note that the Gauss curvature of the pseudosphere is a constant. However, in contrast to a sphere's constant positive curvature, the pseudosphere's curvature is negative. For $c = 1$, we obtain a surface at each point of which the Gauss curvature is -1. Later we will meet up with more geometrically natural surfaces of this kind.

Exercise* 3.3.11. Solve the separable differential equation

$$h' = -\frac{h}{\sqrt{1 - h^2}}$$

in two ways to get (1) $u = \ln|\frac{\sqrt{1-h^2}}{h} + \frac{1}{h}| - \sqrt{1 - h^2}$ and (2) $h(u) = \operatorname{sech} w$, $u = w - \tanh w$. For the first, turn the picture over so we revolve the tractrix about the z-axis and the pseudosphere (with $c = 1$) lies over the disk of radius 1. If we write things in cylindrical coordinates (r, θ, z), then the old u becomes z and the old h becomes r. By substitution in the formula above, we get

$$z = -\sqrt{1 - r^2} - \ln(r) + \ln(1 + \sqrt{1 - r^2}).$$

Of course, rectangular coordinates may now be introduced by $r = \sqrt{x^2 + y^2}$. Use this formula to graph the pseudosphere via Maple. For the second, we obtain a patch for the pseudosphere

$$\mathbf{x}(w, v) = (w - \tanh w,\ \operatorname{sech} w \cos v, \operatorname{sech} w \sin v).$$

Plot this patch with Maple also. Compare the two plots. Hints: For the first, use trigonometric substitution with $h = \cos w$. For the second, use hyperbolic trigonometric substitution.

The pseudosphere (see Figure 3.5) is actually determined by the requirement of constant curvature and certain initial conditions. Suppose we start off by requiring that a surface of

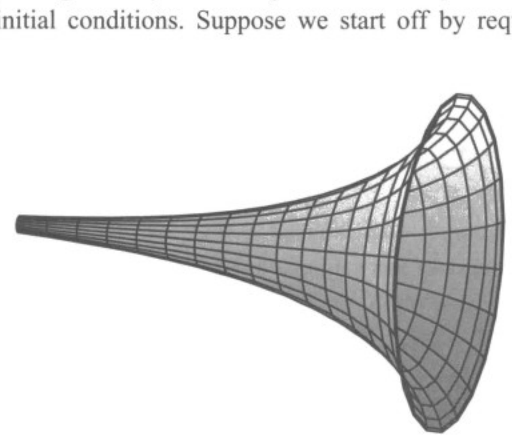

Figure 3.5. A pseudosphere

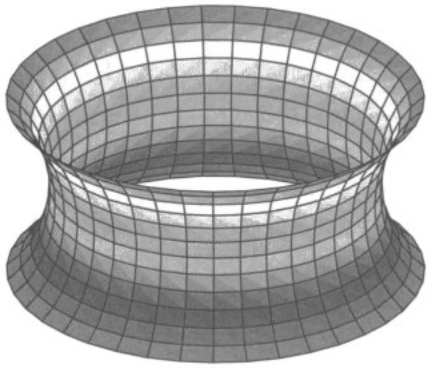

Figure 3.6. A constant negative curvature surface of revolution

revolution M have constant Gauss curvature $K = -1$. We can suppose also that M is parametrized by $\mathbf{x}(u, v) = (g(u), h(u)\cos v, h(u)\sin v)$ with $g'(u)^2 + h'(u)^2 = 1$ (i.e., the profile curve is unit speed). Then, as we have seen, the formula for Gauss curvature reduces to $K = -h''/h$, so the requirement of constant curvature $K = -1$ gives us a linear differential equation to solve,

$$h'' = h.$$

The solution to this differential equation is easy. We obtain

$$h(u) = A\,e^{u} + B\,e^{-u}.$$

Then, plugging $h(u)$ into the the unit speed relation $g'(u)^2 + h'(u)^2 = 1$ and solving for $g(u)$ gives

$$g(u) = \pm \int_{u_0}^{u} \sqrt{1 - (A\,e^{t} - B\,e^{-t})^2}\,dt.$$

In choosing A and B, new surfaces of constant Gauss curvature $K = -1$ are created. See Figure 3.6.

Exercise 3.3.12. Let $A = 1$ and $B = 0$. Show that this surface of constant Gauss curvature $K = -1$ is the pseudosphere with $c = 1$. Hint: let $e^{t} = \operatorname{sech} w$.

Exercise 3.3.13. Carry out the same procedure for the case of positive Gauss curvature $K = +1$. What should A and B be to get the unit sphere? See Exercise 3.7.8 and Section 3.8.

3.4 A Formula for Gauss Curvature

So far, we have seen that Gauss curvature tells us a great deal about the geometry of a surface. However, since we compute K using the unit normal U, it seems that the precise way in which we situate a surface in $\mathbb{R}^3$ may well change K while leaving the essential geometry unaltered. This would mean that Gauss curvature would not be an invariant of the geometry of the surface. We shall now give a formula for K which obviates the use of U and shows that K depends only on E, F, and G, the so-called *metric* of the surface. In fact, although a more general formula exists (see Exercise 3.4.7 below), we shall restrict ourselves to the case where $F = \mathbf{x}_u \cdot \mathbf{x}_v = 0$.

That is, we shall assume that the u and v-parameter curves always meet at right angles. In this case we prove

Theorem 3.4.1. *The Gauss curvature depends only on the metric E, F and G. When $F = 0$, Gauss curvature is given by*

$$(*) \qquad K = -\frac{1}{2\sqrt{EG}}\left(\frac{\partial}{\partial v}\left(\frac{E_v}{\sqrt{EG}}\right) + \frac{\partial}{\partial u}\left(\frac{G_u}{\sqrt{EG}}\right)\right).$$

Here, we have used the notation

$$E_v = \frac{\partial}{\partial v}E = \frac{\partial}{\partial v}(\mathbf{x}_u \cdot \mathbf{x}_u) \quad \text{and} \quad G_u = \frac{\partial}{\partial u}G = \frac{\partial}{\partial u}(\mathbf{x}_v \cdot \mathbf{x}_v).$$

Of course, to prove the theorem, we will show that our usual formula $K = (ln - m^2)/(EG - F^2)$ reduces to the one above. Notice that the formula of the theorem does not depend on the particular patch used, but only on the metric coefficients E, G (and implicitly F). We will consider this a bit more carefully later when we discuss isometries of surfaces, but suffice it to say that, intuitively, a surface may be "bent" without stretching and still have the same Gauss curvature. The prime example of this phenomenon is the usual right circular cylinder. If the cylinder is cut along a ruling it can be made to lie flat on a plane without stretching. This means that, locally, the cylinder and the plane have the same geometry. This further explains, geometrically, the vanishing of the cylinder's Gauss curvature. The dependence of K on the metric alone is known as *Gauss's Theorem Egregium* (meaning "remarkable theorem").

We point out two things. First, this result *does not mean* that two surfaces with the same Gauss curvature are *the same geometrically*. Surfaces may have the same formulas for Gauss curvature while still having fundamentally different geometries encoded in their individual metrics. To make this precise we need the notion of isometry, so for the moment we give

Exercise 3.4.2. Show that the following two patches have the same Gauss curvature:

$$\mathbf{x}(u, v) = (u\cos v, u\sin v, v), \qquad \mathbf{y}(u, v) = (u\cos v, u\sin v, \ln u).$$

These surfaces are not isometric as will be shown in Exercise 5.5.2.

Secondly, the Theorem Egregium holds for Gauss curvature, *but not for mean curvature*. For instance, as we have mentioned, a cylinder and a plane are geometrically the same with the same Gauss curvature $K = 0$, but their mean curvatures are quite different. The mean curvature of the plane is zero while that of the cylinder is one-half the curvature of the base circle. Thus, mean curvature is not truly an invariant of *the surface itself*, but depends on the way in which the surface sits in $\mathbb{R}^3$.

We now turn to the derivation of the formula in Theorem 3.4.1. While the details of the calculations are quite tedious, keep in mind that we are simply finding coefficients for a vector in terms of a particular basis. Because $l = \mathbf{x}_{uu} \cdot U$, $m = \mathbf{x}_{uv} \cdot U$ and $n = \mathbf{x}_{vv} \cdot U$, we need expressions for

$\mathbf{x}_{uu}$, $\mathbf{x}_{uv}$, and $\mathbf{x}_{vv}$ in terms of the basis for 3-space $\{\mathbf{x}_u, \mathbf{x}_v, U\}$. Write

$$\begin{aligned}\mathbf{x}_{uu} &= \Gamma^u_{uu}\mathbf{x}_u + \Gamma^v_{uu}\mathbf{x}_v + lU \quad (\text{since } \mathbf{x}_{uu}\cdot U = l \text{ etc.})\\ \mathbf{x}_{uv} &= \Gamma^u_{uv}\mathbf{x}_u + \Gamma^v_{uv}\mathbf{x}_v + mU\\ \mathbf{x}_{vv} &= \Gamma^u_{vv}\mathbf{x}_u + \Gamma^v_{vv}\mathbf{x}_v + nU. \end{aligned} \tag{**}$$

Our job is to find the Γ's. These are just coefficients in a basis expansion, but they are known by the name *Christoffel Symbols*. We use what we know about dot products to determine the Γ's.

$$\begin{aligned}\mathbf{x}_{uu}\cdot\mathbf{x}_u &= \Gamma^u_{uu}\mathbf{x}_u\cdot\mathbf{x}_u + 0 + 0\\ &= \Gamma^u_{uu}E \qquad \text{by definition of } E.\end{aligned}$$

If we can compute $\mathbf{x}_{uu}\cdot\mathbf{x}_u$, then we will know Γ^u_{uu}. This is simply the product rule.

$$E = \mathbf{x}_u\cdot\mathbf{x}_u, \text{ so } E_u = \mathbf{x}_{uu}\cdot\mathbf{x}_u + \mathbf{x}_u\cdot\mathbf{x}_{uu} = 2\mathbf{x}_{uu}\cdot\mathbf{x}_u.$$

Thus

$$\mathbf{x}_{uu}\cdot\mathbf{x}_u = \frac{E_u}{2} \quad\text{and}\quad \Gamma^u_{uu} = \frac{E_u}{2E}.$$

Further, $\mathbf{x}_u\cdot\mathbf{x}_v = 0$ so taking the partial with respect to u gives

$$0 = \mathbf{x}_{uu}\cdot\mathbf{x}_v + \mathbf{x}_u\cdot\mathbf{x}_{uv} \quad\text{or}\quad \mathbf{x}_{uu}\cdot\mathbf{x}_v = -\mathbf{x}_u\cdot\mathbf{x}_{uv}.$$

Also, $E = \mathbf{x}_u\cdot\mathbf{x}_u$, so taking the partial with respect to v gives $E_v = 2\mathbf{x}_u\cdot\mathbf{x}_{uv}$ and, consequently, $E_v/2 = \mathbf{x}_u\cdot\mathbf{x}_{uv} = -\mathbf{x}_{uu}\cdot\mathbf{x}_v$. Moreover,

$$\Gamma^v_{uu} = (\mathbf{x}_{uu}\cdot\mathbf{x}_v)/G = -E_v/2G \quad\text{and}\quad \Gamma^u_{uv} = \mathbf{x}_{uv}\cdot\mathbf{x}_u/E = E_v/2E.$$

Continuing on, $G = \mathbf{x}_v\cdot\mathbf{x}_v$, so $G_u/2 = \mathbf{x}_{uv}\cdot\mathbf{x}_v$. Then, since $0 = \mathbf{x}_v\cdot\mathbf{x}_u$, we have

$$-\mathbf{x}_v\cdot\mathbf{x}_{uv} = \mathbf{x}_{vv}\cdot\mathbf{x}_u$$

with

$$\Gamma^v_{uv} = \mathbf{x}_{uv}\cdot\mathbf{x}_v/G = G_u/2G \quad\text{and}\quad \Gamma^u_{vv} = \mathbf{x}_{vv}\cdot\mathbf{x}_u/E = -G_u/2E.$$

Finally, $\mathbf{x}_v\cdot\mathbf{x}_v = G$, so $\mathbf{x}_{vv}\cdot\mathbf{x}_v = G_v/2$ and $\Gamma^v_{vv} = \mathbf{x}_{vv}\cdot\mathbf{x}_v/G = G_v/2G$. We end up with the following

Formula(s) 3.4.3 (Fundamental Acceleration Formulas: $F = 0$ Case).

$$\begin{aligned}\mathbf{x}_{uu} &= \frac{E_u}{2E}\mathbf{x}_u - \frac{E_v}{2G}\mathbf{x}_v + lU\\ \mathbf{x}_{uv} &= \frac{E_v}{2E}\mathbf{x}_u + \frac{G_u}{2G}\mathbf{x}_v + mU\\ \mathbf{x}_{vv} &= -\frac{G_u}{2E}\mathbf{x}_u + \frac{G_v}{2G}\mathbf{x}_v + nU\\ U_u &= -\frac{l}{E}\mathbf{x}_u - \frac{m}{G}\mathbf{x}_v\\ U_v &= -\frac{m}{E}\mathbf{x}_u - \frac{n}{G}\mathbf{x}_v\end{aligned}$$

Exercise∗ 3.4.4. Compute U_u and U_v as above. Hint: $U_u \overset{\text{def}}{=} \nabla_{\mathbf{x}_u} U = A\mathbf{x}_u + B\mathbf{x}_v$. Find A by $\nabla_{\mathbf{x}_u} U \cdot \mathbf{x}_u = A\mathbf{x}_u \cdot \mathbf{x}_u = AE$ and $0 = \mathbf{x}_u(U \cdot \mathbf{x}_u) = \nabla_{\mathbf{x}_u} U \cdot \mathbf{x}_u + U \cdot \mathbf{x}_{uu}$.

We know that mixed partial derivatives are equal no matter the order of differentiation, so $\mathbf{x}_{uuv} = \mathbf{x}_{uvu}$, or $\mathbf{x}_{uuv} - \mathbf{x}_{uvu} = 0$. This means that the coefficients of $\mathbf{x}_u$, $\mathbf{x}_v$ and U are *all zero* when $\mathbf{x}_{uuv} - \mathbf{x}_{uvu}$ is written in this basis. Let's concentrate on the $\mathbf{x}_v$-term. (We again use the product rule repeatedly.)

$$\mathbf{x}_{uuv} = \left(\frac{E_u}{2E}\right)_v \mathbf{x}_u + \frac{E_u}{2E}\mathbf{x}_{uv} - \left(\frac{E_v}{2G}\right)_v \mathbf{x}_v - \frac{E_v}{2G}\mathbf{x}_{vv} + l_v U + l U_v.$$

Now replace $\mathbf{x}_{uv}$, $\mathbf{x}_{vv}$ and U_v by their basis expansions to get,

$$\mathbf{x}_{uuv} = [\ ]\mathbf{x}_u + \left[\frac{E_u G_u}{4EG} - \left(\frac{E_v}{2G}\right)_v - \frac{E_v G_v}{4G^2} - \frac{ln}{G}\right]\mathbf{x}_v + [\ ]U$$

$$\mathbf{x}_{uvu} = \left(\frac{E_v}{2E}\right)_u \mathbf{x}_u + \frac{E_v}{2E}\mathbf{x}_{uu} + \left(\frac{G_u}{2G}\right)_u \mathbf{x}_v + \frac{G_u}{2G}\mathbf{x}_{uv} + m_u U + m U_u$$

$$\mathbf{x}_{uvu} = [\ ]\mathbf{x}_u + \left[-\frac{E_v E_v}{4EG} + \left(\frac{G_u}{2G}\right)_u + \frac{G_u G_u}{4G^2} - \frac{m^2}{G}\right]\mathbf{x}_v + [\ ]U.$$

Because the $\mathbf{x}_v$-coefficient of $\mathbf{x}_{uuv} - \mathbf{x}_{uvu}$ is zero, we get,

$$0 = \frac{E_u G_u}{4EG} - \left(\frac{E_v}{2G}\right)_v - \frac{E_v G_v}{4G^2} + \frac{E_v E_v}{4EG} - \left(\frac{G_u}{2G}\right)_u - \frac{G_u G_u}{4G^2} - \frac{ln - m^2}{G}.$$

Notice the last term! Dividing by E, we have

$$\frac{ln - m^2}{EG} = \frac{E_u G_u}{4E^2 G} - \frac{1}{E}\left(\frac{E_v}{2G}\right)_v - \frac{E_v G_v}{4EG^2} + \frac{E_v E_v}{4E^2 G} - \frac{1}{E}\left(\frac{G_u}{2G}\right)_u - \frac{G_u G_u}{4EG^2}.$$

Of course, the left-hand side is K (since $F = 0$) and the right-hand side only depends on E and G. Thus, we have a formula for K which does not make explicit use of the normal U.

Exercise∗ 3.4.5. Show that the right-hand side above is

$$-\frac{1}{2\sqrt{EG}}\left(\frac{\partial}{\partial v}\left(\frac{E_v}{\sqrt{EG}}\right) + \frac{\partial}{\partial u}\left(\frac{G_u}{\sqrt{EG}}\right)\right).$$

Exercise∗ 3.4.6. Compute the curvature of the sphere of radius R using this formula. Does this agree with what the shape operator tells you?

Exercise 3.4.7. Show, by similar arguments, that, if $F \neq 0$, the following formula holds.

$$K = \frac{1}{(EG - F^2)^2}\left(\begin{vmatrix} -\frac{E_{vv}}{2} + F_{uv} - \frac{G_{uu}}{2} & \frac{E_u}{2} & F_u - \frac{E_v}{2} \\ F_v - \frac{G_u}{2} & E & F \\ \frac{G_v}{2} & F & G \end{vmatrix} - \begin{vmatrix} 0 & \frac{E_v}{2} & \frac{G_u}{2} \\ \frac{E_v}{2} & E & F \\ \frac{G_u}{2} & F & G \end{vmatrix}\right)$$

Exercise 3.4.8. Show that the U-terms of $\mathbf{x}_{uuv} - \mathbf{x}_{uvu} = 0$ and $\mathbf{x}_{vvu} - \mathbf{x}_{uvv} = 0$ give

$$\begin{aligned} l_v - m_u &= m\left(\frac{G_u}{2G} - \frac{E_u}{2E}\right) + E_v\, H \\ &= l\,\frac{E_v}{2E} + m\left(\frac{G_u}{2G} - \frac{E_u}{2E}\right) + n\,\frac{E_v}{2G} \end{aligned}$$

and

$$\begin{aligned} n_u - m_v &= m\left(\frac{E_v}{2E} - \frac{G_v}{2G}\right) + G_u\, H \\ &= l\,\frac{G_u}{2E} + m\left(\frac{E_v}{2E} - \frac{G_v}{2G}\right) + n\,\frac{G_u}{2G} \end{aligned}$$

where H is mean curvature (and F is assumed to be zero). These are the Codazzi-Mainardi equations. What do they say in the case where the surface is minimal (i.e., $H = 0$) and the parametrization satisfies $E = G$, $F = 0$?

3.5 Some Effects of Curvature(s)

In this section we will derive some geometric consequences of various conditions on Gauss and mean curvatures. Of course, the point of all this is simply to show that we have not wasted our time so far in learning how to compute K and H. These quantities really do tell us about the geometry of a surface. In the next chapter we will focus on mean curvature and see that it is intimately related to certain structures in Nature. For now, however, our goal is simply to see geometry reflected in the linear algebra and calculus represented by K and H.

Let us start by considering a completely impractical situation! Namely, suppose we know that every point on a surface is an umbilic point. Recall that this means that, at every point, the principal curvatures are equal. Although this does not mean, *a priori*, that the principal curvatures are constant functions on the surface (with the same value), this is precisely what we shall prove below. Of course, a direct verification of such a hypothesis is out of the question, yet we shall see later that this result is useful all the same. First try the following

Exercise* 3.5.1. Suppose $p \in M$ is an umbilic point (i.e., $k_1 = k_2 = k$ at p). Show that, at p,

$$k = \frac{l}{E} = \frac{n}{G}.$$

Moreover, if $F \neq 0$, then $k = \frac{m}{F}$ as well. Hint: Write $S(\mathbf{x}_u) = A\mathbf{x}_u + B\mathbf{x}_v = k\mathbf{x}_u$ by Theorem 2.4.10 since p is umbilic. Use $B = 0$ in

$$l = S(\mathbf{x}_u)\cdot \mathbf{x}_u = AE + BF, \quad m = S(\mathbf{x}_u)\cdot \mathbf{x}_v = AF + BG.$$

Solve for A. Do the same for $S(\mathbf{x}_v)$.

Theorem 3.5.2. *A surface M consisting entirely of umbilic points is contained in either a plane or a sphere.*

Proof. Although we know that $k_1 = k_2 = k$ at any $p \in M$, it is still possible that k may vary from point to point in M. Now, by Theorem 2.4.10, we see that

$$\nabla_{\mathbf{x}_u} U = -S(\mathbf{x}_u) = -k\mathbf{x}_u \quad \text{and} \quad \nabla_{\mathbf{x}_v} U = -S(\mathbf{x}_v) = -k\mathbf{x}_v.$$

Now the mixed covariant derivative may be calculated by Exercise 2.2.9.

$$\begin{aligned}\nabla_{\mathbf{x}_v}\nabla_{\mathbf{x}_u} U &= \sum_k \left\{ \sum_i \left[\left(\sum_j \frac{\partial^2 u_k}{\partial x_i \partial x_j} \frac{\partial x_i}{\partial u} \frac{\partial x_j}{\partial v} \right) + \frac{\partial u_k}{\partial x_i} \frac{\partial^2 x_i}{\partial u \partial v} \right] \right\} e_k \\ &= \nabla_{\mathbf{x}_u}\nabla_{\mathbf{x}_v} U\end{aligned}$$

so differentiating $-k\mathbf{x}_u$ by v and $-k\mathbf{x}_v$ by u gives $-k_v\mathbf{x}_u - k\mathbf{x}_{uv} = -k_u\mathbf{x}_v - k\mathbf{x}_{vu}$ and, hence, $k_v\mathbf{x}_u = k_u\mathbf{x}_v$. But $\mathbf{x}_u$ and $\mathbf{x}_v$ are linearly independent, so we must have $k_v = 0 = k_u$ and this implies that k *is a constant function*.

Case 1. Suppose $k = 0$. Then the shape operator is zero everywhere. By Theorem 2.2.17, M is contained in a plane.

Case 2. Suppose $k \neq 0$. Then consider $\mathbf{x}(u, v) + \frac{1}{k}U$ and compute,

$$\begin{aligned}\frac{\partial}{\partial u}\left[\mathbf{x}(u, v) + \frac{1}{k}U\right] &= \mathbf{x}_u + \frac{1}{k}U_u \\ &= \mathbf{x}_u + \frac{1}{k}[-k\mathbf{x}_u] \qquad \text{by above} \\ &= \mathbf{x}_u - \mathbf{x}_u \\ &= 0.\end{aligned}$$

In a similar fashion

$$\frac{\partial}{\partial v}\left[\mathbf{x}(u, v) + \frac{1}{k}U\right] = 0.$$

Hence, $\mathbf{x}(u, v) + \frac{1}{k}U = p$, a constant. Then $|\mathbf{x}(u, v) - p| = |-\frac{1}{k}| = \frac{1}{|k|}$, so every point $\mathbf{x}(u, v)$ lies a distance $1/|k|$ from p. Hence, $\mathbf{x}(u, v)$ lies on a sphere of radius $1/|k|$.

We note that we have proved the result only for a single patch. However, because M is connected, any patch must overlap some other patch. For a patch which overlaps $\mathbf{x}(u, v)$, the points in the overlap lie on the plane or sphere as above. Since the argument above produces a constant k on the new patch, it must therefore agree with the k of $\mathbf{x}(u, v)$. Hence, the geometry of $\mathbf{x}(u, v)$ propagates to overlapping patches. This then continues over the whole surface, each patch reproducing the geometry of its neighbors. □

Notice that, for an all umbilic surface, by Exercise 3.5.1 we obtain

$$K = \frac{ln - m^2}{EG - F^2} = \frac{\frac{l}{E}\frac{n}{G}(EG) - \frac{m^2}{F^2}F^2}{EG - F^2} = \frac{\frac{l^2}{E^2}(EG - F^2)}{EG - F^2} = \frac{l^2}{E^2} = k^2,$$

so $|k| = \sqrt{K}$ and the radius of the sphere is $1/\sqrt{K}$. The next result restricts the form surfaces in $\mathbb{R}^3$ may take in terms of their possible Gauss curvatures. Recall that a surface in $\mathbb{R}^3$ is *compact* if it is closed and bounded. Here, "bounded" means that the surface may be enclosed by a sphere of sufficient size. The term "closed" means that any sequence of points on the surface which converges to some point in $\mathbb{R}^3$ actually converges to a point on the surface. In the following result the hypothesis of "compactness" is used to ensure that maximums and minimums of functions are actually attained by the functions.

Theorem 3.5.3. *On every compact surface $M \subseteq \mathbb{R}^3$ there is some point p with $K(p) > 0$.*

Proof. Let $f : M \to \mathbb{R}$ be defined by $f(p) = |p|^2$. This function is continuous, so (since M is *compact*) f attains its max and its min. Let p_0 be a max for f. Now $f(p_0) = |p_0|^2$, so p_0 is the farthest point from the origin on M. If $r = |p_0|$, then M is inside the sphere of radius r as shown in Figure 3.7.

Therefore, it seems likely that $K(p_0) \geq \frac{1}{r^2}$, where the $\frac{1}{r^2}$ is the curvature of the r-sphere $S^2(r)$. We verify this and so prove the theorem. Consider a unit tangent vector $\mathbf{u} \in T_{p_0}(M)$ and take a curve α in M with $\alpha(0) = p_0$ and $\alpha'(0) = \mathbf{u}$. Of course the composition $f \circ \alpha$ still has a max at p_0 (since α lies in M), so we have the usual calculus conditions

$$\begin{aligned} \frac{d}{dt}(f \circ \alpha)\,|_{t=0} &= 0 \\ \frac{d^2}{dt^2}(f \circ \alpha)\,|_{t=0} &\leq 0. \end{aligned}$$

Now $f \circ \alpha(t) = |\alpha(t)|^2 = \alpha(t) \cdot \alpha(t)$, so $\frac{d}{dt}(f \circ \alpha) = 2\alpha \cdot \alpha'$. At $t = 0$,

$$0 = 2\alpha(0) \cdot \alpha'(0) = 2p_0 \cdot \mathbf{u}.$$

But $\mathbf{u}$ is any unit vector in $T_{p_0}M$, so $p_0 \cdot \mathbf{u} = 0$ for all $\mathbf{u} \in T_{p_0}M$. Hence, p_0 is normal to M at p_0. Also, $(d^2/dt^2)(f \circ \alpha) = 2\alpha' \cdot \alpha' + 2\alpha \cdot \alpha''$ and at $t = 0$,

$$\begin{aligned} 0 \geq \frac{d^2}{dt^2}(f \circ \alpha) &= 2\alpha'(0) \cdot \alpha'(0) + 2\alpha(0) \cdot \alpha''(0) \\ &= 2\,\mathbf{u} \cdot \mathbf{u} + 2\,p_0 \cdot \alpha''(0) \\ &= 2 + 2\,p_0 \cdot \alpha''(0) \\ -2 &\geq 2\,p_0 \cdot \alpha''(0) \\ -1 &\geq p_0 \cdot \alpha''(0). \end{aligned}$$

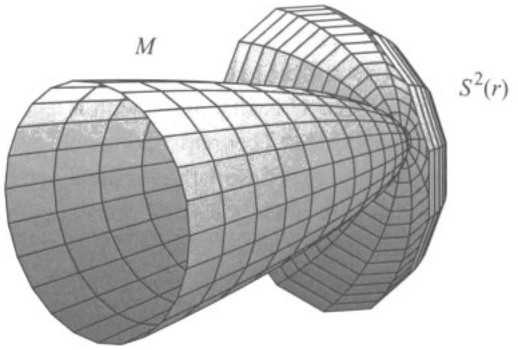

Figure 3.7. Surface at the farthest point p_0

Now, let's calculate normal curvatures at p_0. Since $p_0/r = p_0/|p_0|$ is a unit normal to M at p_0, the calculations above give

$$\begin{aligned} k(\mathbf{u}) &= S(\mathbf{u}) \cdot \mathbf{u} \\ &= S(\alpha') \cdot \alpha' \\ &= U(p_0) \cdot \alpha'' \\ &= \frac{p_0}{r} \cdot \alpha'' \\ &\leq -\frac{1}{r}. \end{aligned}$$

In particular, both k_1 and k_2 are less than or equal to $-1/r$. Thus the Gauss curvature has

$$K(p_0) = k_1(p_0)k_2(p_0) \geq \frac{1}{r} \cdot \frac{1}{r} = \frac{1}{r^2} > 0.$$

□

Corollary 3.5.4. *There are no compact surfaces in $\mathbb{R}^3$ with $K \leq 0$. In particular, no minimal surface embedded in $\mathbb{R}^3$ is compact.*

We now come to one of the main results displaying the influence of curvature on geometry. Previously, we saw that an all umbilic surface is either a plane ($K = 0$) or a sphere ($K > 0$ and constant). There is, however, a much stronger result which is based on the Gauss curvature K itself rather than its factors k_1 and k_2. This beautiful result is

Theorem 3.5.5 (H. Liebmann). *If M is a compact surface of constant Gauss curvature K, then M is a sphere of radius $1/\sqrt{K}$.*

Proof. By Theorem 3.5.3, there is some $p \in M$ with $K(p) > 0$. Since K is constant, then $K > 0$ everywhere on M. Because K is constant and $K = k_1 k_2$, where k_1 and k_2 are the principal curvatures, if p is a point where the function k_1 is a maximum, then p is also a point where k_2 is a minimum. We know that such a p exists since M is compact and k_1, k_2 are continuous functions. We now have two cases to consider.

Case 1. Suppose $k_1 = k_2$ at p. Because k_1 is a maximum and k_2 is a minimum at p, *all* normal curvatures on M must lie between these two values. Therefore, if $k_1 = k_2$ at p, the normal curvature k must be constant on M. Hence M is all umbilic with $K > 0$, so it is a sphere of radius $1/\sqrt{K}$. (This is what we meant by saying that Theorem 3.5.2 would prove useful.) We shall now show that Case 2 below is impossible, so that Case 1 proves the theorem.

Case 2. Suppose $k_1 > k_2$ at p. There is actually a small open neighborhood of p in M where $k_1 > k_2$. If not, we could take a decreasing sequence of open "balls" about p and choose points α_i in the balls with $k_1(\alpha_i) = k_2(\alpha_i)$ and $\alpha_i \to p$. Then, by continuity, we would have $k_1(p) = k_2(p)$. This contradicts our assumption, so we must have the desired neighborhood. Although we shall not prove it, on this neighborhood we may choose two principal directions which are perpendicular at each point and use these to provide a patch with $\mathbf{x}_u \cdot \mathbf{x}_u = E$, $\mathbf{x}_u \cdot \mathbf{x}_v = 0$, $\mathbf{x}_v \cdot \mathbf{x}_v = G$ and, since $\mathbf{x}_u$, $\mathbf{x}_v$ are *principal vectors*,

$$S(\mathbf{x}_u) = k_1 \mathbf{x}_u, \quad S(\mathbf{x}_v) = k_2 \mathbf{x}_v.$$

(A proof of the existence of such a patch $\mathbf{x}$ may be found in [dC76, p. 185].) Note that $m = S(\mathbf{x}_u) \cdot \mathbf{x}_v = k_1 \mathbf{x}_u \cdot \mathbf{x}_v = 0$ also. Moreover, $l = S(\mathbf{x}_u) \cdot \mathbf{x}_u = k_1 \mathbf{x}_u \cdot \mathbf{x}_u = k_1 E$, so $k_1 = \frac{l}{E}$ and, similarly, $k_2 = \frac{n}{G}$. Of course, we have the formula,

$$K = -\frac{1}{2\sqrt{EG}} \left[\frac{\partial}{\partial v} \left(\frac{E_v}{\sqrt{EG}} \right) + \frac{\partial}{\partial u} \left(\frac{G_u}{\sqrt{EG}} \right) \right],$$

and from the U-term of $\mathbf{x}_{uuv} - \mathbf{x}_{uvu} = 0$ (see Exercise 3.4.8), we get

$$\begin{aligned} 0 &= \frac{-nE_v}{2G} + l_v - \frac{E_v l}{2E} \\ l_v &= \frac{E_v}{2} \left[\frac{l}{E} + \frac{n}{G} \right] \\ &= \frac{E_v}{2}(k_1 + k_2). \end{aligned}$$

Similarly, using the U-term of $\mathbf{x}_{vvu} - \mathbf{x}_{vuv} = 0$ we get

$$n_u = \frac{G_u}{2} \left[\frac{l}{E} + \frac{n}{G} \right] = \frac{G_u}{2}(k_1 + k_2).$$

If we differentiate the formulas $k_1 = \frac{l}{E}$ and $k_2 = \frac{n}{G}$ repeatedly and use the expressions for l_v and n_u we get,

$$\begin{aligned} k_{1v} &= \frac{1}{E^2}(El_v - E_v l) = \frac{E_v}{2E}(k_2 - k_1) \\ k_{2u} &= \frac{1}{G^2}(Gn_u - G_u n) = \frac{G_u}{2G}(k_1 - k_2) \\ k_{1vv} &= \frac{E_{vv}}{2E}(k_2 - k_1) + E_v(\ldots) \\ k_{2uu} &= \frac{G_{uu}}{2G}(k_1 - k_2) + G_u(\ldots). \end{aligned}$$

Now, at p, k_1 is a max and k_2 is a min, so

$$\begin{aligned} k_{1v} &= 0 \qquad & k_{1vv} &\le 0 \\ k_{2u} &= 0 \qquad & k_{2uu} &\ge 0. \end{aligned}$$

Plugging these estimates into the equations above we get, at p,

$$\begin{aligned} E_v &= 0 \qquad & E_{vv} &\ge 0 \\ G_u &= 0 \qquad & G_{uu} &\ge 0. \end{aligned}$$

Note that, even though $E_v = 0 = G_u$ at p, the expressions

$$\frac{\partial}{\partial v}\left(\frac{E_v}{\sqrt{EG}}\right) \quad \text{and} \quad \frac{\partial}{\partial u}\left(\frac{G_u}{\sqrt{EG}}\right)$$

may be nonzero at p since the differentiation is done before the evaluation at p. These expressions then give us, at p,

$$K = -\frac{1}{2EG}\left(E_{vv} + G_{uu}\right) \leq 0.$$

But this contradicts our hypothesis that $K > 0$, so our assumption $k_1 > k_2$ must be incorrect. Hence Case 1 holds and M is a sphere. □

Notice that in the course of the proof we have discovered a famous result of David Hilbert (which will prove useful in Exercise 3.5.10).

Lemma 3.5.6 (Hilbert). *If k_1 has a* max *at p, k_2 has a* min *at p and k_1 is strictly greater than k_2 at p, then $K(p) \leq 0$.*

So far, we have concentrated on the effects of Gauss curvature on geometry. We now balance this somewhat by giving a result which indicates the effect mean curvature has on the geometry of a surface. Recall that a surface is *minimal* if the mean curvature is zero at each point of the surface. Just as for other geometric qualities, we may test the notion of minimality on classes of surfaces which we understand best. In Chapter 4 we shall consider other types of minimal surfaces, but for now let's look at the surfaces of revolution.

Theorem 3.5.7. *If a surface of revolution M is minimal, then M is contained in either a plane or a catenoid.*

Proof. Consider the profile curve of M, $\alpha(u) = (g(u), h(u))$. If $g(u)$ is a constant function, then M is a plane. If $g'(u) \neq 0$ at a point, then it is nonzero in an open interval around that point. In that interval then, $g(u)$ has an inverse function, so we could reparametrize the interval of definition so that $g(u)$ is replaced by a new variable w and the profile curve becomes $\alpha(w) = (w, h(w))$. Now, we must have one case or the other throughout the domain of M because $\alpha' = h'/g'$. Therefore, we shall concentrate on this case in what follows. Take a patch $\mathbf{x}(u, v) = (u,\ h(u)\cos v,\ h(u)\sin v)$ for M. Then

$$H = \frac{k_\mu + k_\pi}{2} = \frac{1}{2}\left(\frac{-h''}{(1+h'^2)^{3/2}} + \frac{1}{h(1+h'^2)^{1/2}}\right) = \frac{1}{2}\left(\frac{-hh'' + 1 + h'^2}{h(1+h'^2)^{3/2}}\right).$$

The surface M is minimal, so $H = 0$ and, thus, $hh'' = 1 + h'^2$. Let $w = h'$. Then

$$h'' = w' = \frac{dw}{dh}\frac{dh}{du} = \frac{dw}{dh}\,w.$$

Here we consider w as a function of h on an interval with $h'(u) \neq 0$. We can do this because, on such an interval, h has an inverse function f with $u = f(h)$. Then, taking a derivative and applying the chain rule gives

$$1 = \frac{df}{dh}\frac{dh}{du} = \frac{df}{dh}w \qquad \text{or} \qquad w = \frac{1}{\frac{df}{dh}},$$

so that w is a function of h since f and df/dh are. Thus, $hh'' = 1 + h'^2$ implies $hw\,(dw/dh) = 1 + w^2$; or

$$\frac{w}{1+w^2}dw = \frac{1}{h}dh.$$

After integration, we get,

$$\begin{aligned} \ln(\sqrt{1+w^2}) &= \ln h + C \\ \sqrt{1+w^2} &= ch \qquad \text{where } c = e^C, \\ w &= \pm\sqrt{c^2h^2-1}. \end{aligned}$$

Now, $w = \frac{dh}{du}$, so $(dh)/(\sqrt{c^2h^2-1}) = \pm du$ and integration yields (with $ch = \cosh l$, $l \geq 0$)

$$\begin{aligned} \frac{1}{c}l &= \pm u + D \\ \frac{1}{c}\cosh^{-1}(ch) &= \pm u + D \\ h &= \frac{1}{c}\cosh(cu \pm D). \end{aligned}$$

Therefore, M is part of a catenoid. □

Exercise 3.5.8. In the proof above we assumed that $h'(u) \neq 0$. What happens if $h'(u) = 0$? Explain.

Exercise* 3.5.9. Show that a flat ($K = 0$) surface of revolution is part of a cone or a cylinder. Hint: Model your proof after the theorem above. Then see Exercise 4.9.1.

Exercise 3.5.10. Show that if M is a compact, connected (oriented) surface with $K > 0$ and H constant, then M is a sphere of radius $\frac{1}{\sqrt{K}}$.
Hints: (1) Consider the function $H^2 - K = (k_1 - k_2)^2/4$ and let $p \in M$ be a max for it. (2) If $H^2 - K(p) = 0$, show K is constant and use Liebmann's Theorem (Theorem 3.5.5). (3) Suppose $H^2 - K(p) > 0$ (so $k_1(p) > k_2(p)$). Note $(k_1 - k_2)(p)$ is a max. (4) Use Hilbert's lemma, Lemma 3.5.6.

3.6 Surfaces of Delaunay

Just as we saw that surfaces of revolution of constant Gauss curvature are determined by certain integrals with chosen initial conditions, we can ask whether something similar occurs for constant mean curvature. Let's take a surface of revolution M: $\mathbf{x}(u, v)$, where the patch has the form

4.2 The Euler-Poincaré Formula

The Euler characteristic of a cell complex is computed from this data:

$$c_k(K) := \dim C_k(K).$$

Notice that these numbers resemble (and in the simplest case are equal to) the Betti numbers of the cell complex:

$$\beta_k(K) := \dim H_k(K).$$

What if we evaluate an alternating sum of the latter numbers rather than the former?

Implicitly, we have already done this, in the Euler Formula. Indeed, we have:

$$\chi(\mathbf{S}^2) = 2,$$

which holds regardless of the triangulation. On the other, the alternating sum of the Betti numbers of the sphere

$$\beta_0(\mathbf{S}^2) = 1,\ \beta_1(\mathbf{S}^2) = 0,\ \beta_2(\mathbf{S}^2) = 1,\ \beta_3(\mathbf{S}^2) = 0, ...$$

also produces 2!

Is this a coincidence? Let's check out other complexes.

Example 4.11 (point). First, the point P:

$$\begin{aligned}&\chi(P) = 1 - 0 = 1,\\ &\beta_0(P) - \beta_1(P) = 1 - 0 = 0.\end{aligned}$$

Once again, the Betti numbers add up to the Euler number. $\square$

Example 4.12 (circle). Next, the circle C:

$$\begin{aligned}&\chi(C) = 1 - 1 + 0 = 0,\\ &\beta_0(C) - \beta_1(C) + \beta_2(C) = 1 - 1 + 0 = 0.\end{aligned}$$ $\square$

Example 4.13 (torus). Now the torus $\mathbf{T}^2$. We have:

- 0-cells: 1,
- 1-cells: 2,

For each $i = 0, 1, ..., n$, we have

$$\begin{array}{ll} < C_i(K) \cup C_i(L) > & = C_i(K \cup L), \\ C_i(K) \cap C_i(L) & = C_i(K \cap L). \end{array}$$

Then the alternating sum of the above equations gives us the formula. ■

The Euler characteristic behaves well under products.

Theorem 4.8 (Product Formula for Euler Characteristic). The Euler characteristic is multiplicative; i.e., for two finite cell complexes K and L, we have:

$$\chi(K \times L) = \chi(K) \cdot \chi(L).$$

Exercise 4.9. Prove the theorem. Hint: $\dim(U \oplus V) = \dim U + \dim V$.

Exercise 4.10. Compute the Euler characteristic of the n-dimensional torus $\mathbf{T}^n$.

4.2 The Euler-Poincaré Formula

The Euler characteristic of a cell complex is computed from this data:

$$c_k(K) := \dim C_k(K).$$

Notice that these numbers resemble (and in the simplest case are equal to) the Betti numbers of the cell complex:

$$\beta_k(K) := \dim H_k(K).$$

What if we evaluate an alternating sum of the latter numbers rather than the former?

Implicitly, we have already done this, in the Euler Formula. Indeed, we have:

$$\chi(\mathbf{S}^2) = 2,$$

which holds regardless of the triangulation. On the other, the alternating sum of the Betti numbers of the sphere

$$\beta_0(\mathbf{S}^2) = 1,\ \beta_1(\mathbf{S}^2) = 0,\ \beta_2(\mathbf{S}^2) = 1,\ \beta_3(\mathbf{S}^2) = 0, ...$$

also produces 2!

Is this a coincidence? Let's check out other complexes.

Example 4.11 (point). First, the point P:

$$\begin{array}{l} \chi(P) = 1 - 0 = 1, \\ \beta_0(P) - \beta_1(P) = 1 - 0 = 0. \end{array}$$

Once again, the Betti numbers add up to the Euler number. □

Example 4.12 (circle). Next, the circle C:

$$\begin{array}{l} \chi(C) = 1 - 1 + 0 = 0, \\ \beta_0(C) - \beta_1(C) + \beta_2(C) = 1 - 1 + 0 = 0. \end{array}$$ □

Example 4.13 (torus). Now the torus $\mathbf{T}^2$. We have:

- 0-cells: 1,
- 1-cells: 2,

- 2-cells: 1.

So,

$$\chi(\mathbf{T}^2) = 1 - 2 + 1 = 0.$$

Because this cell complex representation is so efficient, each of the cells also represents an element of a basis element of the corresponding homology group:

$$\begin{array}{ll} H_0(\mathbf{T}^2) = < A > & \Longrightarrow \beta_0(\mathbf{T}^2) = 1, \\ H_1(\mathbf{T}^2) = < a, b > & \Longrightarrow \beta_1(\mathbf{T}^2) = 2, \\ H_2(\mathbf{T}^2) = < \tau > & \Longrightarrow \beta_2(\mathbf{T}^2) = 1, \\ H_3(\mathbf{T}^2) = 0 & \Longrightarrow \beta_3(\mathbf{T}^2) = 0. \end{array}$$

The formula holds:

$$\chi(\mathbf{T}^2) = \beta_0(C) - \beta_1(C) + \beta_2(C) - ... \qquad \square$$

As we have been doing nothing but counting the cells, it's no surprise that the formula holds. Undoubtedly, it will always hold when there is *one cell per homology generator.* We need to show that this formula holds for all cell complexes.

Theorem 4.14 (Euler-Poincaré Formula). If K is a finite cell complex, then its Euler characteristic is equal to the alternating sum of the Betti numbers of each dimension:

$$\chi(K) = \sum_k (-1)^k \beta_k(K).$$

The proof will require a couple of facts from linear algebra of finite dimensional vector spaces.

Proposition 4.15.

- (1) If M, L are vector spaces and $A : M \to L$ is a linear operator, then

$$M/\ker A \simeq \operatorname{Im} A.$$

- (2) If Y is a subspace of vector space X, then

$$\dim X/Y = \dim X - \dim Y.$$

Exercise 4.16. Prove the proposition.

The proposition leads to the following conclusion.

Corollary 4.17. If M, L are vector spaces and $A : M \to L$ is a linear operator, then

$$\dim M - \dim \ker A = \dim \operatorname{Im} A.$$

Now, there are four vector spaces involved in the computation of the Betti numbers of complex K, for each $k = 0, 1, 2, ...$:

$$\begin{array}{lll} \text{chain group:} & C_k, & c_k := \dim C_k; \\ \text{cycle group:} & Z_k = \ker \partial_k, & z_k := \dim Z_k; \\ \text{boundary group:} & B_k = \operatorname{Im} \partial_{k+1}, & b_k := \dim B_k; \\ \text{homology group:} & H_k = Z_k/B_k, & \beta_k := \dim H_k, \end{array}$$

where

$$\partial_k : C_k \to C_{k-1}$$

is the boundary operator.

Applying the corollary to the boundary operator, we obtain:

$$\dim C_k - \dim \ker \partial_k = \dim \operatorname{Im} \partial_k .$$

In other words, we have the following.

Lemma 4.18. $c_k - z_k = b_{k-1}$.

Next, from part (2) of the proposition, we have the following.

Lemma 4.19. $\beta_k = z_k - b_k$.

Finally, the **proof** of the theorem. Suppose n is the highest dimension of a cell in K. Then the right-hand side of the formula is computed as follows:

$$\begin{array}{rllll}
= & \beta_0 & -\beta_1 & +\beta_2 - ... & +(-1)^k\beta_n \\
 & & & \text{substitute from 2nd lemma} & \\
= & (z_0-b_0) & -(z_1-b_1) & +(z_2-b_2) - ... & +(-1)^n(z_n-b_n) \\
 & & & & \\
= & z_0 & -b_0 - z_1 & +b_1+z_2-... & +(-1)^n z_n - (-1)^n b_n \\
 & & & \text{substitute from 1st lemma} & \\
= & z_0 & -(c_1-z_1)-z_1 & +(c_2-z_2)+z_2+... & +(-1)^n z_n - (-1)^n(c_{n+1}-z_{n+1}) \\
 & & & \text{cancel the z's} & \\
= & z_0 & -c_1 & +c_2 - ... & +(-1)^{n+1}c_{n+1} - (-1)^n z_{n+1} \\
= & c_0 & -c_1 & +c_2 - ... & +0 \quad - \quad 0 \\
= & \chi(K). & & &
\end{array}$$

■

The invariance of homology then gives us the following.

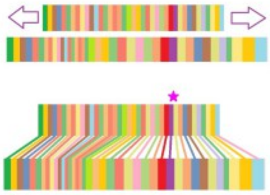
Corollary 4.20. The Euler characteristic is a topological invariant of polyhedra.

An interesting discovery but, because so much information is lost, the Euler characteristic is poor man's homology...

Exercise 4.21. Under what circumstances can the homology of X be derived from its Euler characteristic for (a) X a graph, (b) X a surface?

4.3 Fixed points

Imagine stretching a rubber band by moving one end to the right and the other to the left. After some experimenting one might discover that some point of the band will end up in its original position:



In fact, it doesn't matter if the stretching isn't uniform or if there is some shrinking, or even folding...

This problem is described mathematically as follows.

Fixed Point Problem: If X is a topological space and $f : X \to X$ is a self-map, does f have a *fixed point*, i.e., $x \in X$ such that $f(x) = x$?

The result above is, therefore, about a fixed point of a map $f : [a, b] \to [a, b]$.

Exercise 4.22. Prove this result by using the Intermediate Value Theorem.

Exercise 4.23. Demonstrate that both continuity of the map and the compactness of the interval are crucial.

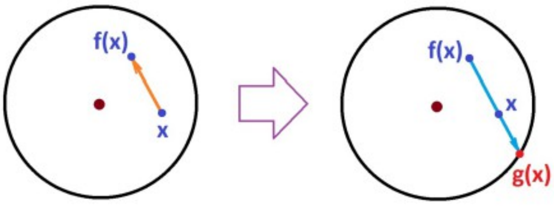
Exercise 4.24. Under what circumstances is the set of fixed points closed?

A similar problem about stretching a disk or a ball will require more advanced techniques.

Theorem 4.25 (Brouwer Fixed Point Theorem). Any self-map of a closed ball has a fixed point. In other words, if $f : \mathbf{B}^n \to \mathbf{B}^n$ is a map then there is a $x \in \mathbf{B}^n$ such that $f(x) = x$.

An informal interpretation of the 2-dimensional version of this theorem is: a page and its crumpled copy placed on it will have two identical words located one exactly over the other:

Exercise 4.26. Prove the theorem. Hint:



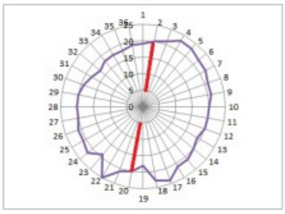
Plainly, the theorem holds if the ball is replaced with anything homeomorphic to it, such a simplex.

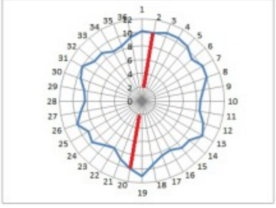
Though technically not a fixed point theorem, the following result is closely related to the last theorem.

Theorem 4.27 (Borsuk-Ulam Theorem). Every map $f : \mathbf{S}^n \to \mathbf{R}^n$ from an n-sphere to n-dimensional Euclidean space maps some pair of antipodal points to the same point:

$$f(x) = f(-x).$$

A common interpretation of the case $n = 1$ is that at any moment there is always a pair of antipodal points on the Earth's surface with exactly equal temperatures (or with equal barometric pressures, etc.).





Furthermore, an interpretation for $n=2$ is that there is always a pair of antipodal points with exactly equal temperatures and equal barometric pressures, *simultaneously*.

Exercise 4.28. Explain how the theorem implies that at any moment there is always a pair of antipodal points on the Earth's surface with identical wind.

Exercise 4.29. Derive the case $n=1$ of the theorem from the Intermediate Value Theorem.

Exercise 4.30. Prove the theorem. Hint: consider this map:

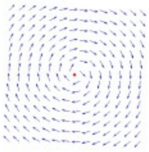
$$g(x)=\frac{f(x)-f(-x)}{||f(x)-f(-x)||}.$$

4.4 An equilibrium of a market economy

Suppose we have a map $F:S\to S$. Applied consecutively, it yields a *discrete dynamical system*:

$$X_{k+1}=F(X_k),$$

where $X_k\in S$ is the current state, at time k, of the system if it started at time $k=0$ at the state $X_0\in S$. Then the meaning of the *equilibrium* of the system is simple: $F(a)=a$. It's a fixed point!



A typical interpretation of such a system is a particle moving through a stream. We will consider instead the *dynamics of prices* in a simple market economy. Is it possible for them to stay constant? In other words, does every price dynamics allow an equilibrium?

Recall that we have n commodities freely traded with possible prices that form a *price vector* $p=(p_1,...,p_n)$, at each moment of time. Then all positive, or even non-negative, prices are considered possible; i.e., the set of prices is

$$P:=\mathbf{R}^n_+.$$

The dynamics of prices is represented by a continuous function $F:P\to P$. However, we can't conclude that there is a fixed point because P isn't compact!

Let's make some additional assumptions in order to be able to guarantee an equilibrium.

How can we make the set of prices compact? One approach is to normalize the prices:

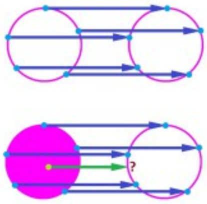
$$p\mapsto\frac{p}{||p||},$$

under some norm so that the new prices form the n-simplex σ.

Exercise 4.31. Show that this is an equivalence relation. What assumptions would guarantee that the price function remains well-defined?

A more natural (if not more realistic) assumption is that the *money supply is fixed.* Suppose there are n commodities. We assume that this is a pure exchange economy; i.e., *there is no production* of goods (other than making up for possible consumption). Then there is only a fixed amount of each of the commodities:

$$\bar{c}:=\sum_i c^i\in\mathbf{R}^n_+.$$



Can we find a continuous F to complete the first diagram below? With the cohomology functor, we answer: only if we can complete the last one.

$$\begin{tikzcd}
\mathbf{S}^{n-1} \arrow[r, hook] \arrow[dr, "\mathrm{Id}"'] & \mathbf{B}^n & & H^{n-1}(\mathbf{S}^{n-1}) & H^{n-1}(\mathbf{B}^n) \arrow[l] & & \mathbf{Z} \arrow[r, "H^*"] & 0 \\
& \mathbf{S}^{n-1} \arrow[u, "F=?"'] & \rightsquigarrow & & H^{n-1}(\mathbf{S}^{n-1}) \arrow[ul, "\mathrm{Id}"] \arrow[u, "?"'] & = & & \mathbf{Z} \arrow[ul, "\mathrm{Id}"] \arrow[u, "?"']
\end{tikzcd}$$

Just as in the case of homology, we see that the last diagram is impossible to complete. ☐

Exercise 3.84. Provide such analysis for the extension problem(s) for: the identity map of the circle to the torus.

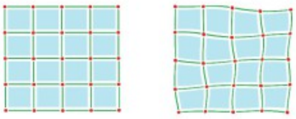
Exercise 3.85. List all possible maps for each of these description based on the possible cohomology maps:
- embeddings of the circle into the torus;
- self-maps of the figure eight;
- embeddings of the circle into the sphere.

4 Metric tensor

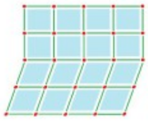
4.1 The need for measuring in calculus

We will learn how to introduce an arbitrary geometry into the (so far) purely topological setting of cell complexes.

It is much easier to separate topology from geometry in the framework of cell complexes (and discrete calculus) because we have built it from scratch! To begin with, it is obvious that only the way the cells are attached to each other affects the matrix of the boundary operator (and the exterior derivative):



It is then clear that the sizes or the shapes of the cells are topologically irrelevant. Note that, even when those are given, the geometry of the domain will remain unspecified unless the angles are also provided:



These two grids can be thought of as different (but homeomorphic) realizations of the same cell complex.

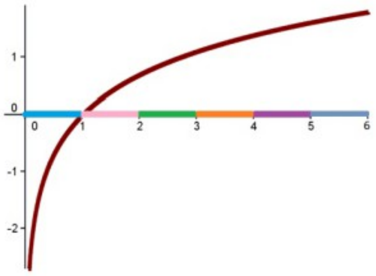
In calculus, we rely only on the topological and algebraic structures to develop the mathematics. There are two main exceptions. One needs the dot product and the norm for the following related concepts:

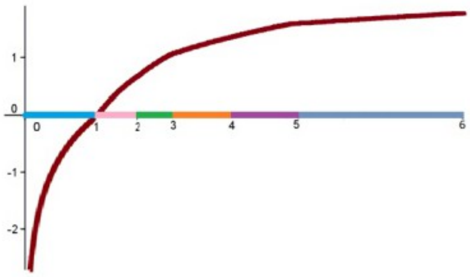
- the concavity,
- the arc-length, and
- the curvature. We'll need to introduce more structure – geometric in nature – to the complex.

Of course, the norm is explicitly present in the formulas for the last two. But first we will consider the role of geometry in the meaning of concavity.

The point where we start to need geometry is when we move from the first to the second derivative.

This is what we observe: shrinking, stretching, or deforming the x- or the y-axes won't change the monotonicity of a function but it will change its concavity. Below, we have deformed the x-axis and changed the concavity of the graph at $x = 1$:





Of course, it is sufficient to know the sign of the derivative to distinguish between increasing and decreasing behavior. Therefore, this behavior depends only on the topology of the spaces, in the above sense. In fact, the chain rule implies the following elementary result.

Proposition 4.1. Monotonicity is preserved under compositions with increasing functions; i.e., given a differentiable function $f : \mathbf{R} \to \mathbf{R}$, we have:

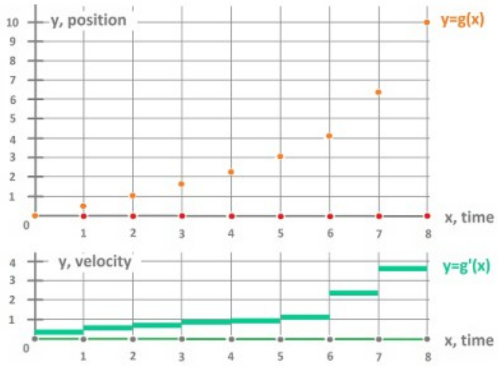
$$f \nearrow \iff fr \nearrow,$$

for any differentiable $r : \mathbf{R} \to \mathbf{R}$ with $r' > 0$.

Exercise 4.2. Give an example of f and r as above so that f and fr have different concavity.

Exercise 4.3. Restate the proposition in the context of discrete calculus.

Similarly, in the discrete calculus we are developing, the sign of the exterior derivative will tell us the difference between increasing and decreasing behavior. Concavity is an important concept that captures the shape of the graph of a function in calculus as well as the acceleration in physics. The upward concavity of the discrete function below is obvious, which indicates a positive acceleration:



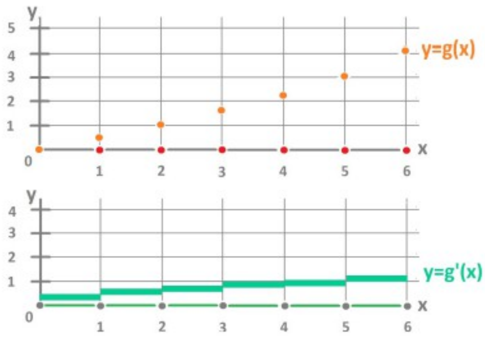
The concavity is computed and studied via the second derivative, the rate of change of the rate of change. But, with $dd=0$, we don't have the second *exterior* derivative...

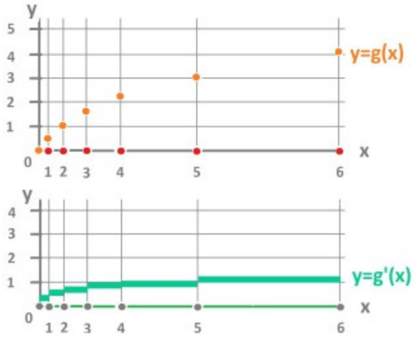
We start over and look at the *change of change*. This quantity can be seen algebraically as the increase of the exterior derivative (i.e., the change):

$$g(2)-g(1) < g(3)-g(2),\ g(3)-g(2) < g(4)-g(3),\ etc.$$

But do these inequalities imply concavity? Not without assuming that the intervals have equal lengths!

Below, on the same, topologically, cell complex, we have the same discrete function with, of course, the same exterior derivative:





...but with the opposite concavity!

4.2 Inner products

In order to develop a complete discrete calculus we need to be able compute:

- the lengths of vectors and
- the angles between vectors.

In linear algebra, we learn how an inner product adds geometry to a vector space. We choose a more general setting.

Suppose R is our ring of coefficients and suppose V is a finitely generated free module over R.

Definition 4.4. An *inner product* on V is a function that associates a number to each pair of vectors in V:

$$\langle\cdot,\cdot\rangle : \begin{cases} V\times V \to R, \\ (u,v)\mapsto \langle u,v\rangle, \end{cases}$$

that satisfies these properties:

- 1. $\diamond$ $\langle v,v\rangle \geq 0$ for any $v \in V$ – *non-degeneracy*,
  $\diamond$ $\langle v,v\rangle = 0$ if and only if $v=0$ – *positive definiteness*;
- 2. $\langle u,v\rangle = \langle v,u\rangle$ – *symmetry* (commutativity);
- 3. $\langle ru,v\rangle = r\langle u,v\rangle$ – *homogeneity*;
- 4. $\langle u+u',v\rangle = \langle u,v\rangle + \langle u',v\rangle$ – *distributivity*.

Items 3 and 4 together make up *bilinearity*. Indeed, consider $p : V \times V \to R$ given by $p(u,v) = \langle u,v\rangle$. Then p is linear with respect to the first variable, and the second variable, separately:

- fix $v=b$, then $p(\cdot,b) : V \to R$ is linear;
- fix $u=a$, then $p(a,\cdot) : V \to R$ is linear.

Exercise 4.5. Show that this isn't the same as linearity.

It is easy to verify these axioms for the *dot product* defined on $V = \mathbf{R}^n$ or any other module with a fixed basis. For

$$u = (u_1, ..., u_n),\ v = (v_1, ..., v_n) \in \mathbf{R}^n,$$

define

$$\langle u,v\rangle := u_1v_1 + u_2v_2 + ... + u_nv_n.$$

Moreover, a *weighted dot product* on $\mathbf{R}^n$ is given by

$$\langle u,v\rangle := w_1u_1v_1 + w_2u_2v_2 + ... + w_nu_nv_n,$$

where $w_i \in \mathbf{R},\ i = 1, ..., n$, are the positive "weights", is also an inner product.

Exercise 4.6. Prove the last statement.

A module equipped with an inner product is called an *inner product space.*

When ring R is a subring of the reals $\mathbf{R}$, such as the integers $\mathbf{Z}$, we can conduct some useful computations with some familiar formulas.

Definition 4.7. The *norm of a vector* v in an inner product space V is defined as

$$\|v\| := \sqrt{\langle v,v\rangle} \in \mathbf{R}.$$

This number measures the length of the vector.

Definition 4.8. The *angle between vectors* $u,v \neq 0$ in V is defined as

$$\cos\widehat{uv} := \frac{\langle u,v\rangle}{\|u\| \cdot \|v\|}.$$

The norm satisfies certain properties that we can also use as *axioms of a normed space.*

Definition 4.9. Given a vector space V, a *norm* on V is a function

$$\|\cdot\| : V \to R$$

that satisfies

- 1. $\diamond$ $\|v\| \geq 0$ for all $v \in V$,
  $\diamond$ $\|v\| = 0$ if and only if $v = 0$;
- 2. $\|rv\| = |r|\|v\|$ for all $v \in V, r \in R$;
- 3. $\|u+v\| \leq \|u\| + \|v\|$ for all $u,v \in V$.

Exercise 4.10. Prove the propositions below.

Proposition 4.11. A normed space is a metric space with the metric $d(x,y) := \|x-y\|$.

Proposition 4.12. A normed space is a topological vector space.

Exercise 4.13. Prove that the inner product is continuous in this metric space.

This is what we know from linear algebra.

Theorem 4.14. Any inner product $\langle \cdot , \cdot \rangle$ on an n-dimensional module V can be computed via matrix multiplication

$$\langle u, v \rangle = u^T Q v,$$

where Q is some positive definite, symmetric $n \times n$ matrix.

In particular, the dot product is represented by the identity matrix I_n, while the weighted dot product is represented by the diagonal matrix:

$$Q = \left(\begin{array}{ccc} w_1 & ... & 0 \\ ... & ... & ... \\ 0 & ... & w_n \end{array} \right).$$

Below we assume that $R = \mathbf{R}$.

To learn about the eigenvalues and eigenvectors of matrix Q of the inner product, we observe that

$$||v||^2 = v^T Q v = v^T \lambda v = \lambda ||v||^2.$$

We have proven the following:

Theorem 4.15. The eigenvalues of a positive-definite matrix are real and positive.

We know from linear algebra that if the eigenvalues are real and *distinct*, the matrix is diagonalizable. As it turns out, having distinct eigenvalues isn't required for a positive-definite matrix. We state the following without proof.

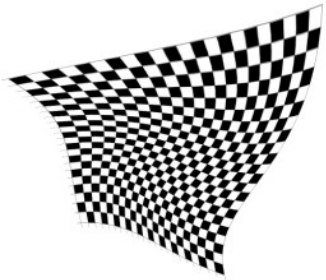
Theorem 4.16. Any inner product $\langle \cdot , \cdot \rangle$ on an n-dimensional vector space V can be represented, via a choice of basis, by a diagonal $n \times n$ matrix Q with positive numbers on the diagonal. In other words, every inner product is a weighted dot product, in some basis.

Also, since the determinant $\det Q$ of Q is the product of the eigenvalues of Q, it is also positive and we have the following:

Theorem 4.17. Matrix Q that represents an inner product is invertible.

4.3 The metric tensor

What if the geometry – as described above – varies from point to point in some space X? Then the inner product of two vectors will depend on their location.



In fact, we'll need to look at a different set of vectors at each location as the angle between two vectors is meaningless unless they have the same origin.

We already have such a construction! For each vertex A in a cell complex K, the *tangent space* at A of K is a submodule of $C_1(K)$ generated by the 1-dimensional star of A:

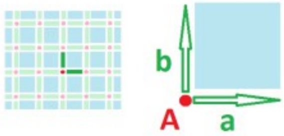
$$T_A(K) := < \{AB \in K\} > \subset C_1(K).$$

However, the tangent bundle $T(K)$ is inadequate because this time we need to consider *two directions* at a time!

Since $V = T_A$ is a module, an inner product can be defined (so far locally). Then we have a collection of bilinear functions for each of the vertices,

$$\psi_A : T_A(K)^2 \to R, \ A \in K^{(0)}.$$

Thus the setup is as follows. We have the *space of locations* $X = K^{(0)}$, the set of all vertices of a cell complex K, and, second, to each location $A \in X$, we associate the *space of pairs of directions* $T_A(K)^2$.



We now collect these "double" tangent spaces into one.

Definition 4.18. The *tangent bundle of degree* 2 of K is defined to be

$$T^2(K) := \bigsqcup_{A \in K} \Big(\{A\} \times T_A(K)^2 \Big).$$

Then a locally defined inner product is seen as a function on this space,

$$\psi = \{\psi_A\} : T^2(K) \to R,$$

bilinear on each tangent space, defined by

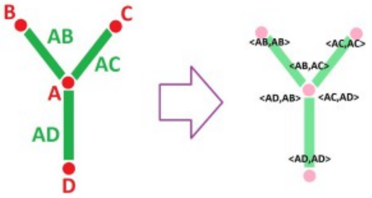
$$\psi(A, AB, AC) := \psi_A(AB, AC).$$

In other words, we have inner products "parametrized" by location.

Furthermore, we have a function that associates to each location, i.e., a vertex A in K, and each pair of directions at that location, i.e., edges $x = AB, y = AC$ adjacent to A with $B, C \neq A$, a number $\langle AB, AC \rangle$:

$$(A, AB, AC) \mapsto \langle AB, AC \rangle (A) \in R.$$

Note: we have used this notation for $f(a) = \langle f, a \rangle$, where f a form, but won't use in the rest of the book.



Definition 4.19. A *metric tensor* on a cell complex K is a collection of functions,

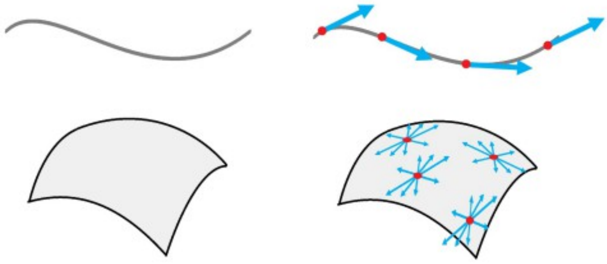
$$\psi = \{\psi_A : \ A \in X\},$$

such that each of them,

$$\psi_A : \{A\} \times T_A(K)^2 \to R,$$

satisfies the axioms of inner product, and also:

$$\psi_A(AB, AB) = \psi_B(BA, BA).$$



Using our notation, a metric tensor is such a function:

$$\langle \cdot , \cdot \rangle(\cdot) : T^2(K) \to R,$$

that, when restricted to any tangent space $T_A(K), \ A \in K^{(0)}$, it produces a function

$$\langle \cdot , \cdot \rangle(A) : T_A(K)^2 \to R,$$

which is an inner product on $T_A(K)$. The last condition,

$$\langle AB, AB \rangle(A) = \langle BA, BA \rangle(B),$$

ensures that these inner products match!

Note: Compare to the standard setup: the location space X is an n-manifold; then $T_AX \cong \mathbf{R}^n$ is its tangent space, when $R = \mathbf{R}$. Then we have a function that associates a number to each location in X and each pair of vectors at that location:

$$\langle \cdot , \cdot \rangle(\cdot) : \begin{cases} X \times \mathbf{R}^n \times \mathbf{R}^n & \to \mathbf{R}, \\ (x, u, v) & \mapsto \langle u, v \rangle(x). \end{cases}$$

It is an inner product that depends continuously on location $x \in X$.

Exercise 4.20. State the axioms of inner product (non-degeneracy, positive-definiteness, symmetry, homogeneity, and distributivity) for the metric tensor.

The end result is similar to a combination of 1-forms, because we have a number assigned to each edge and to each pair of adjacent edges:

- $a \mapsto \langle a, a \rangle$;
- $(a, b) \mapsto \langle a, b \rangle$.

Then the metric tensor is given by the table of its values for each vertex A:

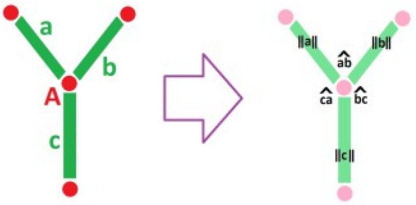
A	AB	AC	AD	...
AB	$\langle AB, AB \rangle$	$\langle AB, AC \rangle$	$\langle AB, AD \rangle$	...
AC	$\langle AC, AB \rangle$	$\langle AC, AC \rangle$	$\langle AC, AD \rangle$	...
AD	$\langle AD, AB \rangle$	$\langle AD, AC \rangle$	$\langle AD, AD \rangle$	...
...	...	...	...	...

Whenever our ring of coefficients happens to be a subring of the reals $\mathbf{R}$, such as the integers $\mathbf{Z}$, this data can be used to extract more usable information:

- $a \mapsto \|a\|$, and
- $(a, b) \mapsto \widehat{ab}$,

where

$$\cos \widehat{ab} = \frac{\langle a, b\rangle}{\|a\|\|b\|}.$$



All the information we need for measuring is contained in this symmetric matrix:

A	AB	AC	AD	...
AB	$\|AB\|$	$\widehat{BAC}$	$\widehat{BAD}$	...
AC	$\widehat{BAC}$	$\|AC\|$	$\widehat{CAD}$	...
AD	$\widehat{BAD}$	$\widehat{CAD}$	$\|AD\|$	...
...	...	...	...	...

Exercise 4.21. In the 1-dimensional cubical complex $\mathbb{R}$, are 01 and 10 parallel?

Proposition 4.22. From any matrix with positive entries on the diagonal, we can (re)construct a metric tensor by the formula:

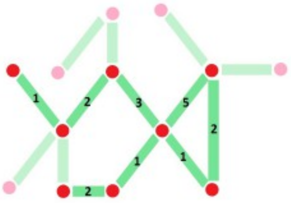
$$\langle AB, AC\rangle = \|AB\|\|AC\| \cos \widehat{BAC}.$$

With a metric tensor, we can define the two main geometric quantities of calculus in a very easy fashion. Suppose we have a *discrete curve* C in the complex K, i.e., a sequence of adjacent vertices and edges

$$C = \{A_0A_1, A_1A_2, ..., A_{N-1}A_N\} \subset K.$$

Definition 4.23. The *arc-length* of curve C is the sum of the lengths of its edges:

$$l_C := \|A_0A_1\| + \|A_1A_2\| + ... + \|A_{N-1}A_N\|.$$

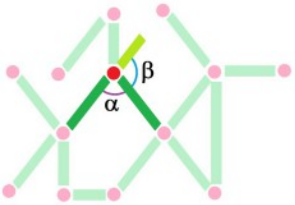


The arc-length is an example of a *line integral* of a 1-form ρ over a 1-chain a in complex K equipped with a metric tensor:

$$\begin{aligned} a = \quad & A_0A_1 + A_1A_2 + ... + A_{n-1}A_n \Longrightarrow \\ & \int_a \rho := \rho(A_0, A_0A_1)\|A_0A_1\| + ... + \rho(A_{N-1}, A_{N-1}A_N)\|A_{N-1}A_N\|. \end{aligned}$$

In particular, if we have a curve made of rods represented by edges in our complex while ρ represents the linear density of each rod, the integral gives us the *weight* of the curve.

For the curvature, the angle $\alpha := A_{s-1}\widehat{A_s}A_{s+1}$ might appear a natural choice to represent it, but, since we are to capture the change of the direction, it should be the "outer" angle β:



Definition 4.24. The *curvature* of curve C at a given vertex $A_s,\ 0 < s < N$, is the value of the angle

$$\kappa_C(A_s) := \pi - A_{s-1}\widehat{A_s}A_{s+1}.$$

As before, the result depends on our choice of a metric tensor.

The following is a simple but important observation.

Theorem 4.25. The set of vertices $K^{(0)}$ of a cell complex K equipped with a metric tensor is a metric space with its metric given by:

$$d(A,B) = \min\{l_C : C \text{ a curve from } A \text{ to } B\},$$

for any two vertices A, B.

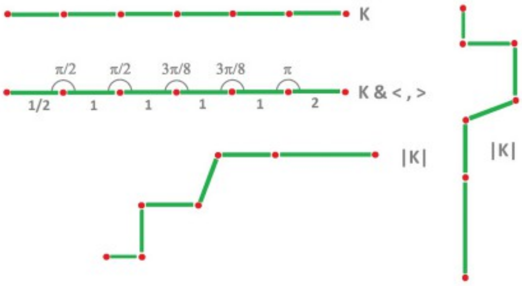
Exercise 4.26. (a) Prove the theorem. (b) What is the relation between the topology of $|K|$ and this metric space?

4.4 Metric tensors in dimension 1

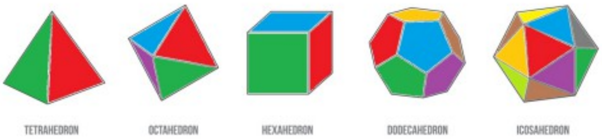
Let's consider examples of how adding a metric tensor turns a cell complex, which is a discrete representation of a topological space, into something more *rigid*.

Example 4.27. In the illustration below you see the following:

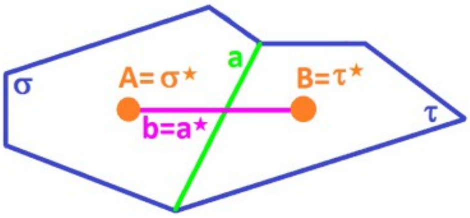
- a cubical complex K, a *topological* entity: cells and their boundaries also made of cells;
- complex K combined with a choice of metric tensor $\langle\cdot,\cdot\rangle$, a *geometric* entity: lengths and angles;
- a realization of K in $\mathbf{R}$ as a segment;
- a realization of K in $\mathbf{R}^2$;
- another realization of K in $\mathbf{R}^2$.



Exercise 1.6. Two polyhedra are called *dual* if the number of faces of one is equal to the number of vertices of the other (and vice versa). Find the dual polyhedra of Platonic solids and explain the relation to the Hodge duality:



This is what the Hodge duality looks like in the case of a general 2-dimensional cell complex. The dual cell is still placed – for the sake of illustration – at the center of mass of the primal cell:



Exercise 1.7. Suppose a simplicial complex K is realized in $\mathbf{R}^n$. Describe explicitly how the dual $K^\star$ can also be realized in $\mathbf{R}^n$ side by side with $|K|$. Hint: use barycentric coordinates.

We summarize the new concept as follows.

Definition 1.8. Suppose a *dimension* n is given. Two cell complexes K and $K^\star$ with $\dim K \le n$, $\dim K^\star \le n$, are called *Hodge-dual* of each other if there is a one-to-one correspondence,

$$K \ni a \longleftrightarrow a^\star \in K^\star,$$

between their cells of complementary dimensions:

$$\dim a^\star + \dim a = n.$$

1.2 Metric complexes

We have already seen metric complexes of dimension $n = 1$ as cell complexes equipped with a geometric structure: the metric tensor of K and $K^\star$. This data allows one to find the lengths and the curvatures of curves. The Hodge star operator is then built from this data.

In this subsection, we present the necessary geometric data for the case of arbitrary dimension.

In dimension $n = 2$, we consider lengths and areas; in dimension $n = 3$, lengths, areas, and volumes, etc. In general, we need to find the "sizes" of all cells of all dimensions in the complex. These sizes are called the *k-dimensional volumes*:

dimension k	k-cell a	k-volume $\lvert a\rvert$
0	vertex	1
1	edge	length
2	face	area
3	solid	volume
...		...
n	n-cell	n-volume

Instead of trying to *derive* these quantities from the metric tensor, we simply *list* them as a part of the definition of a metric complex. In the abstract, we simply have a pair of positive numbers $|b|, |b^\star|$ assigned to each cell $b \in K$.

Definition 1.9. Given a cell complex K, the *volume function* on K defines the k-volumes of the k-cells of K:

$$|\cdot| : K \to R \setminus \{0\},$$

normalized for dimension 0:

$$|A| = 1 \text{ for all vertices } A \in K.$$

For $R = \mathbf{R}$, the definition matches the one for the case of $n = 1$ considered previously if we limit ourselves to positive volumes.

Example 1.10. The simplest choice of the volumes for the 2-cell representation of the sphere is

$$A^0, a^2 \text{ with } |A^0| = |a^2| = 1. \qquad \square$$

In general, we don't assume that $|AB|, |BC|, |CA|$ determine $|ABC|$. Even though the three sides of a triangle determine the triangle and, therefore, its area, this only works under a particular choice of geometry, such as Euclidean. We take the opposite approach and let the lengths and areas determine the geometry.

Exercise 1.11. Give a metric complex representation of a triangulation of the sphere, realized as the unit sphere in $\mathbf{R}^3$.

Example 1.12 (measure). Suppose K is a cell complex with finitely many cells at each vertex and suppose $|K|$ is its realization. Then the set of all cells (open or closed) Σ of K as subsets of $|K|$ form a σ-algebra, i.e., a collection closed under the operations of complement, countable union, and countable intersection. If, furthermore, K has a volume function, the function $\mu : \Sigma \to \mathbf{R} \cup \{\infty\}$ given by

$$\mu(a) = \begin{cases} |a| & \text{if } \dim a = \dim K, \\ 0 & \text{if } \dim a < \dim K, \end{cases}$$

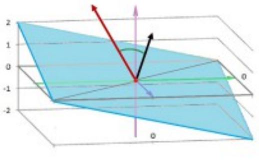
is a *measure* on $|K|$; i.e., it satisfies:

- non-negativity: for all $a \in \Sigma$ we have $\mu(a) \geq 0$;
- null empty set: $\mu(\emptyset) = 0$;
- σ-additivity: for all countable collections $\{a_i\}$ of pairwise disjoint sets in Σ we have:

$$\mu\Big(\bigcup_{k=1}^{\infty} a_k \Big) = \sum_{k=1}^{\infty} \mu(a_k). \qquad \square$$

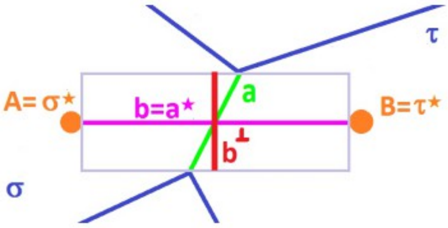
In addition to the volumes, the *angles* between every pair of dual cells will be taken into account in the new representation of the geometry.

We don't need to specify the meaning of the angle between *every choice* of a primal k-cell and its dual $(n-k)$-cell, for all k. For our purposes, it suffices to take care of the case $k = 1$. We are then in a familiar situation because the angle α between 1- and $(n-1)$-dimensional subspaces of an n-dimensional inner product space is always understood as the angle between the direction vector of the former and the normal vector of the latter.

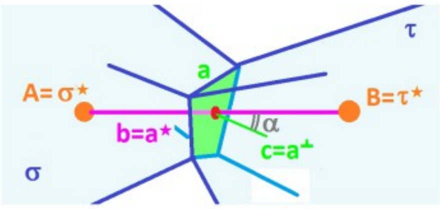


They are orthogonal when this angle is zero. It is also assumed that (for $k = 0$) a point and the whole space are orthogonal and $\cos\alpha = 1$. This assumption explains why these angles did not have to come into play in the case of a 1-dimensional complex.

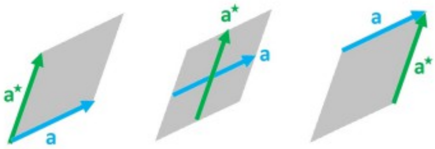
For cells in the higher dimensional case, we are looking at the angle between a and the normal $b^\perp$ of $b = a^\star$, illustrated for dimension $n = 2$:



Dually, this angle can also be understood as the angle between the normal $c = a^\perp$ of a and $a^\star$, illustrated for dimension $n = 3$:



Even though these angles don't affect the volumes of either primal or dual cells, they do affect the volumes of *new* n-cells, the cells determined by each dual pair:



The area of this parallelogram does not depend on how a and $a^\star$ are attached to each other (they aren't) but only on the angle between them.

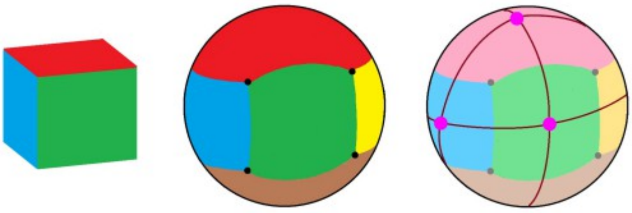
The way we handle angles is, of course, via the inner product: $\langle a, b\rangle \in R$ is defined for these three cases:

- adjacent $a, b \in K$,
- adjacent $a, b \in K^\star$, and now also
- $a \in K, a^\star \in K^\star$.

Definition 1.13. A *metric (cell) complex of dimension* n is a pair of Hodge-dual cell complexes K and $K^\star$ of dimension n equipped with a *joint metric tensor*, which is a combination of metric tensors for K and $K^\star$ as well as inner products of all dual pairs:

$$(a, a^\star) \mapsto \langle a, a^\star\rangle \in R.$$

Exercise 1.14. Represent a hollow cube as a metric complex. Hint:



Exercise 1.15. Suppose K is a metric complex. Show how the set of its vertices K^0 becomes a metric space.

It follows from the definition that, in addition to the two volume functions of these complexes, we can also derive the *angle function*:

$$(a, a^\star) \mapsto \cos \widehat{aa^\star} = \frac{\langle a, a^\star \rangle}{|a||a^\star|}.$$

The function is well-defined whenever the expression in the right-hand belongs to our ring R. This is always the case when R is a field or $|a| = |a^\star| = 1$.

Definition 1.16. We say that K has a *rectangular geometry* if

$$\langle a, a^\star \rangle = \pm |a||a^\star|.$$

In other words, all dual pairs are orthogonal:

$$\cos \widehat{aa^\star} = \pm 1.$$

The case of $n = 1$ previously considered is rectangular.

Definition 1.17. We will say that the complex K has the *standard geometry* if it is rectangular and also fully normalized:

$$|a| = 1 \text{ for all cells } a \in K \sqcup K^\star.$$

We always assume that $\mathbb{R}^n$ has the standard geometry.

1.3 The Hodge star operator

We continue to take the concepts we have considered previously for the case of dimension 1 and define them for the general case of dimension n. We define an operator from primal to dual chains that incorporate the geometry of the complex. Its formula is based on the analysis above.

Definition 1.18. The (chain) *Hodge star operator* of a metric complex K of dimension n is the pair of homomorphisms on chains of complementary dimensions:

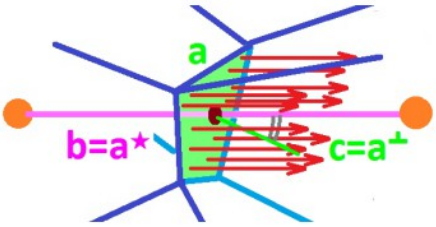
$$\begin{array}{ll} \star : C_k(K) \to C_{n-k}(K^\star), & k = 0, 1, ..., n, \\ \star : C_k(K^\star) \to C_{n-k}(K), & k = 0, 1, ..., n, \end{array}$$

defined by

$$\star(a) := \pm \frac{\langle a, a^\star \rangle}{|a^\star|} a^\star.$$

for any cell a, dual or primal, with the sign to be defined later.

The expression can be understood as the total flux of a across a region of area 1 on $a^\star$:



The two operators then satisfy:

$$\star(a)|a^\star| = \langle a, a^\star\rangle = \star(a^\star)|a|$$

The following statements are easy to prove.

Proposition 1.19. The matrix of the Hodge star operator $\star$ is diagonal with:

$$\star_{ii} = \pm\tfrac{|a_i|}{|a_i^\star|}\cos\widehat{a_i a_i^\star},$$

where a_i is the ith cell of K.

Theorem 1.20. The two star operators are the inverses of each other, up to a sign:

$$\star\star = \pm\,\mathrm{Id}\,.$$

Theorem 1.21. For a rectangular geometry, the Hodge star operator $\star$ preserves volumes of cells:

$$|\star(a)| = |a|.$$

Proposition 1.22. The Hodge star operator is always well-defined when

- R is a field, or
- the geometry of K is standard.

Exercise 1.23. Provide the Hodge star operator for a metric complex representation of a triangulation of the sphere realized as the hollow unit cube in $\mathbf{R}^3$.

Exercise 1.24. Provide the Hodge star operators for the examples of metric tensors presented in this and the last sections.

Next, what happens to the *forms* under Hodge duality?

Definition 1.25. In a metric complex K, the *Hodge-dual form* $\psi^\star$ of a form ψ over K is given by

$$\psi^\star(\sigma) := \psi(\sigma^\star).$$

The operation is extended from cells to chains by linearity making these diagrams commutative:

$$\begin{tikzcd}
C_k(K) \arrow[r, "\star"] \arrow[d, "\varphi"] & C_{n-k}(K^\star) \arrow[d, "\varphi^\star"] \\
R \arrow[r, phantom, "="] & R
\end{tikzcd}
\qquad
\begin{tikzcd}
C_k(K) \arrow[d, "\psi^\star"] & C_{n-k}(K^\star) \arrow[l, "\star"'] \arrow[d, "\psi"] \\
R \arrow[r, phantom, "="] & R
\end{tikzcd}$$

Then the formula is written for any chain:

$$(\star\psi)(a) := \psi(\star a),$$

where $\star$ in the right-hand side is the chain Hodge star operator.

Definition 1.26. The (cochain) *Hodge star operator* of a metric complex K is the dual of the chain Hodge star operator ($\star = \star^*$); i.e., it is the pair of homomorphisms,

$$\begin{array}{ll}\star : C^k(K) \to C^{n-k}(K^\star), & k = 0, 1, ..., n,\\ \star : C^k(K^\star) \to C^{n-k}(K), & k = 0, 1, ..., n,\end{array}$$

defined by

$$\star(\psi) := \psi^\star.$$

Proposition 1.27. The matrix of the Hodge star operator is diagonal with

$$\star_{ii} = \frac{|a_i|}{|a_i^\star|} \cos \widehat{aa^\star},$$

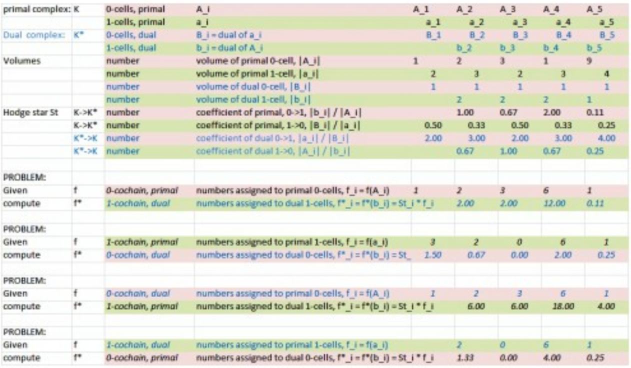
where a_i is the ith cell of K.

Exercise 1.28. Prove the proposition.

As before, we use in dimension $n = 1$:

$$\star^1_{ii} = \frac{|\text{point}|}{|\text{edge}|} = \frac{1}{\text{length}} = \frac{1}{\Delta x}.$$

Computing Hodge duality of forms over a complex with a non-trivial geometry is only slightly more complicated than for the standard case:



primal complex:	K	0-cells, primal	A_i	A_1	A_2	A_3	A_4	A_5
		1-cells, primal	a_i	a_1	a_2	a_3	a_4	a_5
Dual complex:	K*	0-cells, dual	B_i = dual of a_i	B_1	B_2	B_3	B_4	B_5
		1-cells, dual	b_i = dual of A_i		b_2	b_3	b_4	b_5
Volumes		number	volume of primal 0-cell, |A_i|	1	2	3	1	9
		number	volume of primal 1-cell, |a_i|	2	3	2	3	4
		number	volume of dual 0-cell, |B_i|	1	1	1	1	1
		number	volume of dual 1-cell, |b_i|		2	2	2	1

Note: See the files online.

In dimension $n = 2$, we have the following diagonal entries for a rectangular grid:

$$\begin{array}{lllll}\star^2_{ii} & = \frac{|\text{point}|}{|\text{rectangle}|} & = \frac{1}{\text{area}} & = \frac{1}{\Delta x \Delta y},\\ \star^1_{ii} & = \frac{|\text{edge}|}{|\text{edge}|} & = \frac{\text{length}}{\text{length}} & = \frac{\Delta y}{\Delta x}.\end{array}$$

In a 2-dimensional cubical complex, combining two 1-cells may produce different orientations and, therefore, different signs. Since $a \times d = \tau$ but $d \times a = -\tau$, the duality operator is

$$\begin{array}{ll}\Big([0,1] \times \{0\}\Big)^\star & = \{0\} \times [0,1],\\ \Big(\{0\} \times [0,1]\Big)^\star & = -[0,1] \times \{0\}.\end{array}$$

In general, we are guided by the following rule.

Sign convention: The sign of the Hodge star is determined by:

$$\star \star \alpha = (-1)^{k(n-k)} \alpha,$$

for a k-form α.

Exercise 1.29. Confirm the sign convention for $\mathbb{R}^n$.

Exercise 1.15

Suppose K is a metric complex. Show how the set of its vertices K^0 becomes a metric space.

It follows from the definition that, in addition to the two volume functions of these complexes, we can also derive the angle function:

$(a, a^*) \to$

$$\cos \widehat{a\, a^*} = \frac{\langle a, a^* \rangle}{|a|\,|a^*|}$$

importantíssimo

A área do paralelogramo depende do ângulo dos lados ou vetores.

The function is well-defined whenever the expression in the right-hand

17.04.2020

belongs to our ring R.
This is always the case when R is a field or $|a| = |a^*| = 1$.

Definition 1.16

We say that K has a rectangular geometry if

$$\langle a, a^* \rangle = \pm |a| |a^*| .$$

In other words, all dual pairs are orthogonal:

$$\cos \widehat{a\, a^*} = \pm 1$$

The case of $n=1$ previously considered is rectangular.

Definition 1.17

We will say that the complex K has the standard geometry if it is rectangular and also fully normalized:

$|a| = 1$ for all cells $a \in K \sqcup K^*$.

We always assume that $\mathbb{R}^n$ has the standard geometry.

Making use of the notation of theorem 7, we may now say: The points A, A' are situated in space *upon one and the same side of the plane* α, and the points A, B are situated in space *upon different sides of the plane* α.

Theorem 7 gives us the most important facts relating to the order of sequence of the elements of space. These facts are the results, exclusively, of the axioms already considered, and, hence, no new space axioms are required in group II.

§ 5. GROUP III. AXIOM OF PARALLELS. (EUCLID'S AXIOM.)

The introduction of this axiom simplifies greatly the fundamental principles of geometry and facilitates in no small degree its development. This axiom may be expressed as follows:

> III. *In a plane* α *there can be drawn through any point* A, *lying outside of a straight line* a, *one and only one straight line which does not intersect the line* a. *This straight line is called the parallel to* a *through the given point* A.

This statement of the axiom of parallels contains two assertions. The first of these is that, in the plane α, there is always a straight line passing through A which does not intersect the given line a. The second states that only one such line is possible. The latter of these statements is the essential one, and it may also be expressed as follows:

> THEOREM 8. If two straight lines a, b of a plane do not meet a third straight line c of the same plane, then they do not meet each other.

For, if a, b had a point A in common, there would then exist in the same plane with c two straight lines *a* and *b* each passing through the point *A* and not meeting the straight line *c*. This condition of affairs is, however, contradictory to the second assertion contained in the axiom of parallels as originally stated. Conversely, the second part of the axiom of parallels, in its original form, follows as a consequence of theorem 8.

The axiom of parallels is a *plane axiom.*

§ 6. GROUP IV. AXIOMS OF CONGRUENCE.

The axioms of this group define the idea of congruence or displacement.

Segments stand in a certain relation to one another which is described by the word "*congruent.*"

IV, 1. *If A, B are two points on a straight line **a**, and if A' is a point upon the same or another straight line a', then, upon a given side of A'* on *the straight line a', we can always find one and only one point B' so that the segment AB (or BA) is congruent to the segment $A'B'$. We indicate this relation by writing*

$$AB \equiv A'B'.$$

Every segment is congruent to itself; that is, we always have

$$AB \equiv AB.$$

We can state the above axiom briefly by saying that every segment can be *laid off* upon a given side of a given point of a given straight line in one and and only one way.

IV, 2. ***If a segment AB is congruent to the segment $A'B'$ and also to the segment $A''B''$, then the segment $A'B'$ is congruent to the segment $A''B''$; that***

Chapter 5

Coordinate Transformations: Definitions of Vectors and Tensors

We consider the formal definitions of vectors and tensors, and the equations for their components in a transformed coordinate system. We restrict the analysis to straight coordinates. We first consider Cartesian coordinates and afterward non-Cartesian coordinates.

5.1 Coordinate Transformation

We consider a Cartesian system $\mathscr{B}$ with coordinate axes $(\tilde{1},\tilde{2},\tilde{3})$, representing a point in this system as $\tilde{x}_i$. The origin of $\mathscr{B}$ in terms of the original coordinate system $\mathscr{A}$ (1,2,3) is given by the coordinates b_j, see Figure 5.1. Both coordinate systems are Cartesian, and the scales in both systems are the same. The vectors $\underset{m}{\tau}^i$, defined as

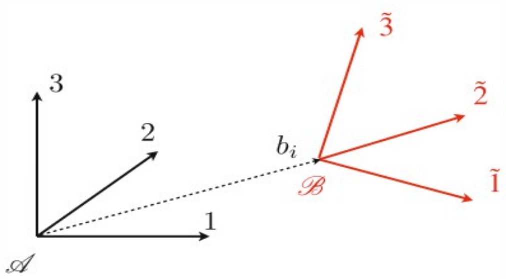

Figure 5.1: Transformation of Cartesian system $\mathscr{A}$ into Cartesian system $\mathscr{B}$

© Springer Nature Switzerland AG 2020
O. D. L. Strack, *Applications of Vector Analysis and Complex Variables in Engineering*, https://doi.org/10.1007/978-3-030-41168-8_5

$$\underset{m}{\tau}^i = \frac{\partial x_i}{\partial \tilde{x}_m} \qquad i = 1,2,3 \qquad m = 1,2,3, \tag{5.1}$$

are unit vectors tangent to the coordinate directions $\tilde{i}$ (compare (2.5)) with $\tilde{x}_m$ replacing the arc length along the curve, s. We define similar vectors that are tangent to the coordinates in system $\mathscr{A}$ in terms of the coordinates in system $\mathscr{B}$. We call these unit tangent vectors $\overset{m}{\gamma}_i$:

$$\overset{m}{\gamma}_i = \frac{\partial \tilde{x}_m}{\partial x_i}. \tag{5.2}$$

We express the original coordinates of a point x_i in terms of the new coordinates of that same point, and vice-versa, by integrating the latter two equations:

$$x_i = \underset{m}{\tau}^i \tilde{x}_m + b_i, \tag{5.3}$$

where b_i represents the origin of $\mathscr{B}$ in terms of x_i, and

$$\tilde{x}_m = \overset{m}{\gamma}_i x_i + \tilde{b}_m, \tag{5.4}$$

where $\tilde{b}_m$ represents the origin of the original system $\mathscr{A}$ in terms of the new coordinates.

The vectors $\underset{m}{\tau}^i$ are mutually orthogonal unit vectors,

$$\underset{m}{\tau}^i \underset{n}{\tau}^i = \delta_{mn}. \tag{5.5}$$

A similar equation holds for the unit vectors $\overset{m}{\gamma}_i$,

$$\overset{m}{\gamma}_i \overset{n}{\gamma}_i = \delta_{mn}. \tag{5.6}$$

We obtain a relationship between the vectors $\underset{m}{\tau}^i$ and $\overset{m}{\gamma}_i$ from (5.1) and (5.2)

$$\underset{m}{\tau}^i \overset{n}{\gamma}_i = \frac{\partial x_i}{\partial \tilde{x}_m} \frac{\partial \tilde{x}_n}{\partial x_i} = \frac{\partial \tilde{x}_n}{\partial \tilde{x}_m} = \delta_{mn}. \tag{5.7}$$

The moduli of $\underset{m}{\tau}^i$ and of $\overset{m}{\gamma}_i$ are 1; we combine this with the latter equation:

$$\underset{m}{\tau}^i = \overset{m}{\gamma}_i. \tag{5.8}$$

We introduce a matrix a_{ij},

$$a_{im} = \underset{m}{\tau}^i = \overset{m}{\gamma}_i = \frac{\partial x_i}{\partial \tilde{x}_m} = \frac{\partial \tilde{x}_m}{\partial x_i}, \tag{5.9}$$

and write (5.3) and (5.4) as

$$x_i = a_{ij} \tilde{x}_j + b_i, \tag{5.10}$$

and

$$\tilde{x}_i = a_{ji} x_j + \tilde{b}_i. \tag{5.11}$$

We observe from (5.9) that

$$a_{im} a_{in} = \frac{\partial x_i}{\partial \tilde{x}_m} \frac{\partial \tilde{x}_n}{\partial x_i} = \delta_{mn}, \tag{5.12}$$

and that

$$a_{im} a_{jm} = \frac{\partial \tilde{x}_m}{\partial x_i} \frac{\partial x_j}{\partial \tilde{x}_m} = \delta_{ij}. \tag{5.13}$$

5.2 Definition of Vectors and Tensors

A vector is a mathematical representation of some quantity that has both an orientation and a magnitude; it usually represents a physical quantity, such as the velocity of a water particle. A vector does not change its orientation and magnitude in space as a result of a coordinate transformation, which enables us to establish equations to determine if a set of three expressions represents a vector.

The differences between the coordinates of one point in space and another are the components of a vector; its length and position are invariant with respect to a coordinate transformation. Accordingly we introduce a vector A_i as

$$A_i = y_i - x_i \qquad i = 1,2,3, \tag{5.14}$$

where y_i and x_i are the coordinates of two arbitrary points in space. We use (5.11) to transform A_i into $\tilde{A}_i$:

$$\tilde{A}_i = \tilde{y}_i - \tilde{x}_i = a_{ji}(y_j - x_j) + \tilde{b}_i - \tilde{b}_i, \tag{5.15}$$

or

$$\tilde{A}_i = a_{ji} A_j. \tag{5.16}$$

We obtain the inverse transformation the same way from (5.10):

$$A_i = a_{ij} \tilde{A}_j. \tag{5.17}$$

The first index in a_{ij} corresponds to A_i in both equations. Equations (5.16) and (5.17) are the transformation formulas for a vector; any set of three components that transforms according to (5.16) and (5.17) is a vector in the sense defined above and represents a quantity that will not change due to a coordinate transformation.

5.2.1 Tensors of the Second Rank

A tensor of the second rank has nine components in three-dimensional space and has two indices, each ranging from 1 to 3. A tensor is an operator that produces a vector upon being applied to another vector. Thus, if the tensor A_{ij} operates on a vector X_j, the result is a new vector Y_i:

$$Y_i = A_{ij} X_j. \tag{5.18}$$

We obtain the transformation rules for a tensor of the second rank from those of a vector. We have, from (5.16)

$$\tilde{Y}_i = a_{ji} Y_j = a_{ji} A_{jm} X_m. \tag{5.19}$$

We use (5.17) to express X_m in terms of $\tilde{X}_m$;

$$\tilde{Y}_i = a_{ji} A_{jm} a_{mk} \tilde{X}_k = a_{ji} a_{mk} A_{jm} \tilde{X}_k. \tag{5.20}$$

We have, by definition

$$\tilde{Y}_i = \tilde{A}_{ij} \tilde{X}_j, \tag{5.21}$$

so that

$$\tilde{A}_{mn} = a_{im} a_{jn} A_{ij}. \tag{5.22}$$

The first index in the matrices a_{im} and a_{jn} refers to the original tensor components; the second index to those of the transformed one.

We obtain the inverse transformation in a similar way:

$$A_{mn} = a_{mi} a_{nj} \tilde{A}_{ij}. \tag{5.23}$$

Again, the first index in each transformation matrix refers to the original tensor.

A special tensor of the second rank is the Kronecker delta; its transformation is:

$$\tilde{\delta}_{mn} = a_{im} a_{jn} \delta_{ij} = a_{im} a_{in}, \tag{5.24}$$

or, with (5.13)

$$\tilde{\delta}_{mn} = \delta_{mn}. \tag{5.25}$$

The Kronecker delta is invariant with respect to a Cartesian coordinate transformation.

5.2.2 The Gradient Tensor

Consider a vector field A_i. We apply the operator ∂_i to this vector field to obtain a tensor, called the gradient tensor,

$$A_{ij} = \partial_i A_j \tag{5.26}$$

Problem 5.1

Demonstrate that $\partial_i A_j$ is a tensor of the second rank.

5.2.3 Principal Directions

A tensor operating on a vector X_i produces a new vector Y_i,

$$Y_i = A_{ij} X_j. \tag{5.27}$$

We choose the direction of the vector X_i such that the vector Y_i is collinear with X_i; the direction of this vector is the principal direction of the tensor. For this case, Y_i equals λX_i, where λ is some scalar quantity,

$$Y_i = \lambda X_i = A_{ij} X_j, \tag{5.28}$$

or

$$A_{ij}X_j - \lambda X_i = (A_{ij} - \lambda \delta_{ij})X_j = 0. \tag{5.29}$$

This represents a system of three homogeneous equations for the components of X_i, which has non-trivial solutions only if the determinant of the system is zero, i.e., if

$$\det(A_{ij} - \lambda \delta_{ij}) = \begin{vmatrix} A_{11} - \lambda & A_{12} & A_{13} \\ A_{21} & A_{22} - \lambda & A_{23} \\ A_{31} & A_{32} & A_{33} - \lambda \end{vmatrix} = 0. \tag{5.30}$$

This third-order equation is the characteristic equation of the tensor A_{ij}; its roots are the principal values of the tensor. The corresponding three directions of X_i are the characteristic directions, or principal directions, of the tensor. The homogenous equations can be divided by a fixed constant. If we choose for this constant the magnitude (modulus) of X_i, the result will be a unit vector, fully determined by two values. The principal values and directions are also known as the eigenvalues and eigenvectors of the tensor.

5.3 Non-Cartesian Transformations with Straight Axes

We consider straight transformed coordinates $\tilde{1},\tilde{2},\tilde{3}$ that are not orthogonal. That the coordinate axes are straight is an important restriction; differentiation along curves adds terms to derivatives, as we saw when establishing equations for the acceleration; the additional terms are the centrifugal acceleration, which is due entirely to the curvature of the path. Since we make restrictions to straight axes, such additional terms do not appear.

The definitions of the base vectors $\underset{m}{\tau}^i$ and $\overset{m}{\gamma}_i$ remain as before:

$$\underset{m}{\tau}^i = \frac{\partial x_i}{\partial \tilde{x}_m}, \tag{5.31}$$

and

$$\overset{m}{\gamma}_i = \frac{\partial \tilde{x}_m}{\partial x_i}. \tag{5.32}$$

The base vectors $\underset{m}{\tau}^i$ represent the tangent vectors to the coordinate axes $\tilde{1},\tilde{2},\tilde{3}$, but are not orthogonal. We interpret the base vectors $\overset{m}{\gamma}_i$ now in a different manner; we view them as the gradients of the functions $\tilde{x}_m(x_1,x_2,x_3)$, i.e., the base vector $\overset{1}{\gamma}_i$ points in the direction of the gradient of the function $\tilde{x}_1(x_1,x_2,x_3)$. The planes $\tilde{x}_1$=constant are, by definition, parallel to the $\tilde{2},\tilde{3}$-plane and the base vector $\overset{1}{\gamma}_i$ is normal to the $\tilde{2},\tilde{3}$-plane. The three base vectors $\overset{m}{\gamma}_i$, m=1,2,3 are thus orthogonal to the three planes $\tilde{2},\tilde{3}$, $\tilde{1},\tilde{3}$, and $\tilde{1},\tilde{2}$, respectively, see Figure 5.2.

An important difference between Cartesian and non-Cartesian coordinate systems is that the base vectors cannot all be unit vectors. We have the following relationships between the two sets of base vectors

$$\underset{m}{\tau}^i \overset{n}{\gamma}_i = \frac{\partial x_i}{\partial \tilde{x}_m} \frac{\partial \tilde{x}_n}{\partial x_i} = \delta_{mn}, \tag{5.33}$$

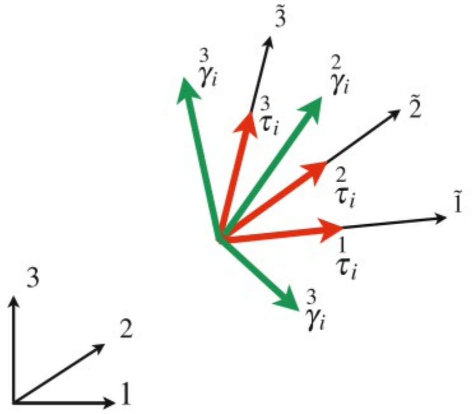

Figure 5.2: Non-orthogonal coordinates; the coordinates 1,2,3 are Cartesian; the coordinates $\tilde{1},\tilde{2},\tilde{3}$ are not. The three base vectors $\underset{m}{\tau}^i$ are tangent to the $\tilde{1},\tilde{2},\tilde{3}$ coordinates, the three gradient vectors $\overset{m}{\gamma}_i$ are orthogonal to the planes of the two coordinate axes that do not contain the number m.

and

$$\underset{m}{\tau}^i\overset{m}{\gamma}_j = \frac{\partial x_i}{\partial \tilde{x}_m}\frac{\partial \tilde{x}_m}{\partial x_j} = \delta_{ij}. \tag{5.34}$$

The dot product of tangential and gradient base vectors is zero because the tangential base vectors $\underset{m}{\tau}^i$ are normal to the gradient base vectors $\overset{n}{\gamma}_i$, except when $m = n$, in which case their dot product is one. The base vectors $\underset{m}{\tau}^i$ and $\overset{m}{\gamma}_i$ are generally not at right angles; the dot product of the base vectors is equal to

$$\underset{m}{\tau}^i\overset{n}{\gamma}_i = \underset{m}{\tau}\overset{n}{\gamma}\cos\underset{m}{\overset{n}{\alpha}} = \delta_{mn}, \tag{5.35}$$

where $\underset{m}{\overset{n}{\alpha}}$ is the angle between the base vectors. Since $\cos\underset{m}{\overset{n}{\alpha}} \neq 1$ unless $\underset{m}{\overset{n}{\alpha}} = \pi/2$, the lengths of the base vectors will generally not be equal to one, as in the Cartesian case. This is the result of the scale of measurement along the non-orthogonal coordinate axes being different from those along the Cartesian axes. In the present case the scales of measurement do not vary in space because the coordinate transformations are linear; the components of the base vectors are constants that depend upon the angles between the coordinate axes.

The components of a vector in the non-orthogonal system are not equal to their projections on the coordinate directions. There are two different sets of base vectors; we may decompose a vector in terms of components either along the tangent bases, or along the gradient bases. The former components are called the *contravariant* components and are denoted with the index in the place where normally an exponent appears, i.e., the contravariant components of a vector A_i in the transformed system are written as $\tilde{A}^i$. The Cartesian components of the vector A_i are related to the contravariant components $\tilde{A}^i$ as:

$$A_i = \underset{m}{\tau}^{i}\tilde{A}^m. \tag{5.36}$$

We may also decompose the vector in terms of components along the gradient bases. The corresponding components are the *covariant* components; we place the indices at the lower right corner of the symbol:

$$A_i = \overset{m}{\gamma}_i\tilde{A}_m \tag{5.37}$$

The two different kinds of decomposition into components are illustrated in Figure 5.3 for the two-dimensional case. The components $\tilde{A}_i$ and $\tilde{A}^i$ are not equal in length to the projections of A_i onto the base vectors; the projections consist of the dot product of $\tilde{A}^m$ and $\underset{m}{\tau}^{i}$ and that of $\tilde{A}_m$ and $\overset{m}{\gamma}_i$ and the base vectors are not of unit length. Since the covariant and contravariant components of the vectors are not equal to their projections, we distinguish them from their projections, called the physical components.

Figure 5.3: Decomposition of a vector A_i in its contra variant and covariant components

The Cartesian coordinate system is a special case, where covariant and contravariant components are equal; we place the index denoting Cartesian components at the lower right corner.

We determine a relationship between the contravariant and covariant components of the vector by first setting the right-hand sides of (5.36) and (5.37) equal to each other

$$\underset{m}{\tau}^{i}\tilde{A}^m = \overset{m}{\gamma}_i\tilde{A}_m, \tag{5.38}$$

and next contract both sides of this equation with $\overset{n}{\gamma}_i$:

$$\overset{n}{\gamma}_i\underset{m}{\tau}^{i}\tilde{A}^m = \overset{n}{\gamma}_i\overset{m}{\gamma}_i\tilde{A}_m. \tag{5.39}$$

We apply (5.34) to the left-hand side:

$$\delta_{nm}\tilde{A}^m = \tilde{A}^n = g^{nm}\tilde{A}_m. \tag{5.40}$$

The dot product of the covariant bases, g^{mn}, is called the *contravariant metric tensor*, and represents the scales of measurement in the directions normal to the axes. Indeed, the metric tensor is the dot product of the various covariant base vectors and thus indeed reflect the scales of measurement,

$$g^{nm} = \overset{n}{\gamma}_i \overset{m}{\gamma}_i. \tag{5.41}$$

If we contract both sides of (5.38) with $\underset{n}{\tau}^i$, we obtain:

$$\underset{m}{\tau}^i \underset{n}{\tau}^i \tilde{A}^m = \underset{n}{\tau}^i \overset{m}{\gamma}_i \tilde{A}_m = \delta_{nm}\tilde{A}_m = \tilde{A}_n, \tag{5.42}$$

or, introducing the *covariant metric tensor* g_{mn} as

$$g_{mn} = \underset{m}{\tau}^i \underset{n}{\tau}^i, \tag{5.43}$$

we obtain

$$\tilde{A}_n = g_{mn}\tilde{A}^m. \tag{5.44}$$

We say that contraction of the contravariant components $\tilde{A}^m$ with the covariant metric tensor g_{mn} 'brings the index down', i.e., results in producing the covariant components of the vector. Similarly, contraction of the covariant components $\tilde{A}_m$ with the contravariant metric tensor g^{mn} 'raises the index up', i.e., produces the contravariant components of the vector. We recall the definitions of the two metric tensors

$$g^{mn} = \overset{m}{\gamma}_i \overset{n}{\gamma}_i = \frac{\partial \tilde{x}_m}{\partial x_i}\frac{\partial \tilde{x}_n}{\partial x_i} \tag{5.45}$$

$$g_{mn} = \underset{m}{\tau}^i \underset{n}{\tau}^i = \frac{\partial x_i}{\partial \tilde{x}_m}\frac{\partial x_i}{\partial \tilde{x}_n}. \tag{5.46}$$

The two metric tensors are symmetrical.

We obtain the contravariant components $\tilde{A}^m$ from (5.36) by contraction with $\overset{n}{\gamma}_i$

$$A_i \overset{n}{\gamma}_i = \overset{n}{\gamma}_i \underset{m}{\tau}^i \tilde{A}^m = \tilde{A}^m \delta_{mn} = \tilde{A}^n, \tag{5.47}$$

and obtain the covariant components by contracting (5.37) with $\underset{n}{\tau}^i$

$$A_i \underset{n}{\tau}^i = \underset{n}{\tau}^i \overset{m}{\gamma}_i \tilde{A}_m = \delta_{mn}\tilde{A}_m = \tilde{A}_n. \tag{5.48}$$

The transformation rules for vectors are given by four equations in this case, two each for the contravariant and two each for the covariant components of the vector, i.e., by (5.36) with (5.47) and by (5.37) with (5.48)

Similar transformation rules apply to tensors; the rules for the contravariant components become

$$\tilde{A}^{mn} = \overset{m}{\gamma}_i \overset{n}{\gamma}_j A_{ij} \tag{5.49}$$

There exist a mix of components as well

$$\tilde{A}^m{}_n = \overset{m}{\gamma}_i \underset{n}{\tau}^j A_{ij}, \tag{5.50}$$

and

$$\tilde{A}_m{}^n = \underset{m}{\tau}^i \overset{n}{\gamma}_j A_{ij}. \tag{5.51}$$

5.3.1 Invariants

We concluded when dealing with Cartesian systems that contraction that eliminates all free indices results in a scalar quantity. This is not true for components in general coordinate systems. For example, the quantity A_{ii} is a scalar if the components of this tensor are in a Cartesian coordinate system. However, the quantities $\tilde{A}^{ii}$ and $\tilde{A}_{ii}$ are not invariants. We see this by expressing these quantities in terms of Cartesian coordinates

$$\tilde{A}^{mm} = \overset{m}{\gamma}_i \overset{m}{\gamma}_j A_{ij}, \tag{5.52}$$

which is not an invariant since the base vectors are unrelated to the components of the tensor A_{ij}. However, the quantities $\tilde{A}^m{}_m$ and $\tilde{A}_m{}^m$ are invariant scalars as follows from the transformation rules and (5.34),

$$\tilde{A}^m{}_m = \overset{m}{\gamma}_i \underset{m}{\tau}^j A_{ij} = \delta_{ij} A_{ij} = A_{ii}. \tag{5.53}$$

We obtain a similar result for $\tilde{A}_m{}^m$.

We create invariants by contracting indices in opposite positions, i.e., an index in the upper right position balanced by one in the lower right position of the contracting term. The dot product, an invariant, is

$$A_i A_i = \tilde{A}^i \tilde{A}_i, \tag{5.54}$$

which is invariant and matches A_iA_i as we see by contracting (5.36) with (5.37),

$$A_i A_i = \underset{m}{\tau}^i \tilde{A}^m \overset{n}{\gamma}_i \tilde{A}_n = \delta_{mn} \tilde{A}^m \tilde{A}_n = \tilde{A}^m \tilde{A}_m. \tag{5.55}$$

5.3.2 The Gradient

Vectors are usually expressed in terms of their contravariant components, whereas the components of the gradient of a scalar are preferably expressed in terms of their covariant components. This becomes clear by considering the definition of the gradient of some scalar function F,

$$\frac{\partial F}{\partial \tilde{x}_i} = \frac{\partial F}{\partial x_m} \frac{\partial x_m}{\partial \tilde{x}_i} = \underset{i}{\tau}^m \frac{\partial F}{\partial x_m}, \tag{5.56}$$

which conforms to the transformation rule for a covariant vector, (5.48).

Of particular interest for later use is the transformation of the Laplacian, $L_{ii} = \partial_i \partial_i F$. The Laplacian is an invariant, so that we need to transform the gradient tensor L_{ij} as follows:

$$\tilde{L}^m{}_m = \overset{m}{\gamma}_i \underset{m}{\tau}^j L_{ij} = \delta_{ij} L_{ij} = L_{ii} = \nabla^2 F. \tag{5.57}$$

We discuss in the remainder of this chapter the stress, displacement gradient, and strain tensors. We do this in terms of Cartesian coordinates.

5.4 The Stress Tensor

The stress tensor is of the second rank, and operates on the vector normal to a plane to produce the stress vector, or traction, that operates on that plane,

$$t_i = \sigma_{ji} n_j, \tag{5.58}$$

where t_i represents the stress vector, and n_i the unit normal to the plane. The unit normals to the planes in the positive coordinate directions are:

$$\overset{m}{n}_i = \delta_{mi}, \tag{5.59}$$

where m represents the coordinate axis that serves as the normal to the plane considered. We apply (5.58) to the three normal vectors of (5.59) and obtain the following for the corresponding stress vectors $\overset{m}{t}_i$:

$$\overset{m}{t}_i = \sigma_{ji} \delta_{mj} = \sigma_{mi}. \tag{5.60}$$

It appears that the components σ_{mi} for $m = 1,2,3$ represent the three stress vectors, or tractions, on the planes with normals in the $1,2,3$ directions, respectively, see Figure 5.4. The stresses that act on the planes with their normals in the negative coordinate directions are obtained from (5.58) by replacing n_i by $\overset{m}{n}_i$ with

$$\overset{m}{n}_i = -\delta_{mi}, \tag{5.61}$$

so that (5.58) becomes

$$\overset{m}{t}_i = -\sigma_{ji} \delta_{mi} = -\sigma_{mi}. \tag{5.62}$$

The expression σ_{ii} is a scalar since there is no free index, and is invariant to a coordinate transformation; this invariant is called the first invariant of the stress tensor. The isotropic stress is defined as one-third of the first invariant and is usually represented as $\overset{0}{\sigma}$

$$\overset{0}{\sigma} = \tfrac{1}{3} \sigma_{ii}. \tag{5.63}$$

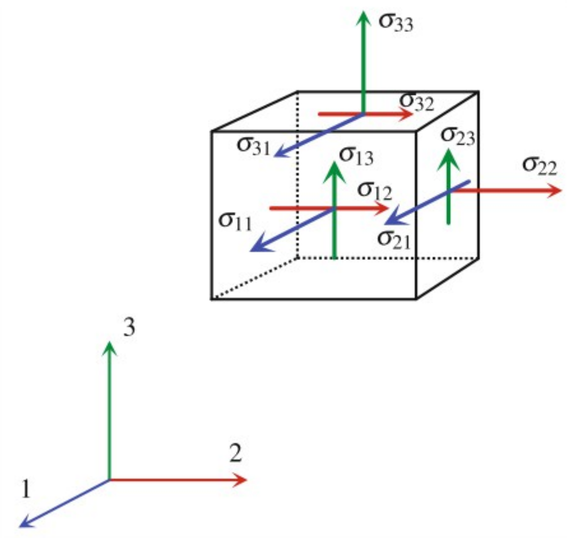

Figure 5.4: Definition of the components of the stress tensor.

5.4.1 The Normal and Shear Stress Components

We decompose the stress vector that acts on a plane into two components: the normal stress and the shear stress; the former is normal to the plane, and the latter acts in the plane. We contract t_i with n_i to obtain the normal stress:

$$\overset{n}{t} = t_i n_i = \sigma_{ij} n_i n_j. \tag{5.64}$$

The normal stress is positive if pointing in the direction of the unit normal n_i. We multiply $\overset{n}{t}$ with n_j to obtain the normal stress as a vector:

$$\overset{n}{t}_j = t_i n_i n_j = \sigma_{nm} n_n n_m n_j. \tag{5.65}$$

The tangential component of the stress vector is the difference between the stress vector t_i and its normal component:

$$\overset{s}{t}_j = t_j - t_i n_i n_j. \tag{5.66}$$

5.4.2 Principal Directions and Principal Values of the Stress Tensor in Two Dimensions.

We determine the principal directions and the principal values of the stress tensor in two dimensions for the case of plane stress, i.e., the case that there are no stresses in planes with normals in the 3-direction.

Principal Directions

The principal directions are the directions of the normals to the planes that carry only normal stresses, i.e., the planes where the shear stresses are zero. We rotate the 1,2-coordinate system in such a way that the shear stress on the plane with its normal in the $\tilde{1}$-direction is zero.

The transformed stress tensor $\tilde{\sigma}_{1j} = a_{m1}a_{nj}\sigma_{mn}$ represents the stresses on the plane normal to the $\tilde{1}$ axis and $\tilde{\sigma}_{12} = 0$,

$$\tilde{\sigma}_{12} = 0 = a_{m1}a_{n2}\sigma_{mn}, \tag{5.67}$$

where

$$a_{mj} = \underset{j}{\tau}^{m}. \tag{5.68}$$

If we represent the angle between the 1-axis and the $\tilde{1}$-axis as ψ then

$$\begin{aligned} a_{m1} &= \underset{1}{\tau}^{m} = (\cos\psi, \sin\psi) \\ a_{m2} &= \underset{2}{\tau}^{m} = (-\sin\psi, \cos\psi). \end{aligned} \tag{5.69}$$

We work out (5.67):

$$\begin{aligned} 0 &= a_{11}a_{12}\sigma_{11} + a_{11}a_{22}\sigma_{12} + a_{21}a_{12}\sigma_{21} + a_{21}a_{22}\sigma_{22} \\ &= -\sigma_{11}\sin\psi\cos\psi + \sigma_{12}\cos^2\psi - \sigma_{12}\sin^2\psi + \sigma_{22}\sin\psi\cos\psi \\ &= -\tfrac{1}{2}\sin(2\psi)(\sigma_{11} - \sigma_{22}) + \sigma_{12}\cos(2\psi). \end{aligned} \tag{5.70}$$

We solve for the tangent of 2ψ, i.e., the tangent of twice the angle that the principal direction makes with the 1-axis,

$$\tan(2\psi) = \frac{\sigma_{12}}{\frac{1}{2}(\sigma_{11} - \sigma_{22})}\ . \tag{5.71}$$

Principal Values

With the principal directions known, we determine the principal values in terms of the principal directions. We obtain an expression for the principal stress σ_{11} from $\tilde{\sigma}_{ij} = a_{mi}a_{nj}\sigma_{mn}$ by setting both i and j equal to 1:

$$\begin{aligned} \tilde{\sigma}_{11} = a_{m1}a_{n1}\sigma_{mn} &= a_{11}^2\sigma_{11} + a_{21}a_{11}\sigma_{21} + a_{11}a_{21}\sigma_{12} + a_{21}^2\sigma_{22} \\ &= \sigma_{11}\cos^2\psi + 2\sigma_{12}\sin\psi\cos\psi + \sigma_{22}\sin^2\psi \\ &= \tfrac{1}{2}\sigma_{11}[1 + \cos(2\psi)] + \tfrac{1}{2}\sigma_{22}[1 - \cos(2\psi)] + \sigma_{12}\sin(2\psi) \\ &= \tfrac{1}{2}(\sigma_{11} + \sigma_{22}) + \tfrac{1}{2}(\sigma_{11} - \sigma_{22})\cos(2\psi) + \sigma_{12}\sin(2\psi). \end{aligned} \tag{5.72}$$

The second principal stress acts on a plane that is at right angles to the plane with its normal in the direction ψ. Since the angle ψ is multiplied by a factor 2, and since the signs of both the cosine and the sine function change upon adding π to the argument, we obtain for $\tilde{\sigma}_{22}$:

$$\tilde{\sigma}_{22} = \tfrac{1}{2}(\sigma_{11} + \sigma_{22}) - \tfrac{1}{2}(\sigma_{11} - \sigma_{22})\cos(2\psi) - \sigma_{12}\sin(2\psi). \tag{5.73}$$

5.4.3 Stress Deviator

The difference between the major and minor principal stresses is the *stress deviator*, half of which we represent by the symbol λ. It is sometimes useful to express the three components of the stress tensor in terms of λ, ψ, and $\overset{0}{\sigma}$. We write the major principal stress, (5.72), as $\overset{0}{\sigma}+\lambda$, and subtract $\overset{0}{\sigma}$ from both sides of the equation,

$$\lambda = \tfrac{1}{2}(\sigma_{11}-\sigma_{22})\cos(2\psi)+\sigma_{12}\sin(2\psi). \tag{5.74}$$

We use (5.71),

$$\tfrac{1}{2}(\sigma_{11}-\sigma_{22})\sin(2\psi)-\sigma_{12}\cos(2\psi)=0, \tag{5.75}$$

multiply (5.74) by $\cos(2\psi)$ and (5.75) by $\sin(2\psi)$, and add:

$$\lambda\cos(2\psi)=\tfrac{1}{2}(\sigma_{11}-\sigma_{22}). \tag{5.76}$$

We find the expression for σ_{12} by multiplying (5.74) by $\sin(2\psi)$, multiplying (5.75) by $\cos(2\psi)$, and subtracting the results,

$$\lambda\sin(2\psi)=\sigma_{12}. \tag{5.77}$$

We first square, then add, the two sides of the latter two equations in order to obtain an expression for λ in terms of the components of the stress tensor:

$$\lambda^2=\left[\tfrac{1}{2}(\sigma_{11}-\sigma_{22})\right]^2+\sigma_{12}^2. \tag{5.78}$$

We find expressions for σ_{11} and σ_{22} from (5.76) and $\overset{0}{\sigma}=\frac{1}{2}(\sigma_{11}+\sigma_{22})$,

$$\begin{aligned}\sigma_{11}&=\overset{0}{\sigma}+\lambda\cos(2\psi)\\ \sigma_{22}&=\overset{0}{\sigma}-\lambda\cos(2\psi).\end{aligned} \tag{5.79}$$

5.4.4 Invariants

The first invariant of the stress tensor, σ_{ii}, equals twice the isotropic stress,

$$\underset{1}{I}=\sigma_{kk}=2\overset{0}{\sigma}. \tag{5.80}$$

We obtain the expression for a second invariant by contracting σ_{ij} with itself:

$$\underset{2}{I}=\sigma_{ij}\sigma_{ij}. \tag{5.81}$$

The stress deviator is also an invariant. In order to demonstrate this, we form the combination:

$$\begin{aligned}\underset{2}{I}-\underset{1}{I}^2 &=\sigma_{ij}\sigma_{ij}-\sigma_{kk}\sigma_{mm}\\ &=\sigma_{11}^2+2\sigma_{12}^2+\sigma_{22}^2-(\sigma_{11}+\sigma_{22})^2=2\sigma_{12}^2-2\sigma_{11}\sigma_{22}.\end{aligned} \tag{5.82}$$

We expand the expression for λ^2, (5.78),

$$\lambda^2 = \tfrac{1}{4}\left[\sigma_{11}^2 + \sigma_{22}^2 - 2\sigma_{11}\sigma_{22}\right] + \sigma_{12}^2 = \tfrac{1}{4}\left[\sigma_{11}^2 + \sigma_{22}^2 + 2\sigma_{11}\sigma_{22}\right] - \sigma_{11}\sigma_{22} + \sigma_{12}^2, \tag{5.83}$$

or with (5.82),

$$\lambda^2 = \tfrac{1}{4}\sigma_{kk}^2 + \tfrac{1}{2}(-I_1^2 + I_2) = -\tfrac{1}{4}I_1^2 + \tfrac{1}{2}I_2, \tag{5.84}$$

which is indeed an invariant.

Problem 5.2

Derive equations for the angle ψ between the major principal stress and the 1-axis, using (5.66), by setting the shear stress component equal to zero, expressing the traction in terms of the stress tensor and the unit normal to the plane. Compare your answer with (5.71).

5.4.5 The Equilibrium Conditions

The stresses that act on the six planes of the cube in Figure 5.4 act on opposite planes in opposite direction from one another. Thus, if the stresses are constant, they are in equilibrium. The situation changes if the stresses vary with position. We apply the condition of equilibrium to the stresses in the 2-direction on a volume of sides $\Delta x_1, \Delta x_2, \Delta x_3$ and centered at x_i, see Figure 5.5

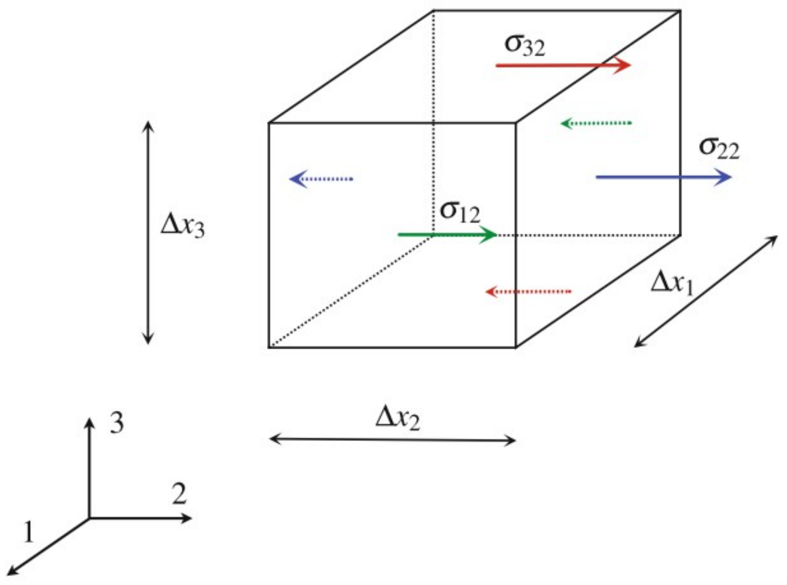

Figure 5.5: Equilibrium in the 2-direction

$$\begin{aligned}
&[\sigma_{22}(x_1,x_2+\tfrac{1}{2}\Delta x_2,x_3)-\sigma_{22}(x_1,x_2-\tfrac{1}{2}\Delta x_2,x_3)]\Delta x_1\Delta x_3\\
&+[\sigma_{12}(x_1+\tfrac{1}{2}\Delta x_1,x_2,x_3)-\sigma_{12}(x_1-\tfrac{1}{2}\Delta x_1,x_2,x_3)]\Delta x_2\Delta x_3\\
&+[\sigma_{32}(x_1,x_2,x_3+\tfrac{1}{2}\Delta x_3)-\sigma_{32}(x_1,x_2,x_3-\tfrac{1}{2}\Delta x_3)]\Delta x_1\Delta x_2\\
&+B_2\Delta x_1\Delta x_2\Delta x_3=F_2\Delta x_1\Delta x_2\Delta x_3.
\end{aligned} \tag{5.85}$$

where B_2 is the component of the body force B_i per unit volume. The force F_i, also per unit volume, is the resultant force due to the stresses and the body force B_i. This force is zero if the system is in equilibrium; if it is not, then $F_i = \rho e_i$, where ρ is the mass per unit volume, i.e., the density, and e_i is a unit vector pointing in the direction of the resultant force. We pass to the limit for $\Delta x_1 \to 0, \Delta x_2 \to 0, \Delta x_3 \to 0$ and obtain

$$\partial_i \sigma_{i2} + B_2 = F_2 = \rho a_2. \tag{5.86}$$

We generalize this equation to apply to all three coordinate directions,

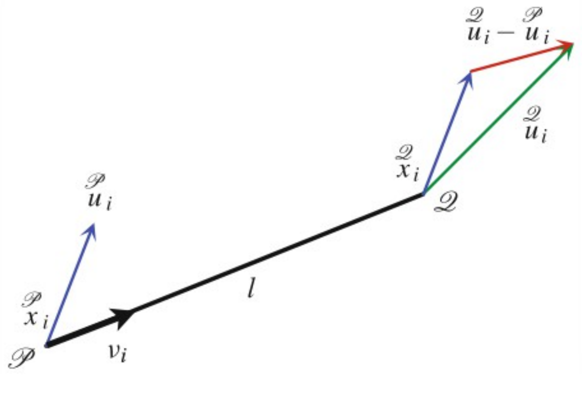
$$\partial_i \sigma_{ij} + B_j = F_j = \rho a_j. \tag{5.87}$$

5.5 The Displacement Gradient and Strain Tensors

We consider a deforming body and represent the displacements of points in that body relative to some fixed initial state as u_i. We begin by examining a linear displacement, and consider displacement vectors of two points, $\overset{\mathscr{P}}{u}_i$ at $\mathscr{P}$ and $\overset{\mathscr{Q}}{u}_i$ at $\mathscr{Q}$. The vector $l\nu_i$, where ν_i is a unit vector, points from point $\mathscr{P}$ to point $\mathscr{Q}$

$$l\nu_i = \overset{\mathscr{Q}}{x}_i - \overset{\mathscr{P}}{x}_i, \tag{5.88}$$

where $\overset{\mathscr{P}}{x}_i$ and $\overset{\mathscr{Q}}{x}_i$ are the coordinates of points $\mathscr{P}$ and $\mathscr{Q}$, see Figure 5.6. The relative displacement per unit length is a_i, with



$\overset{\mathscr{Q}}{u}_i - \overset{\mathscr{P}}{u}_i$
$\overset{\mathscr{Q}}{u}_i$
$\overset{\mathscr{Q}}{x}_i$
$\mathscr{Q}$
$\overset{\mathscr{P}}{u}_i$
l
$\overset{\mathscr{P}}{x}_i$
$\mathscr{P}$
ν_i

Figure 5.6: Relative displacement of the endpoints of a filament of length l with orientation ν_i

$$a_i = \frac{\Delta u_i}{l} = \frac{\overset{\mathscr{Q}}{u}_i - \overset{\mathscr{P}}{u}_i}{l} \tag{5.89}$$

The relative displacement vector a_i is useful to describe the deformation of a body that experiences linear displacements.

5.5.1 The Displacement Gradient Tensor

The displacements generally vary with position; we use the displacement gradient tensor rather than the relative displacement vector to describe the deformation of the body:

$$\alpha_{ij} = \partial_i u_j = \frac{\partial u_j}{\partial x_i}. \tag{5.90}$$

We express the relative displacement vector a_i in terms of the displacement gradient tensor as:

$$a_j = \lim_{|\Delta x_i| \to 0} \frac{\partial u_j}{\partial x_i} \frac{\Delta x_i}{\sqrt{\Delta x_m \Delta x_m}} = \alpha_{ij} \nu_i, \tag{5.91}$$

where ν_i is a unit vector in the direction of the filament considered. This equation is similar to that obtained for the stress vector acting on an arbitrary plane.

The vector a_i represents the relative displacement of the end points of a filament of incremental length oriented in the direction ν_i. As for stresses, we define relative displacements in the direction normal to ν_i and in the direction of ν_i. The latter displacement represents the stretch of the filament, whereas the former represents rotation of the filament. The relative rotation of two filaments that are originally at right angles represents a change in angle between the filaments, the shear strain γ. The rotation of both filaments together represents local body rotation. We distinguish between the relative and absolute rotations of the filaments by separating the symmetrical and antisymmetrical parts of the displacement gradient tensor:

$$\partial_i u_j = e_{ij} + \omega_{ij}. \tag{5.92}$$

5.5.2 The Strain Tensor and the Rotation Tensor

The strain tensor e_{ij} is the symmetrical part of the displacement gradient tensor:

$$e_{ij} = \tfrac{1}{2}(\partial_i u_j + \partial_j u_i). \tag{5.93}$$

We illustrate application of the strain tensor by considering strain of two filaments at ninety degrees from one another, see Figure 5.7; the first filament has an orientation $\nu_i = \delta_{1i}$ and the second one has an orientation $\nu_i = \delta_{2i}$. The relative displacements e_i for these filaments are:

$$\begin{aligned} a_j &= e_{ij}\nu_i = e_{ij}\delta_{1i} = e_{1j} \\ a_j &= e_{ij}\nu_i = e_{ij}\delta_{2i} = e_{2j} \end{aligned} \tag{5.94}$$

These strains are shown in Figure 5.7; the strains e_{11} and e_{22} represent stretching and the strains $e_{12} = e_{21}$ represent a change in angle between the two filaments; the ends of the filaments move toward one another over a distance $e_{12} = e_{21}$.

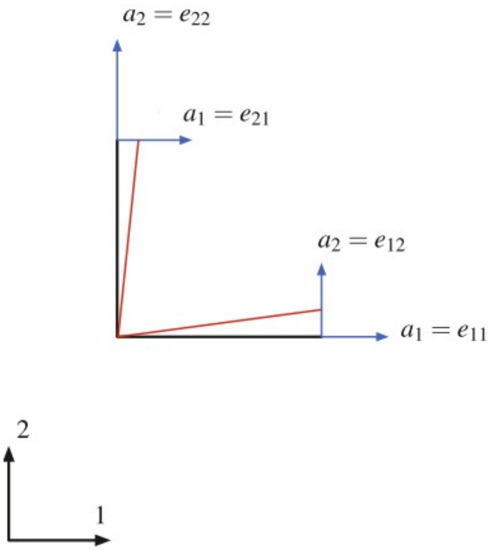


Figure 5.7: Strains in the 1,2 plane

The rotation tensor ω_{ij} represents the anti-symmetrical part of the displacement gradient tensor:

$$\omega_{ij} = \tfrac{1}{2}(\partial_i u_j - \partial_j u_i). \tag{5.95}$$

We use the relationship between the epsilon and delta tensors, (3.75) to write

$$\omega_{ij} = \tfrac{1}{2}(\partial_i u_j - \partial_j u_i) = \tfrac{1}{2}(\delta_{ip}\delta_{jq} - \delta_{iq}\delta_{jp})\partial_p u_q = \tfrac{1}{2}\varepsilon_{mij}\varepsilon_{mpq}\partial_p u_q = \tfrac{1}{2}\varepsilon_{mij}C_m, \tag{5.96}$$

where C_m is the curl of the displacement vector. It follows that the rotation tensor is fully defined by three components in three dimensions.

For the two-dimensional case, i and j range from 1 to 2 and the only non-zero component in (5.96) exists for $m = 3$,

$$\omega_{ij} = \tfrac{1}{2}\varepsilon_{3ij}C_3. \tag{5.97}$$

The rotation tensor in two dimensions is fully defined by a single scalar, ω, where $\omega = \frac{1}{2}C_3$, so that (5.96) reduces to

$$\omega_{ij} = \omega\varepsilon_{3ij}. \tag{5.98}$$

We demonstrate the effect of the rotation tensor ω_{ij} as for the strain tensor, by considering two orthogonal filaments. We obtain the following for the displacement vector:

$$\begin{aligned} v_i &= \delta_{1i} \qquad a_j = \omega_{ij}v_i = \omega_{ij}\delta_{1i} = \omega_{1j} = \tfrac{1}{2}\varepsilon_{31j}\omega_3 = (0, \omega) \\ v_i &= \delta_{2i} \qquad a_j = \omega_{ij}v_i = \omega_{ij}\delta_{2i} = \omega_{2j} = \tfrac{1}{2}\varepsilon_{32j}\omega_3 = (-\omega, 0), \end{aligned} \tag{5.99}$$

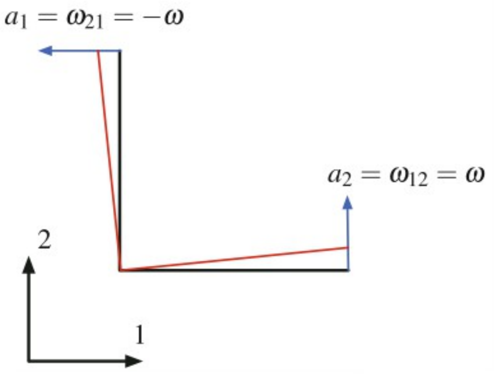

Figure 5.8: Rotation in the 1,2 plane.

or:

$$\begin{aligned}\omega_{ij} &= \tfrac{1}{2}\varepsilon_{1ij}C_1 + \tfrac{1}{2}\varepsilon_{2ij}C_2 + \tfrac{1}{2}\varepsilon_{3ij}C_3\\ \omega_{12} &= \tfrac{1}{2}\varepsilon_{312}C_3 = \tfrac{1}{2}C_3 = \omega\\ \omega_{21} &= \tfrac{1}{2}\varepsilon_{321}C_3 = -\tfrac{1}{2}C_3 = -\omega,\end{aligned} \tag{5.100}$$

The rotation tensor indeed represents true rotation, but only in an incremental sense; this is true only for small displacement gradients. That the rotation tensor represents pure rotation is in accordance with (5.96); the displacement vector is:

$$a_j = \omega_{ij}v_i = \tfrac{1}{2}\varepsilon_{mij}v_iC_m. \tag{5.101}$$

The vector a_i is the cross product of the vector v_i, which points in the direction of the filament, and the curl of the displacement vector; for the two-dimensional case, illustrated in Figure 5.8, the curl points in the 3-direction, the displacement is normal to v_i, and is always oriented the same way with respect to v_i.

As for the stress tensor, the first invariant of the strain tensor plays a special role in stress-strain relationships, for example in the theory of linear elasticity, discussed in Section 9.5. The first invariant e_{ii} is the volume strain

$$e_{ii} = \partial_i u_i, \tag{5.102}$$

which is the divergence of the displacement vector.

5.6 Integrability; The Compatibility Conditions

We consider a vector or tensor that is defined as the gradient of a scalar or a tensor of lower rank. It is generally not true that integration of the higher order tensor yields the lower order scalar or tensor, from which it was derived. This follows from the notion that the derived quantity has a greater number of components than the original one;

degrees of freedom have been added and these degrees of freedom must be subjected to constraints in order to make them compatible with the fewer number of degrees of freedom of the original quantity.

5.6.1 The Gradient of a Scalar

The conditions of integrability of a vector, defined as the gradient of a scalar,

$$v_i = -\partial_i \Phi, \tag{5.103}$$

are that the vector field is irrotational:

$$C_i = \varepsilon_{ijk}\partial_j v_k = \varepsilon_{ijk}\partial_j\partial_k \Phi = 0. \tag{5.104}$$

The three homogeneous equations (5.104), which the three components of v_i must satisfy, are sufficient to guarantee that equations (5.103) are integrable.

5.6.2 The Gradient of a Vector

A similar case applies if a tensor, for example the strain tensor e_{ij}, is derived from the gradient of a vector field. We obtain the integrability conditions as for the case of a vector. We first consider the definition of the displacement gradient tensor, in terms of the displacement vector u_i,

$$\alpha_{km} = \partial_k u_m. \tag{5.105}$$

Integrability of these equations requires that

$$\varepsilon_{ijk}\partial_j \alpha_{km} = \varepsilon_{ijk}\partial_j\partial_k u_m = 0. \tag{5.106}$$

We obtain the integrability conditions for the strains by using the definitions of the strain and rotation tensors:

$$\varepsilon_{ijk}\partial_j \alpha_{km} = \varepsilon_{ijk}\partial_j e_{km} + \varepsilon_{ijk}\partial_j \omega_{km}. \tag{5.107}$$

We use (5.96) to rewrite the trailing term as

$$\varepsilon_{ijk}\partial_j \omega_{km} = \tfrac{1}{2}\varepsilon_{ijk}\varepsilon_{kmn}\partial_j C_n = \tfrac{1}{2}(\delta_{im}\delta_{jn} - \delta_{in}\delta_{jm})\partial_j C_n = \tfrac{1}{2}\delta_{im}\partial_j C_j - \tfrac{1}{2}\partial_m C_i, \tag{5.108}$$

where C_n is the curl,

$$C_n = \varepsilon_{npq}\partial_p u_q. \tag{5.109}$$

The curl is divergence-free, as is seen from (5.109) by taking the divergence, so that (5.108) reduces to

$$\varepsilon_{ijk}\partial_j \omega_{km} = -\tfrac{1}{2}\partial_m C_i. \tag{5.110}$$

We combine (5.107) with (5.110),

$$\varepsilon_{ijk}\partial_j \alpha_{km} = \varepsilon_{ijk}\partial_j e_{km} - \tfrac{1}{2}\partial_m C_i. \tag{5.111}$$

These equations represent nine conditions for the six independent components of the strain tensor and the three components of the curl; we eliminate the curl in what follows.

Equation (5.111) represents a tensor with free indices i and m, which we call A_{im} and take the curl, $\varepsilon_{pnm}\partial_n A_{im}$, which gives:

$$\varepsilon_{pnm}\partial_n A_{im} = \varepsilon_{pnm}\varepsilon_{ijk}\partial_j\partial_n \alpha_{km} = \varepsilon_{ijk}\varepsilon_{pnm}\partial_j\partial_n\partial_k u_m = 0, \tag{5.112}$$

because $\partial_j\partial_k = \partial_k\partial_j$. We replace A_{im} by (5.111),

$$\varepsilon_{pnm}\partial A_{im} = \varepsilon_{pnm}\varepsilon_{ijk}\partial_n\partial_j\varepsilon_{km} - \tfrac{1}{2}\varepsilon_{pnm}\partial_m\partial_n C_i = 0, \tag{5.113}$$

so that:

$$\varepsilon_{pnm}\varepsilon_{ijk}\partial_n\partial_j e_{km} = \tfrac{1}{2}\varepsilon_{pnm}\partial_m\partial_n C_i = 0. \tag{5.114}$$

These equations are the nine integrability conditions that must be imposed on the components of the strain tensor. If these conditions are met, integration of the strains produces a set of unique displacements. Three of the nine equations occur twice as a result of the symmetry of both the operators $\partial_i\partial_j$ and the strain tensor e_{ij}. We demonstrate that equations (5.114) are symmetrical in terms of the indices p and i by contracting with ε_{piq} and showing that the result is zero:

$$\begin{aligned}\varepsilon_{piq}\varepsilon_{pmn}\varepsilon_{ijk}\partial_n\partial_j e_{km} &= (\delta_{im}\delta_{qn} - \delta_{in}\delta_{qm})\varepsilon_{ijk}\partial_n\partial_j e_{km} \\ &= \varepsilon_{mjk}\partial_q\partial_j e_{km} - \varepsilon_{ijk}\partial_i\partial_j e_{kq}\end{aligned} \tag{5.115}$$

This represents three equations, one for each of the three possible values of q. The first term is zero because of the symmetry of e_{km} and the second term is zero because of the symmetry of $\partial_i\partial_j$, so that

$$\varepsilon_{piq}\varepsilon_{pmn}\varepsilon_{ijk}\partial_n\partial_j e_{km} = 0. \tag{5.116}$$

The equations obtained from (5.114) are thus indeed symmetrical in terms of the indices i and p. The nine equations (5.114) for the strain tensor components,

$$\varepsilon_{pmn}\varepsilon_{ijk}\partial_n\partial_j e_{km} = 0, \tag{5.117}$$

reduce to the six independent ones, obtained by letting p and i assume the following values:

$$\begin{array}{ll} p = 1 & i = 1, 2, 3 \\ p = 2 & i = 2, 3 \\ p = 3 & i = 3. \end{array} \tag{5.118}$$

These equations are the compatibility conditions for the strain tensor for small displacement gradients.

Problem 5.3

Work out the compatibility equations for plane strain (i.e., for the case that $e_{m3} = 0, m = 1, 2, 3$.

Problem 5.4

Work out the six compatibility equations in terms of $(x, y, z) \equiv x_i$ and compare your result with the equations as found in the literature.

5.7 The Velocity Gradient Tensor

The velocity gradient tensor plays a role in fluids similar to that of the displacement gradient tensor for solids. The velocity gradient tensor is:

$$\dot{\alpha}_{ij} = \partial_i v_j, \tag{5.119}$$

where v_j is the velocity. As for the displacements, we separate the velocity gradient tensor into its symmetrical and anti-symmetrical parts:

$$\dot{\alpha}_{ij} = \tfrac{1}{2}(\dot{\alpha}_{ij} + \dot{\alpha}_{ji}) + \tfrac{1}{2}(\dot{\alpha}_{ij} - \dot{\alpha}_{ji}). \tag{5.120}$$

The symmetrical part is $\dot{e}_{ij}$:

$$\dot{e}_{ij} = \tfrac{1}{2}(\partial_i v_j + \partial_j v_i). \tag{5.121}$$

The anti-symmetrical part is (compare (5.96))

$$\dot{\omega}_{ij} = \tfrac{1}{2}(\partial_i v_j - \partial_j v_i) = \varepsilon_{ijm} C_m, \tag{5.122}$$

where C_m is the curl. The divergence of the velocity field plays a role similar to that of the volume strain for the displacement gradient and is sometimes represented as D

$$D = \partial_i v_i. \tag{5.123}$$

Coordinate Transformations:

data 18 04 2020

Definition of Vectors and Tensors

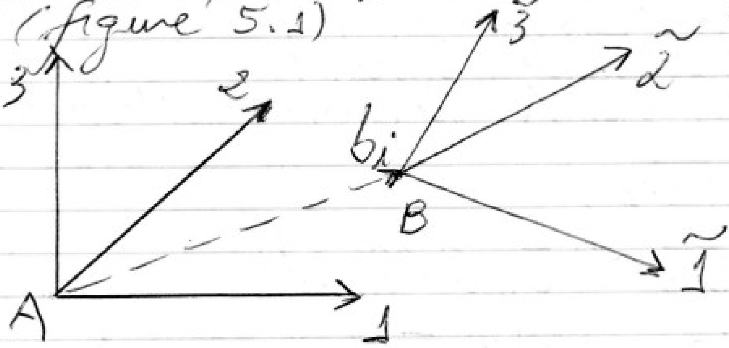
Figure 5.1 Coordinate Transformation

Transformation of Cartesian A into Cartesian System B.

We consider a Cartesian B with coordinate axes ($\tilde{1}, \tilde{2}, \tilde{3}$), representing a point in this system as $\tilde{x}_i$.

The origin of B in terms of the original coordinate system A (1, 2, 3) is given by the coordinates b_i.

(figure 5.1)



Both coordinate system are Cartesian, and the scales in both systems are the same

the vectors $\underset{m}{\tau}^i$, defined as

$$\underset{m}{\tau}^i = \frac{\partial x_1}{\partial \tilde{x}_m} \quad i = 1, 2, 3 \quad m = 1, 2, 3$$

are unit vectors tangent to the coordinate directions $\tilde{i}$ (compare (2.5))

data 18 04 2020

with $\tilde{x}_m$ replacing the arc length along the curve, s.

We define similar vectors that are tangent to the coordinates in system A in terms of the coordinates in system B.

We call these unit tangent vectors $\overset{m}{\underset{i}{\gamma}}$:

$$\overset{m}{\underset{i}{\gamma}} = \frac{\partial \tilde{x}_m}{\partial x_i}$$

We express the original coordinates of a point x_i in terms of the new coordinates of that same point and vice-versa by integrating the latter two equations:

$$x_i = \overset{i}{\underset{m}{\tau}} \tilde{x}_m + b_i,$$

where b_i represents the origin of B in terms of x_i, and

$$\tilde{x}_m = \overset{m}{\underset{i}{\gamma}} x_i + \tilde{b}_m,$$

where $\tilde{b}_m$ represents the origin of the original system A in terms of the new coordinates.

data 18.04.2020

The vectors $\underset{m}{\tau}^i$ are mutually orthogonal unit vectors,

$$\underset{m}{\tau}^i \underset{n}{\tau}^i = \delta_{mn}.$$

A similar equation holds for unit vectors $\overset{m}{\gamma}_i$,

$$\overset{m}{\gamma}_i \overset{n}{\gamma}_i = \delta_{mn}.$$

We obtain a relationship between vectors $\underset{m}{\tau}^i$ and $\overset{m}{\gamma}_i$ from (5.1) and (5.2)

$$\underset{m}{\tau}^i \overset{n}{\gamma}_i = \frac{\partial x_i}{\partial \tilde{x}_m} \frac{\partial \tilde{x}_n}{\partial x_i} = \frac{\partial \tilde{x}_n}{\partial \tilde{x}_m} = \delta_{mn}$$

The moduli of $\underset{m}{\tau}^i$ and of $\overset{m}{\gamma}_i$ are 1;

we combine this with the latter equation:

$$\underset{m}{\tau}^i = \overset{m}{\gamma}_i.$$

We introduce a matrix a_{ij},

landaia

18.04.2020
8

$$a_{im} = \tau^{i}_{m} = \gamma^{m}_{i} = \frac{\partial x_i}{\partial x_m} = \frac{\partial \tilde{x}_m}{\partial x_i}$$

and write (5.3) and (5.4) as

$$x_i = a_{ij}\tilde{x}_j + b_i,$$

and

$$\tilde{x}_i = a_{ji}x_j + \tilde{b}_i.$$

We observe from (5.9) that

$$a_{im}a_{in} = \frac{\partial x_i}{\partial \tilde{x}_m}\frac{\partial \tilde{x}_n}{\partial x_i} = \delta_{mn},$$

and that

$$a_{im}a_{jm} = \frac{\partial \tilde{x}_m}{\partial x_i}\frac{\partial x_j}{\partial \tilde{x}_m} = \delta_{ij}.$$

1.2.3 Types of Coordinates Systems.

vectors are given by (5.31) and (5.32) on page 55,

$$\underset{m}{\tau}^k = \frac{\partial x_k}{\partial \tilde{x}_m} \tag{8.39}$$

$$\overset{m}{\gamma}_k = \frac{\partial \tilde{x}_m}{\partial x_k}, \tag{8.40}$$

where

$$\tilde{x}_m = (\bar{z}, z) \qquad x_m = (x, y). \tag{8.41}$$

The covariant base vectors are

$$\overset{1}{\gamma}_k = \frac{\partial \tilde{x}_1}{\partial x_i} = \left(\frac{\partial \bar{z}}{\partial x}, \frac{\partial \bar{z}}{\partial y} \right) = (1, -\mathrm{i}) \tag{8.42}$$

$$\overset{2}{\gamma}_k = \frac{\partial \tilde{x}_2}{\partial x_i} = \left(\frac{\partial z}{\partial x}, \frac{\partial z}{\partial y} \right) = (1, \mathrm{i}). \tag{8.43}$$

The second base vector $\overset{2}{\gamma}_k$ is related to the first base vector $\overset{1}{\gamma}_k$; it is the complex conjugate of $\overset{1}{\gamma}_k$,

$$\overset{2}{\gamma}_k = \overline{\overset{1}{\gamma}}_k. \tag{8.44}$$

We obtain similar expressions for the contravariant base vectors

$$\underset{1}{\tau}^m = \frac{\partial x_m}{\partial \tilde{x}_1} = \left(\frac{\partial x}{\partial \bar{z}}, \frac{\partial y}{\partial \bar{z}} \right) = \tfrac{1}{2}(1, \mathrm{i}) \tag{8.45}$$

$$\underset{2}{\tau}^k = \frac{\partial x_m}{\partial \tilde{x}_2} = \left(\frac{\partial x}{\partial z}, \frac{\partial y}{\partial z} \right) = \tfrac{1}{2}(1, -\mathrm{i}). \tag{8.46}$$

As for the covariant bases, the second contravariant base vector is the complex conjugate of the first one:

$$\underset{2}{\tau}^k = \overline{\underset{1}{\tau}^k}. \tag{8.47}$$

The covariant and contravariant base vectors are related:

$$\overset{m}{\gamma}_k = 2\overline{\underset{m}{\tau}^k}. \tag{8.48}$$

8.3.2 Transformation of Vectors

We use the expressions for the base vectors to transform vectors and tensors. We obtain the contravariant components from

$$\tilde{v}^1 = \overset{1}{\gamma}_j v_j = v_1 - \mathrm{i} v_2 \tag{8.49}$$

$$\tilde{v}^2 = \overset{2}{\gamma}_j v_j = v_1 + \mathrm{i} v_2, \tag{8.50}$$

and observe that, as for the independent variables $\bar{z}$ and z, the one component is the complex conjugate of the other. We use a single symbol, w, to represent both

$$w = \tilde{v}^1 = v_x - \mathrm{i}v_y \tag{8.51}$$

$$\bar{w} = \tilde{v}^2 = v_x + \mathrm{i}v_y, \tag{8.52}$$

and find the expressions for the covariant components of a vector in a similar fashion,

$$\tilde{v}_1 = \underset{1}{\tau}{}^j v_j = \tfrac{1}{2}(v_x + \mathrm{i}v_y) = \tfrac{1}{2}\overline{w} \tag{8.53}$$

$$\tilde{v}_2 = \underset{2}{\tau}{}^j v_j = \tfrac{1}{2}(v_x - \mathrm{i}v_y) = \tfrac{1}{2}w. \tag{8.54}$$

The modules of the vector, $v_i v_i$, is an invariant, which transforms as

$$v_i v_i = \tilde{v}_k \tilde{v}^k = \tfrac{1}{2}w\overline{w} + \tfrac{1}{2}w\overline{w} = w\overline{w}, \tag{8.55}$$

which indeed equals $v_x^2 + v_y^2$ as follows from (8.51). The differential operator is a covariant vector;

$$\tilde{\partial}_m = \left(\frac{\partial}{\partial \bar{z}}, \frac{\partial}{\partial z}\right), \tag{8.56}$$

and its contravariant components are:

$$\tilde{\partial}^m = 2\left(\frac{\partial}{\partial z}, \frac{\partial}{\partial \bar{z}}\right). \tag{8.57}$$

As for non-Cartesian coordinate systems, the natural way to write the gradient of a scalar function is in terms of its covariant components,

$$\frac{\partial F}{\partial \bar{z}} = \tfrac{1}{2}\left(\frac{\partial F}{\partial x} + \mathrm{i}\frac{\partial F}{\partial y}\right) \tag{8.58}$$

$$\frac{\partial F}{\partial z} = \tfrac{1}{2}\left(\frac{\partial F}{\partial x} - \mathrm{i}\frac{\partial F}{\partial y}\right). \tag{8.59}$$

We are now in a position to transform the divergence of the velocity vector v_i by contracting the covariant components of the gradient with the contravariant components of the velocity vector; this is necessary to obtain the invariant, i.e., to write an expression in terms of the new coordinates in such a way that it is equivalent to the corresponding one in the Cartesian system,

$$\partial_j v_j = \tilde{\partial}_j \tilde{v}^j = \frac{\partial w}{\partial \bar{z}} + \frac{\partial \bar{w}}{\partial z} = -\gamma. \tag{8.60}$$

8.3.3 Transformation of Tensors

We transform a tensor A_{mn} into a purely contravariant tensor:

$$\tilde{A}^{pq} = \overset{p}{\gamma}_m \overset{q}{\gamma}_n A_{mn}. \tag{8.61}$$

There are only two independent components of a tensor of the second rank; the component $\tilde{A}^{21}$ is the complex conjugate of the component $\tilde{A}^{12}$; we apply (8.44):

$$\tilde{A}^{21} = \overset{2}{\gamma}_m \overset{1}{\gamma}_n A_{mn} = \overline{\overset{1}{\gamma}_m \overset{2}{\gamma}_n} A_{mn} = \overline{\tilde{A}^{12}}. \tag{8.62}$$

The component $\tilde{A}^{22}$ is the complex conjugate of $\tilde{A}^{11}$:

$$\tilde{A}^{22} = \overset{2}{\gamma}_m \overset{2}{\gamma}_n A_{mn} = \overline{\overset{1}{\gamma}_m \overset{1}{\gamma}_n} A_{mn} = \overline{\tilde{A}^{11}}. \tag{8.63}$$

The purely covariant tensor components are related to the contravariant ones; we use (8.48),

$$\tilde{A}_{mn} = \underset{m}{\tau}^p \underset{n}{\tau}^q A_{pq} = \tfrac{1}{4} \overline{\overset{m}{\gamma}_p \overset{n}{\gamma}_q} A_{pq} = \tfrac{1}{4} \overline{\tilde{A}^{mn}}. \tag{8.64}$$

We obtain similar relations between the mixed transformed tensor components

$$\tilde{A}^m{}_n = \overset{m}{\gamma}_p \underset{n}{\tau}^q A_{pq} = \overline{\underset{m}{\tau}^p \overset{n}{\gamma}_q} A_{pq} = \overline{\tilde{A}_m{}^n}. \tag{8.65}$$

Only two independent tensor components exist, $\tilde{A}^{11}$ and $\tilde{A}^{12}$; we obtain all the other ones from these two by applying equations (8.61) through (8.65).

Problem 8.1
Demonstrate that $\tilde{A}^1{}_1 = \tilde{A}_{21}$ and $\tilde{A}^1{}_2 = \tilde{A}_{22}$.

8.3.4 A Combined Kronecker Delta and Alternating Tensor: The Combination Matrix

Working in complex space with vectorial properties such as divergence and curl, requires that the Kronecker delta and the epsilon tensor be transformed. There are four possible choices for each tensor; we begin by obtaining the transformed tensor $\tilde{\delta}^m{}_n$. Application of the transformation rule gives

$$\tilde{\delta}^m{}_n = \overset{m}{\gamma}_j \underset{n}{\tau}^k \delta_{jk} = \overset{m}{\gamma}_j \underset{n}{\tau}^j = \delta_{mn}. \tag{8.66}$$

We find, similarly

$$\tilde{\delta}_m{}^n = \underset{m}{\tau}^j \overset{n}{\gamma}_k \delta_{jk} = \underset{m}{\tau}^j \overset{n}{\gamma}_j = \delta_{mn}. \tag{8.67}$$

The transformed Kronecker delta with both components contravariant becomes

$$\tilde{\delta}^{mn} = \overset{m}{\gamma}_k \overset{n}{\gamma}_j \delta_{ij} = \overset{m}{\gamma}_k \overset{n}{\gamma}_k = g^{mn} = \begin{pmatrix} 0 & 2 \\ 2 & 0 \end{pmatrix}, \tag{8.68}$$

and with both components covariant:

$$\tilde{\delta}_{mn} = \underset{m}{\tau}^k \underset{n}{\tau}^j \delta_{ij} = \underset{m}{\tau}^j \underset{n}{\tau}^j = g_{mn} = \begin{pmatrix} 0 & \frac{1}{2} \\ \frac{1}{2} & 0 \end{pmatrix}. \tag{8.69}$$

The transformed Kronecker delta is called the metric tensor; the metric tensor equals the Kronecker delta for the case of mixed covariant/contravariant components.

We transform the epsilon tensor in a similar manner. Again, there are four possible combinations; we consider them in the same sequence as for the Kronecker delta. We obtain for $\tilde{\varepsilon}^m{}_n$

$$\tilde{\varepsilon}^m{}_n = \overset{m}{\gamma}_j \underset{n}{\tau}^k \varepsilon_{jk}. \tag{8.70}$$

The individual components are:

$$\begin{aligned} \tilde{\varepsilon}^1{}_1 &= \overset{1}{\gamma}_1 \underset{1}{\tau}^2 - \overset{1}{\gamma}_2 \underset{1}{\tau}^1 = \mathrm{i}/2 - (-\mathrm{i})/2 = \mathrm{i} \\ \tilde{\varepsilon}^1{}_2 &= \overset{1}{\gamma}_1 \underset{2}{\tau}^2 - \overset{1}{\gamma}_2 \underset{2}{\tau}^1 = -\frac{1}{2}\mathrm{i} + \frac{1}{2}\mathrm{i} = 0 \\ \tilde{\varepsilon}^2{}_2 &= \overline{\tilde{\varepsilon}^1{}_1} = -\mathrm{i}. \end{aligned} \tag{8.71}$$

or

$$\tilde{\varepsilon}^m{}_n = \begin{pmatrix} \mathrm{i} & 0 \\ 0 & -\mathrm{i} \end{pmatrix}. \tag{8.72}$$

We obtain the components of $\tilde{\varepsilon}_m{}^n$ similarly:

$$\tilde{\varepsilon}_m{}^n = \underset{m}{\tau}^j \overset{n}{\gamma}_k \varepsilon_{jk} = \overline{\tilde{\varepsilon}^m{}_n}, \tag{8.73}$$

which gives

$$\begin{aligned} \tilde{\varepsilon}_1{}^1 &= -\mathrm{i}/2 + (-\mathrm{i})/2 = -\mathrm{i} \\ \tilde{\varepsilon}_1{}^2 &= \tilde{\varepsilon}_2{}^1 = 0 \\ \tilde{\varepsilon}_2{}^2 &= \mathrm{i}, \end{aligned} \tag{8.74}$$

or

$$\tilde{\varepsilon}^n{}_m = \begin{pmatrix} -\mathrm{i} & 0 \\ 0 & \mathrm{i} \end{pmatrix}. \tag{8.75}$$

The purely covariant components of the epsilon tensor are

$$\tilde{\varepsilon}_{mn} = \underset{m}{\tau}^i \underset{n}{\tau}^j \varepsilon_{ij}, \tag{8.76}$$

which gives

$$\begin{aligned} \tilde{\varepsilon}_{11} &= \overline{\tilde{\varepsilon}_{22}} = \underset{1}{\tau}^1 \underset{1}{\tau}^2 - \underset{1}{\tau}^2 \underset{2}{\tau}^1 = 0 \\ \tilde{\varepsilon}_{12} &= \underset{1}{\tau}^1 \underset{2}{\tau}^2 - \underset{1}{\tau}^2 \underset{2}{\tau}^1 = -\frac{1}{4}\mathrm{i} - \frac{1}{4}\mathrm{i} = -\mathrm{i}/2 \\ \tilde{\varepsilon}_{21} &= \overline{\tilde{\varepsilon}_{12}} = \mathrm{i}/2, \end{aligned} \tag{8.77}$$

or

$$\tilde{\varepsilon}_{mn} = \begin{pmatrix} 0 & -\mathrm{i}/2 \\ \mathrm{i}/2 & 0 \end{pmatrix}. \tag{8.78}$$

The purely contravariant components $\tilde{\varepsilon}^{mn}$ are:

$$\tilde{\varepsilon}^{mn} = \overset{m}{\gamma}_k \overset{n}{\gamma}_j \varepsilon_{ij} = 4\overline{\tilde{\varepsilon}_{mn}}, \tag{8.79}$$

which gives

$$\begin{aligned} \tilde{\varepsilon}^{11} &= \tilde{\varepsilon}^{22} = 0 \\ \tilde{\varepsilon}^{12} &= 2\mathrm{i} \\ \tilde{\varepsilon}^{21} &= -2\mathrm{i}, \end{aligned} \tag{8.80}$$

or

$$\tilde{\varepsilon}^{mn} = \begin{pmatrix} 0 & 2\mathrm{i} \\ -2\mathrm{i} & 0 \end{pmatrix}. \tag{8.81}$$

The Combination Matrix

We construct a useful matrix by combining the Kronecker delta and the epsilon tensor, which we call the combination matrix. There are two possible representations for this matrix in Cartesian space, κ_{mn} and K_{mn}, that we define as:

$$\kappa_{mn} = \delta_{mn} - \mathrm{i}\varepsilon_{mn}, \tag{8.82}$$

and

$$K_{mn} = \delta_{mn} + \mathrm{i}\varepsilon_{mn} = \bar{\kappa}_{mn}. \tag{8.83}$$

We add to the transformed Kronecker delta the corresponding epsilon tensor times i for κ and $-\mathrm{i}$ for K. The mixed contravariant/covariant components are

$$\tilde{\kappa}^{m}{}_{n} = \begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix} \qquad \tilde{K}^{m}{}_{n} = \begin{pmatrix} 0 & 0 \\ 0 & 2 \end{pmatrix}, \tag{8.84}$$

the mixed covariant/contravariant ones are

$$\tilde{\kappa}_{m}{}^{n} = \begin{pmatrix} 0 & 0 \\ 0 & 2 \end{pmatrix} \qquad \tilde{K}_{m}{}^{n} = \begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix}, \tag{8.85}$$

and the purely contravariant components are

$$\tilde{\kappa}^{mn} = \begin{pmatrix} 0 & 4 \\ 0 & 0 \end{pmatrix} \qquad \tilde{K}^{mn} = \begin{pmatrix} 0 & 0 \\ 4 & 0 \end{pmatrix}. \tag{8.86}$$

The components, finally, of the purely covariant components are

$$\tilde{\kappa}_{mn} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \qquad \tilde{K}_{mn} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}. \tag{8.87}$$

The combination matrices are not tensors; they do not obey the transformation rules (8.62) through (8.65), even though δ_{ij} and ε_{ij} do.

$ (' %'& !96 : : !

Questions:

- Determine the function w that has the divergence and curl given by ω.
- Determine the areal integral of ω over area $\mathscr{A}$ by integration.
- Determine the same integral, but now by applying (8.114).
- Determine the tangential and normal components of w along $\mathscr{C}$.

8.4 Irrotational and Divergence-Free Vector Fields

If the vector field is both irrotational and divergence-free, (8.23) reduces to

$$\frac{\partial w}{\partial \bar{z}} = 0, \tag{8.125}$$

so that w is a function of z only, i.e.,

$$w = w(z). \tag{8.126}$$

Because the flow is both irrotational and divergence-free, we can represent the complex velocity function either as the gradient of a real potential, or as the curl of a real scalar stream function. If we express w in terms of a velocity potential, we write the gradient of the potential in terms of derivatives with respect to the complex variables z and $\bar{z}$

$$\begin{aligned} w = v_x - \mathrm{i}v_y = -\left[\frac{\partial \Phi}{\partial x} - \mathrm{i}\frac{\partial \Phi}{\partial y}\right] = - & \left[\frac{\partial \Phi}{\partial z}\frac{\partial z}{\partial x} + \frac{\partial \Phi}{\partial \bar{z}}\frac{\partial \bar{z}}{\partial x}\right] \\ & + \mathrm{i}\left[\frac{\partial \Phi}{\partial z}\frac{\partial z}{\partial y} + \frac{\partial \Phi}{\partial \bar{z}}\frac{\partial \bar{z}}{\partial y}\right], \end{aligned} \tag{8.127}$$

or, with $\partial z/\partial x = 1, \partial z/\partial y = \mathrm{i}$ and $\partial \bar{z}/\partial x = 1, \partial \bar{z}/\partial y = -\mathrm{i}$

$$w = -2\frac{\partial \Phi}{\partial z}. \tag{8.128}$$

As an alternative, we write the velocity vector as minus the curl of a scalar stream function,

$$v_k = -\varepsilon_{ij}\partial_j \Psi, \tag{8.129}$$

so that

$$w = v_x - \mathrm{i}v_y = -\frac{\partial \Psi}{\partial y} - \mathrm{i}\frac{\partial \Psi}{\partial x} = -\mathrm{i}\left[\frac{\partial \Psi}{\partial x} - \mathrm{i}\frac{\partial \Psi}{\partial y}\right]. \tag{8.130}$$

Comparing the latter equation with (8.127) and (8.128), we see that we may express w in terms of the derivative of Ψ with respect to z,

$$w = -2\mathrm{i}\frac{\partial \Psi}{\partial z}. \tag{8.131}$$

The representations of w in terms of the derivatives of Φ and Ψ with respect to z gives us several possibilities to represent w:

$$w = w(z) = -2\frac{\partial\Phi}{\partial z} = -2\mathrm{i}\frac{\partial\Psi}{\partial z} = -\left(\frac{\partial\Phi}{\partial z} + \mathrm{i}\frac{\partial\Psi}{\partial z}\right). \tag{8.132}$$

The final expression in the latter equation distributes the contribution to w equally between a real potential and a real stream function. We observe from the third and fourth expressions in the latter equation that

$$\frac{\partial\Phi}{\partial z} = \mathrm{i}\frac{\partial\Psi}{\partial z}, \tag{8.133}$$

and take the complex conjugate of both sides of this equation. The real functions Φ and Ψ are not affected, but i changes to $-\mathrm{i}$ and z to $\bar{z}$:

$$\frac{\partial\Phi}{\partial\bar{z}} = -\mathrm{i}\frac{\partial\Psi}{\partial\bar{z}}. \tag{8.134}$$

Equations (8.133) and (8.134) are equivalent complex forms of the Cauchy-Riemann equations; the latter equations are obtained in real form by separating the real and imaginary parts of these equations; both equations lead to the same two real equations:

$$\begin{aligned}\frac{\partial\Phi}{\partial x} &= \frac{\partial\Psi}{\partial y}\\ \frac{\partial\Phi}{\partial y} &= -\frac{\partial\Psi}{\partial x}.\end{aligned} \tag{8.135}$$

Integration of (8.134) with respect to $\bar{z}$ gives

$$\Phi + \mathrm{i}\Psi = f(z), \tag{8.136}$$

where $f(z)$ is a function of z only, which we call the complex potential and represent by the letter Ω,

$$\Omega = \Omega(z) = \Phi + \mathrm{i}\Psi. \tag{8.137}$$

We represent w as minus the derivative with respect to z of this complex potential:

$$w = -\frac{d\Omega}{dz}. \tag{8.138}$$

This is an ordinary derivative; Ω is a function of z only, in contrast to both the potential Φ and the stream function Ψ, which are real functions and must be functions of both z and $\bar{z}$.

We observe from (8.135) that the gradients of the velocity potential and the stream function are mutually orthogonal; their dot product is zero. Since the gradient of the velocity potential is parallel to the velocity, the gradient of the stream function is at right angles to the flow. Both the contours $\Psi = const$ and the velocity are normal to the gradient of the stream function; the velocity vector must be tangent to the contours $\Psi = const$.

8.4.1 Summary

The real and imaginary parts of a complex potential $\Omega(z)$, which is a function of z only, i.e., does not contain $\bar{z}$ in its expression, produces a complex derivative $d\Omega/dz$, which is minus the complex form of a velocity field, w. This velocity field is both divergence-free and irrotational. The real and imaginary parts of the complex potential are harmonic functions, i.e., they satisfy Laplace's equation, as follows from (8.95) and (8.102).

8.5 Functions of a Single Complex Variable

Functions of a single complex variable that can be differentiated an infinite number of times in a certain region are called *analytic* or *holomorphic* inside that region. We use the term holomorphic to identify this property for functions of a single complex variable; we use the term analytic if the function depends on both z and $\bar{z}$ and can be differentiated an infinite number of times with respect to either of the independent variables z and $\bar{z}$. Note that we call these variables independent, which they are only in the strict sense of a coordinate transformation; the special property of the number i, however, makes it possible to determine the second variable once the first is known.

We allow the divergence to be non-zero at isolated points and along lines, and possibly inside isolated domains in the area considered. In such cases the stream function cannot be single-valued, and will be singular at isolated points. For very special cases rotation may be permitted at isolated points, along lines, and in isolated domains. In this case the potential function will not be single-valued at the points or singular at isolated points. A singularity of a holomorphic function is defined as a point where the function cannot be differentiated an infinite number of times without producing an infinite value at the singular point.

Working with complex variables requires certain formulas to understand the meaning of the various forms of complex functions. We present a brief summary of such formulas below without giving formal proof of the equations; the reader is referred to the multitude of texts on this topic.

The complex variable z can be represented in terms of Cartesian coordinates (x,y) and in terms of radial coordinates (r,θ),

$$z = x + \mathrm{i}y = r(\cos\theta + \mathrm{i}\sin\theta). \tag{8.139}$$

A useful formula was developed by Euler and is obtained from the Taylor series expansion of the exponential function of $(\mathrm{i}\theta)$ about $\theta = 0$:

$$\mathrm{e}^{\mathrm{i}\theta} = 1 + \mathrm{i}\theta - \frac{\theta^2}{2!} - \mathrm{i}\frac{\theta^3}{3!} + \frac{\theta^4}{4!} + \mathrm{i}\frac{\theta^5}{5!} + \cdots . \tag{8.140}$$

We separate the real and imaginary parts:

$$\Re\mathrm{e}^{\mathrm{i}\theta} = 1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} + \cdots , \tag{8.141}$$

Similar to the 2D rectangle that was constructed, a rectangular parallelepiped is created using the 3D coordinate system by establishing coordinate values for each vertex, and then inserting the appropriate edges, as shown in Fig. 1.8.

This coordinate system is used in multiview drawings and 3D modeling, using CAD tools.

1.2.2 *Right-Hand Rule*

The right-hand rule is used to determine the positive direction of the axes; it defines the X-, Y-, and Z-axes as well as the positive and negative directions of rotation on each axis.

The simplest way to remember the right-hand rule is to first make a fist with your right hand—hence the rule name—ensuring that your thumb points upward. The direction in which your thumb points is the positive direction of the Z-axis. Now straighten your index finger so that it points straight at right angles with your thumb, thereby defining the X-axis. Finally, straighten your middle finger at right angles with both your thumb and your index finger, thereby defining the Y-axis.

It is noteworthy that, opposite to the right-hand rule, there exists a left-hand rule, which defines all of the previous axes in the same way as the right-hand rule, only *reflected*. While the left-hand rule is used in some situations to describe the coordinate axes, in this book we will only employ the conventional right-hand rule for the sake of consistency, simplicity, and while following established convention.

1.2.3 *Types of Coordinate Systems*

1.2.3.1 Polar Coordinates

Polar coordinates are used to locate points in the plane; they specify a distance ρ from a prescribed point, denoted the origin $O(0, 0)$, and an angle θ from a prescribed line, usually denoted the X-axis. Figure 1.9 shows a point P in the XY-plane, a distance ρ from the origin O, segment $\overline{OP}$ making an angle of θ with the X-axis, measured ccw[1] in the positive direction. Polar coordinates are commonly used by CAD systems to locate points because of their inherent simplicity.

The relations between polar and Cartesian coordinates are straightforward:

$$\rho = \sqrt{x^2 + y^2}, \quad \theta = \arctan(x, y) \tag{1.1a}$$

$$x = r\cos\theta, \quad y = r\sin\theta \tag{1.1b}$$

where $\arctan(x, y)$ is the *single-valued* arctan function, which returns the unique value of θ whose tangent is x/y, the correct quadrant being indicated by the sign of each x and y.

---

[1] Usual abbreviation for "counterclockwise"

Fig. 1.9 Polar coordinates

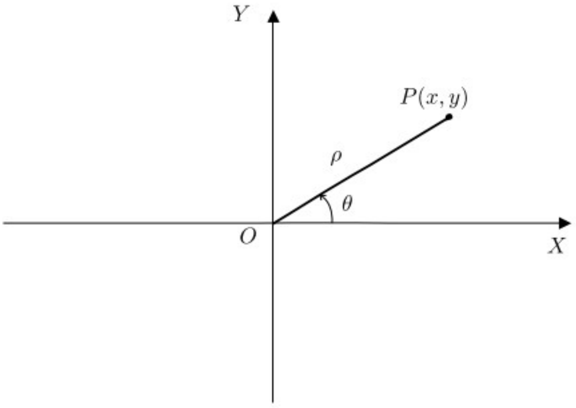

Fig. 1.10 Cylindrical coordinates

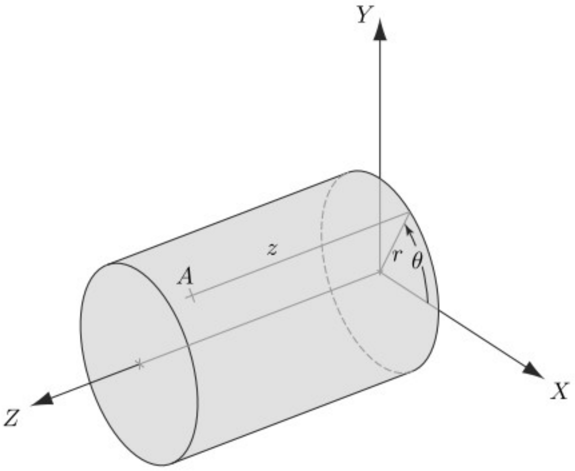

1.2.3.2 Cylindrical Coordinates

Cylindrical coordinates locate a point on the surface of a cylinder by specifying a distance from the origin and an angle from the X-axis in the XY-plane, besides the distance in the direction of Z. In Fig. 1.10, for example, point A is a distance z from the XY-plane, a distance r from the origin as measured on a line that makes an angle θ with the X-axis and lying in the XY-plane. Notice that the radius of the cylinder corresponds to the value of the cylindrical coordinate in question, with the point located on the surface of the cylinder itself.

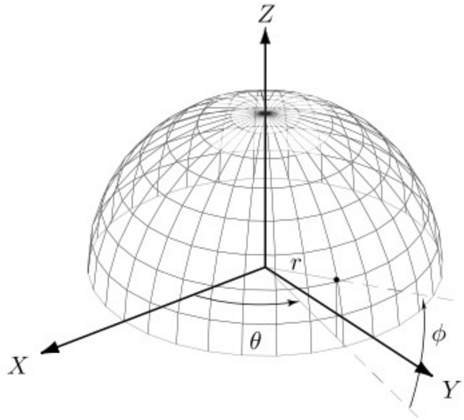

Fig. 1.11 Spherical coordinates

In general, cylindrical coordinates are used in designing axially symmetric shapes. The relations between cylindrical and Cartesian coordinates are given below:

$$r = \sqrt{x^2 + y^2}, \quad \theta = \arctan(x, y), \quad z = z \tag{1.2a}$$

$$x = r\cos\theta, \quad y = r\sin\theta, \quad z = z \tag{1.2b}$$

1.2.3.3 Spherical Coordinates

Spherical coordinates locate a point P on the surface of a sphere, as depicted in Fig. 1.11, by means of three *spherical coordinates*: the radius r of the sphere on which P lies; the *longitude* of the point, measured by angle θ; and the *latitude* of the point, measured by angle ϕ. In the figure, apparently, the X–Y plane defines the *equator*, the X–Z plane the *Greenwich meridian*.

The relations between Cartesian and spherical coordinates are readily derived from Fig. 1.11:

$$r = \sqrt{x^2 + y^2 + z^2}, \quad \phi = \arcsin\left(\frac{z}{r}\right), \quad \theta = \arccos\left(\frac{x}{\sqrt{x^2 + y^2}}\right) \tag{1.3a}$$

$$x = r\cos\phi\cos\theta, \quad y = r\cos\phi\sin\theta, z = r\sin\phi \tag{1.3b}$$

the ranges of ϕ and θ being

$$-\frac{\pi}{2} \le \phi \le \frac{\pi}{2}, \quad 0 \le \theta \le 2\pi \tag{1.3c}$$

That is, the sign of ϕ is the same as that of z, while the quadrant of θ is uniquely determined from the signs of x and y.

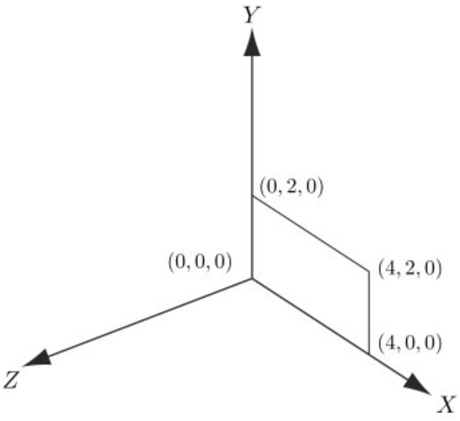

Fig. 1.12 Absolute coordinates

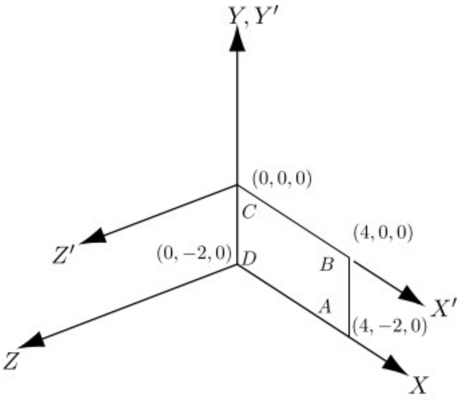

Fig. 1.13 World coordinates (x, y, x) versus relative coordinates (x', y', z')

1.2.3.4 Absolute/Relative/World Coordinate Systems

As illustrated in Fig. 1.12, *absolute coordinates* always refer to the origin (0, 0, 0).

Relative coordinates are always referenced to a previously defined location and are sometimes referred to as Δ-coordinates, as pertaining to the $\{X',\ Y',\ Z'\}$ frame, and shown in Fig. 1.13. Thus, you can have several different coordinate systems within one larger coordinate system; each object may have its own local (relative) system, but each local system is referenced to an encompassing "world" coordinate system.

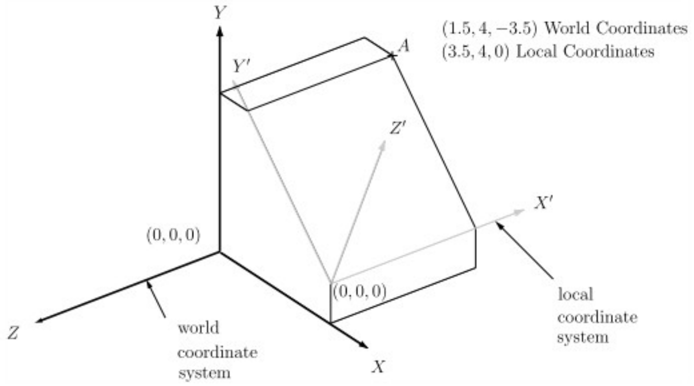

Fig. 1.14 World and local coordinates

As illustrated in Fig. 1.14, the *world coordinate system* uses a set of three numbers (x, y, z) located on three mutually perpendicular axes and measured from the origin $(0, 0, 0)$; the local coordinate system is a moving system that can be positioned anywhere in 3D space to assist in the construction of geometric objects.

1.2.4 Homogeneous Coordinates

One of the many purposes of *homogeneous coordinates* is to capture the concept of infinity. In the Euclidean coordinate system, infinity is something that does not exist. Mathematicians have discovered that many geometric concepts and computations can be greatly simplified if the concept of infinity is used. This will become apparent when we move to curve and surface design. Without the use of a homogeneous-coordinate system, it would be difficult to design certain classes of frequently used curves and surfaces in computer graphics and computer-aided design software, as well as perform transformations on these curves and surfaces. The concept of *point at infinity* is fundamental in geometry, but, as said above, difficult to represent with the aid of Euclidean geometry. *Projective geometry* comes to the rescue. In this concept, a point at infinity can be regarded as one whose distance from the observer is so large that its distance does not matter, only its *line of sight*, as in the case of stars, as far as the casual stargazer is concerned.

Any point P in the XY-plane has two coordinates. Adding a third component whose value is 1 to the coordinates of this point leads to the corresponding homogeneous coordinates. Thus, the homogeneous coordinates of any point P in the said plane, represented in the three-dimensional array $\boldsymbol{p}$, are

$$\boldsymbol{p} = \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} \tag{1.4}$$

The distance d of P from the origin is known to be $d = \sqrt{x^2 + y^2}$. If we factor d out from the $\boldsymbol{p}$ array of Eq. (1.4), we obtain

$$\boldsymbol{p} = d \begin{bmatrix} \cos\theta \\ \sin\theta \\ 1/d \end{bmatrix}, \quad \theta = \cos^{-1}\left(\frac{y}{x}\right) \tag{1.5}$$

A point P_∞ lying at infinity, with a line of sight making an angle θ with the X-axis, has the homogeneous coordinates stored in the array $\boldsymbol{p}_\infty$ given below[2]:

$$\boldsymbol{p}_\infty = \begin{bmatrix} \cos\theta \\ \sin\theta \\ 0 \end{bmatrix} \tag{1.6}$$

which results from the array of Eq. (1.5) upon letting $d \to \infty$.

Similarly, the homogeneous coordinates of a point in 3D are defined as

$$\boldsymbol{p} = \begin{bmatrix} x \\ y \\ z \\ 1 \end{bmatrix} \tag{1.7}$$

Likewise, the homogeneous coordinates of a point P_∞ lying at infinity in 3D space, with a line of sight of direction cosines (λ, μ, ν), as formally defined in Eq. (1.19), are stored in an array $\boldsymbol{p}_\infty$ given as

$$\boldsymbol{p}_\infty = \begin{bmatrix} \lambda \\ \mu \\ \nu \\ 0 \end{bmatrix} \tag{1.8}$$

Homogeneous coordinates have been traditionally used instead of ordinary Cartesian coordinates in computer graphics and geometric modeling. The representation of points in homogeneous coordinates provides a unified approach to the description of geometric transformations and allows these transformations to be represented as simple matrix operations.

---

[2] Only the array is of interest, its coefficient, d in Eq. (1.5), being left out.

($ $

We will use homogeneous coordinates in Chap. 4 when we will study *affine transformations*. As we will see, homogenous coordinates simplify (and in many cases, make possible) the mathematics needed to represent the desired transformations and manipulations.

This follows from $\boldsymbol{v} = \boldsymbol{v}_x + \boldsymbol{v}_y + \boldsymbol{v}_z$, where $\boldsymbol{v}_x = v_x \boldsymbol{i}$, $\boldsymbol{v}_y = v_y \boldsymbol{j}$, and $\boldsymbol{v}_z = v_z \boldsymbol{k}$. The same vector $\boldsymbol{v}$ can be described as a *column array*:

$$\boldsymbol{v} = \begin{bmatrix} v_x \\ v_y \\ v_z \end{bmatrix} \tag{1.11}$$

where $v_x, v_y, and v_z$ are the *components* of $\boldsymbol{v}$. The components may be negative, depending on the direction of the vector.

1.3.3 Basic Properties

1.3.3.1 Magnitude of a Vector

The magnitude of a vector, also known as the *Euclidean vector norm*, is non-negative and vanishes only when the vector itself does. The magnitude of $\boldsymbol{v}$ is thus a non-negative scalar quantity, denoted by $\|\boldsymbol{v}\|$ and given by

$$\|\boldsymbol{v}\| = \sqrt{v_x^2 + v_y^2 + v_z^2} \tag{1.12}$$

which is a simple application of the Pythagorean theorem used to find the length of the diagonal of a parallelepiped of sides with lengths v_x, v_y, v_z, such as the one shown in Fig. 1.8. Hence,

$$\|\boldsymbol{v}\|^2 = v_x^2 + v_y^2 + v_z^2 \tag{1.13}$$

1.3.3.2 Unit Vector

We define a unit vector as any vector whose magnitude is equal to unity, regardless of its direction. As we saw, $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$ are special cases of unit vectors, with specific directions assigned to them. An arbitrary unit vector in the direction of $\boldsymbol{v}$ can be obtained as follows:

$$\boldsymbol{w} = \frac{\boldsymbol{v}}{\|\boldsymbol{v}\|} \tag{1.14}$$

with

$$\|\boldsymbol{w}\| = 1 \tag{1.15}$$

A unit vector can be also written in the form

$$\boldsymbol{w} = \begin{bmatrix} v_x/\|\boldsymbol{v}\| \\ v_y/\|\boldsymbol{v}\| \\ v_z/|\boldsymbol{v}\| \end{bmatrix} \equiv \frac{1}{\|\boldsymbol{v}\|} \begin{bmatrix} v_x \\ v_y \\ v_z \end{bmatrix} \tag{1.16}$$

We can make this more concise with the definitions:

$$w_x = \frac{v_x}{\|\boldsymbol{v}\|},\ w_y = \frac{v_y}{\|\boldsymbol{v}\|},\ w_z = \frac{v_z}{\|\boldsymbol{v}\|} \tag{1.17}$$

so that

$$\boldsymbol{w} = \begin{bmatrix} w_x \\ w_y \\ w_z \end{bmatrix} \tag{1.18}$$

Note that if α, β, and γ are the angles between $\boldsymbol{v}$ and the X-, Y-, and Z-axes, respectively, then

$$w_x = \frac{v_x}{\|\boldsymbol{v}\|} = \cos\alpha \qquad w_y = \frac{v_y}{\|\boldsymbol{v}\|} = \cos\beta \qquad w_z = \frac{v_z}{\|\boldsymbol{v}\|} = \cos\gamma \tag{1.19}$$

which indicates that w_x, w_y, and w_z are the *direction cosines* of $\boldsymbol{v}$, whose squares add up to unity.

1.3.3.3 Multiplication by a Scalar

Multiplying any vector $\boldsymbol{v}$ by a scalar k produces a new vector $k\boldsymbol{v}$:

$$k\boldsymbol{v} = \begin{bmatrix} kv_x \\ kv_y \\ kv_z \end{bmatrix} \tag{1.20}$$

If k is positive, then $\boldsymbol{v}$ and $k\boldsymbol{v}$ are in the same direction; if k is negative, then $\boldsymbol{v}$ and $k\boldsymbol{v}$ are in opposite directions. The magnitude of $k\boldsymbol{v}$ is

$$\|k\boldsymbol{v}\| = \sqrt{k^2v_x^2 + k^2v_y^2 + k^2v_z^2} \tag{1.21}$$

so that

$$\|k\boldsymbol{v}\| = |k|\|\boldsymbol{v}\| \tag{1.22}$$

1.3.3.4 Vector Addition

Given $\boldsymbol{a} = [a_x\ a_y\ a_z]^T$ and $\boldsymbol{b} = [b_x\ b_y\ b_z]^T$, the sum of these two vectors is defined as

$$\boldsymbol{a} + \boldsymbol{b} = \begin{bmatrix} a_x + b_x \\ a_y + b_y \\ a_z + b_z \end{bmatrix} \tag{1.23}$$

Given vectors $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$ and scalars k and l, vector addition and scalar multiplication obey the properties below:

1. $\boldsymbol{a} + \boldsymbol{b} = \boldsymbol{b} + \boldsymbol{a}$,
2. $\boldsymbol{a} + (\boldsymbol{b} + \boldsymbol{c}) = (\boldsymbol{a} + \boldsymbol{b}) + \boldsymbol{c}$,
3. $k(l\boldsymbol{a}) = kl\boldsymbol{a}$,
4. $(k + l)\boldsymbol{a} = k\boldsymbol{a} + l\boldsymbol{a}$, and
5. $k(\boldsymbol{a} + \boldsymbol{b}) = k\boldsymbol{a} + k\boldsymbol{b}$.

1.3.4 Scalar Product

The scalar product, also known as the *dot product*, of two vectors $\boldsymbol{a}$ and $\boldsymbol{b}$ is the sum of the products of their corresponding components:

$$\boldsymbol{a} \cdot \boldsymbol{b} = a_x b_x + a_y b_y + a_z b_z \tag{1.24}$$

which returns a scalar quantity, not another vector. An alternative form representing the scalar product is

$$\boldsymbol{a}^T \boldsymbol{b} = a_x b_x + a_y b_y + a_z b_z \tag{1.25}$$

with superscript T indicating *transposition*, i.e., $\boldsymbol{a}^T$ is the transpose of $\boldsymbol{a}$. Since a vector array was defined in Sect. 1.2.4 as a *column array*, $\boldsymbol{a}^T$ is a *row array*.

In addition, we can readily show that the scalar product is commutative, meaning that:

$$\boldsymbol{a} \cdot \boldsymbol{b} = \boldsymbol{b} \cdot \boldsymbol{a} \tag{1.26}$$

Alternatively, the scalar product may be calculated using the angle θ between the vectors $\boldsymbol{a}$ and $\boldsymbol{b}$:

$$\boldsymbol{a} \cdot \boldsymbol{b} = \|\boldsymbol{a}\| \|\boldsymbol{b}\| \cos\theta \tag{1.27}$$

Moreover, the following two statements are equivalent: for any $\boldsymbol{a}, \boldsymbol{b} \neq \boldsymbol{0}$,

$$\boldsymbol{a} \cdot \boldsymbol{b} = 0 \Longleftrightarrow \boldsymbol{a} \text{ and } \boldsymbol{b} \text{ are perpendicular.} \tag{1.28}$$

In summary, the scalar product has the following properties:

1. $\boldsymbol{a} \cdot \boldsymbol{b} = \|\boldsymbol{a}\| \|\boldsymbol{b}\| \cos\theta$, where θ is the angle between $\boldsymbol{a}$ and $\boldsymbol{b}$;
2. $\boldsymbol{a} \cdot \boldsymbol{a} = \|\boldsymbol{a}\|^2$;
3. $\boldsymbol{a} \cdot \boldsymbol{b} = \boldsymbol{b} \cdot \boldsymbol{a}$, *commutativity*;
4. $\boldsymbol{a} \cdot (\boldsymbol{b} + \boldsymbol{c}) = \boldsymbol{a} \cdot \boldsymbol{b} + \boldsymbol{a} \cdot \boldsymbol{c}$, *distributivity*;
5. $(k\boldsymbol{a}) \cdot \boldsymbol{b} = \boldsymbol{a} \cdot (k\boldsymbol{b}) = k(\boldsymbol{a} \cdot \boldsymbol{b})$, *associativity*; and
6. $\boldsymbol{a}$ is perpendicular to $\boldsymbol{b} \Longleftrightarrow \boldsymbol{a} \cdot \boldsymbol{b} = 0$.

1.3.5 *Inequalities*

In connection with vector norms, there are two important inequalities that arise, as given below:

- Cauchy–Schwartz inequality:

$$(\boldsymbol{v} \cdot \boldsymbol{w})^2 \leq \|\boldsymbol{v}\|^2 \|\boldsymbol{w}\|^2 \tag{1.29}$$

- Triangle inequality:

$$\|\boldsymbol{v} + \boldsymbol{w}\| \leq \|\boldsymbol{v}\| + \|\boldsymbol{w}\| \tag{1.30}$$

These properties are quite useful for the derivation of other identities and inequalities, and are fundamental to the understanding and application of vectors in computer graphics.

1.4 Matrices

1.4.1 *Definition*

A matrix is a rectangular array of numbers arranged in m rows and n columns, namely,

$$\boldsymbol{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & \dots & a_{1n} \\ a_{21} & a_{22} & a_{23} & \dots & a_{2n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & a_{m3} & \dots & a_{mn} \end{bmatrix} \tag{1.31}$$

1.4.2 *Special Matrices*

- Square matrix:
  A square matrix has an equal number of rows and columns ($m = n$), e.g.,

$$\boldsymbol{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix} \tag{1.32}$$

- Row matrix:
  A row matrix has one row:

$$\boldsymbol{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \end{bmatrix} = \boldsymbol{a}^T \tag{1.33}$$

That is, a row matrix is a *transposed* vector.

- Column matrix:
  A column matrix has one column. In our choice of notation, this column matrix becomes a vector array, namely,

$$\boldsymbol{b} = \begin{bmatrix} b_{11} \\ b_{21} \\ b_{31} \end{bmatrix} \tag{1.34}$$

  Note the use of a bold *lowercase* font in Eqs. (1.33) and (1.34), indicating that this array is a vector.
- Diagonal matrix:
  A square matrix that has zero entries everywhere except on its main diagonal is termed *diagonal*:

$$\boldsymbol{A} = \begin{bmatrix} a_{11} & 0 & 0 & 0 & \dots & 0 \\ 0 & a_{22} & 0 & 0 & \dots & \vdots \\ 0 & 0 & a_{33} & 0 & \dots & \vdots \\ 0 & 0 & 0 & a_{44} & \dots & \vdots \\ \vdots & \vdots & \vdots & \vdots & \ddots & 0 \\ 0 & \dots & \dots & \dots & 0 & a_{mm} \end{bmatrix} \tag{1.35}$$

  Diagonal matrices satisfy: $a_{ij} = 0$ if $i \neq j$.
- Identity matrix:
  This is a special diagonal matrix with unit elements on the main diagonal, and zero elsewhere. This matrix is denoted by the symbol **1**. For example, the 3 × 3 identity matrix is defined as

$$\mathbf{1} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{1.36}$$

  The elements of **1** are sometimes represented by the *Kronecker delta*, namely,

$$\begin{aligned} \delta_{ij} &= 0 \quad \text{if } i \neq j \\ \delta_{ij} &= 1 \quad \text{if } i = j \end{aligned} \tag{1.37}$$

- Zero matrix:
  The $m \times n$ zero matrix has all its elements equal to zero. We will denote it by $\boldsymbol{O}$. For example, the 3 × 3 zero matrix is

$$\boldsymbol{O} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{1.38}$$

- Symmetric matrix:
  Symmetric matrices are symmetric about the main diagonal: $a_{ij} = a_{ji}$, i.e.,

$$\boldsymbol{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{12} & a_{22} & a_{23} \\ a_{13} & a_{23} & a_{33} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ \vdots & a_{22} & a_{23} \\ \text{symmetric} & \ldots & a_{33} \end{bmatrix} \tag{1.39}$$

- Skew-symmetric matrix:
  A matrix is skew-symmetric if $a_{ij} = -a_{ji}$, namely,

$$\boldsymbol{A} = \begin{bmatrix} 0 & a_{12} & a_{13} \\ -a_{12} & 0 & a_{23} \\ -a_{13} & -a_{23} & 0 \end{bmatrix} \tag{1.40}$$

  Notice that the diagonal entries of a skew-symmetric matrix vanish necessarily.
- Triangular matrix: An *upper triangular* matrix has all its entries below the diagonal equal to zero, namely,

$$\boldsymbol{U} = \begin{bmatrix} a_{11} & a_{12} & \ldots & a_{1n} \\ 0 & a_{22} & \ldots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & a_{nn} \end{bmatrix} \tag{1.41}$$

  A *lower triangular* matrix is defined correspondingly. Furthermore, while upper (lower) triangular matrices can be rectangular, *symmetric* and *skew-symmetric* matrices are necessarily square.

1.4.3 Properties

- Matrix equality: Let us assume that matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ have the same numbers of rows and columns. Then,

$$\boldsymbol{A} = \boldsymbol{B} \Longleftrightarrow a_{ij} = b_{ij}, \text{ for all } i, j \tag{1.42}$$

- Matrix addition:
  Adding two $m \times n$ matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ produces a third $m \times n$ matrix $\boldsymbol{C}$, whose entries are equal to the sum of the corresponding entries of $\boldsymbol{A}$ and $\boldsymbol{B}$. Thus,

$$\boldsymbol{A} + \boldsymbol{B} = \boldsymbol{C} \tag{1.43}$$

  and

$$a_{ij} + b_{ij} = c_{ij} \tag{1.44}$$

Of course, we can add or subtract two matrices if and only if they have the same numbers of rows and columns. Moreover, matrix addition is commutative, i.e., $\boldsymbol{A} + \boldsymbol{B} = \boldsymbol{B} + \boldsymbol{A}$.

- Matrix multiplication by a scalar:
  Multiplying a matrix $\boldsymbol{A}$ by a scalar k produces a new matrix $\boldsymbol{B}$ with the same number of rows and columns. Each entry of $\boldsymbol{B}$ is obtained by multiplying the corresponding entry of $\boldsymbol{A}$ by the scalar k:

$$k\boldsymbol{A} = \boldsymbol{B} \tag{1.45}$$

and

$$ka_{ij} = b_{ij} \tag{1.46}$$

- Matrix product:
  The product $\boldsymbol{AB}$ of two matrices is another matrix $\boldsymbol{C}$. This operation is possible if and only if the number of columns of the first matrix is equal to the number of rows of the second matrix. In general, the product of two matrices is not commutative:

$$\boldsymbol{AB} \neq \boldsymbol{BA} \tag{1.47}$$

The product $\boldsymbol{C}$ of two matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ in terms of their entries is

$$\boldsymbol{C} = \boldsymbol{AB} \quad \Rightarrow \quad c_{ij} = a_{i1}b_{1j} + a_{i2}b_{2j} + \cdots + a_{in}b_{nj} \tag{1.48}$$

- Transpose matrix
  By interchanging the rows and columns of a matrix $\boldsymbol{A}$, we obtain its transpose $\boldsymbol{A}^T$, so that $a_{ij}^T = a_{ji}$, where a_{ij}^T is the (i, j) entry of the transpose of $\boldsymbol{A}$, i.e.,

$$\boldsymbol{A} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \\ a_{31} & a_{32} \end{bmatrix} \quad \Rightarrow \quad \boldsymbol{A}^T = \begin{bmatrix} a_{11} & a_{21} & a_{31} \\ a_{12} & a_{22} & a_{32} \end{bmatrix} \tag{1.49}$$

1.4.4 The Vector Product

The vector product of two 3D vectors $\boldsymbol{a}$ and $\boldsymbol{b}$, also known as the *cross product*, is defined as

$$\boldsymbol{a} \times \boldsymbol{b} = (a_y b_z - a_z b_y)\boldsymbol{i} - (a_x b_z - a_z b_x)\boldsymbol{j} + (a_x b_y - a_y b_x)\boldsymbol{k} \tag{1.50}$$

In array form,

$$\boldsymbol{a} \times \boldsymbol{b} = \begin{bmatrix} a_y b_z - a_z b_y \\ a_z b_x - a_x b_z \\ a_x b_y - a_y b_x \end{bmatrix} \tag{1.51}$$

One *mnemonic* means to compute the vector product relies on the expansion of a determinant (cofactor expansion, as outlined in Sect. 1.4.6), namely,

$$\begin{aligned} \boldsymbol{a} \times \boldsymbol{b} &= \det \begin{bmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ a_x & a_y & a_z \\ b_x & b_y & b_z \end{bmatrix} \\ &= (a_y b_z - a_z b_y)\boldsymbol{i} - (a_x b_z - a_z b_x)\boldsymbol{j} + (a_x b_y - a_y b_x)\boldsymbol{k} \end{aligned} \tag{1.52}$$

The properties of the vector product are given below:

- If $\boldsymbol{c} = \boldsymbol{a} \times \boldsymbol{b}$, then $\boldsymbol{c}$ is perpendicular to both $\boldsymbol{a}$ and $\boldsymbol{b}$. Consequently, $\boldsymbol{c}$ is also perpendicular to the plane defined by $\boldsymbol{a}$ and $\boldsymbol{b}$.
- The vector product is *skew-symmetric*: $\boldsymbol{a} \times \boldsymbol{b} = -(\boldsymbol{b} \times \boldsymbol{a})$.
- $\boldsymbol{a}$ and $\boldsymbol{b}$ are parallel $\Longleftrightarrow \boldsymbol{a} \times \boldsymbol{b} = \boldsymbol{0}$.

Also note that, if $\boldsymbol{c} = \boldsymbol{a} \times \boldsymbol{b}$ and θ denotes the angle from $\boldsymbol{a}$ to $\boldsymbol{b}$, in this direction, when the tails of the two vectors coincide, then

$$\boldsymbol{c} = (\|\boldsymbol{a}\| \|\boldsymbol{b}\| \sin\theta)\boldsymbol{n} \tag{1.53}$$

where $\boldsymbol{n}$ is the unit vector normal to both $\boldsymbol{a}$ and $\boldsymbol{b}$, so that $(\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{n})$ is a right-hand triad.

The *geometric interpretation* of the vector product is now straightforward: As depicted in Fig. 1.15, the expression in parentheses in Eq. (1.53) is nothing but *twice* the area of the triangle AOB, i.e., the area of the parallelogram $OADB$.

1.4.5 The 2D Form of the Vector (Cross) Product

The vector product, or cross product, of two 3D vectors was defined in Sect. 1.4.4. This product exists only in three dimensions. However, in 2D geometry one is confronted frequently with the calculation of the cross product. To ease the solution of 2D geometric problems involving the cross product, we introduce below a *2D form of the cross product*.

Let $\boldsymbol{E}$ be an *orthogonal matrix* that rotates vectors in the plane through an angle of 90° counterclockwise (ccw), namely,

$$\boldsymbol{E} \equiv \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} \tag{1.54}$$

With this definition, we can readily prove that

$$\boldsymbol{E}^T \boldsymbol{E} = \boldsymbol{E}\boldsymbol{E}^T = \boldsymbol{1} \tag{1.55}$$

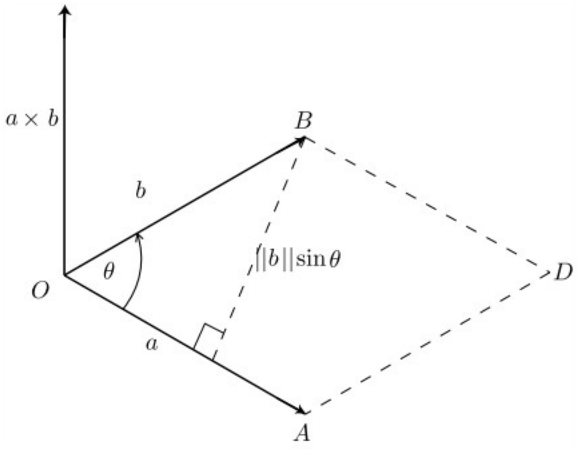

Fig. 1.15 Geometric interpretation of the vector product

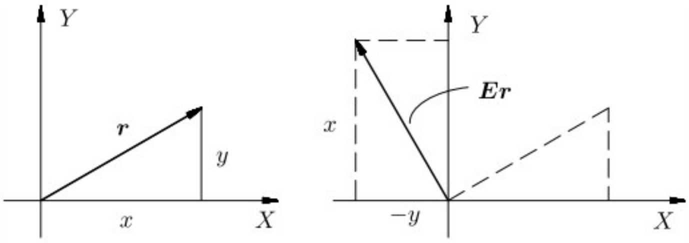

Fig. 1.16 Vector $\boldsymbol{r}$ and its image under $\boldsymbol{E}$

in which $\mathbf{1}$ is the 2×2 identity matrix. Moreover, note that $\boldsymbol{E}$ is *skew-symmetric*, i.e., $\boldsymbol{E} = -\boldsymbol{E}^T$, and hence $\boldsymbol{E}^2 = -\mathbf{1}$.

Also note that, given any vector $\boldsymbol{r} = \begin{bmatrix} x & y \end{bmatrix}^T$ in a plane Π, its image under $\boldsymbol{E}$ is given by

$$\boldsymbol{Er} = \begin{bmatrix} -y \\ x \end{bmatrix} \tag{1.56}$$

as illustrated in Fig. 1.16.

Now, let us compute the cross product $\boldsymbol{a} \times \boldsymbol{b}$, where $\boldsymbol{a} = A\boldsymbol{k}$, and $\boldsymbol{k}$ is a unit vector normal to Π, pointing toward the viewer, $\boldsymbol{a}$ thus being a 3D vector normal to Π, of magnitude $|A|$. Moreover, we assume that $\boldsymbol{b}$ lies in Π, its Z-component thus vanishing. The cross product of interest thus takes the form[4].

$$\boldsymbol{a} \times \boldsymbol{b} = \det \begin{bmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ 0 & 0 & A \\ b_x & b_y & 0 \end{bmatrix} = -Ab_y\boldsymbol{i} + Ab_x\boldsymbol{j} \tag{1.57}$$

---

[4] "det" is abbreviation for *determinant*. A concept formally defined in Subsection 1.4.6.

where we have recalled that the unit vectors $\boldsymbol{i}$ and $\boldsymbol{j}$ are parallel to the X- and Y-axes, respectively. The two-dimensional form of the foregoing product, then, becomes

$$(\boldsymbol{a} \times \boldsymbol{b})_{2D} = A \begin{bmatrix} -b_y \\ b_x \end{bmatrix} \equiv A\boldsymbol{E}\overline{\boldsymbol{b}} \tag{1.58}$$

where we have recalled Eq. (1.56) and $\overline{\boldsymbol{b}}$ denotes the 2D version of the three-dimensional $\boldsymbol{b}$, i.e.,

$$\overline{\boldsymbol{b}} = \begin{bmatrix} b_x \\ b_y \end{bmatrix}$$

Likewise, the cross product $\boldsymbol{b} \times \boldsymbol{c}$, for both $\boldsymbol{b}$ and $\boldsymbol{c}$ in the plane Π, is a vector perpendicular to this plane, of *signed* magnitude,[5] $\|\boldsymbol{b}\|\|\boldsymbol{c}\| \sin(\boldsymbol{b},\ \boldsymbol{c})$, where $(\boldsymbol{b},\ \boldsymbol{c})$ denotes the angle between these two vectors, measured from $\boldsymbol{b}$ to $\boldsymbol{c}$.

Thus, if $\sin(\boldsymbol{b},\ \boldsymbol{c})$ is positive, the cross-product vector points in the direction of $\boldsymbol{k}$; otherwise, in the direction of $-\boldsymbol{k}$.

More concretely, let $\boldsymbol{b}$ be defined as before, $\boldsymbol{c}$ being defined, in turn, as

$$\boldsymbol{c} \equiv \begin{bmatrix} c_x \\ c_y \\ 0 \end{bmatrix} \tag{1.59}$$

Hence,

$$\boldsymbol{b} \times \boldsymbol{c} = \det \begin{bmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ b_x & b_y & 0 \\ c_x & c_y & 0 \end{bmatrix} = (b_x c_y - b_y c_x)\boldsymbol{k} \ \equiv\ C\boldsymbol{k} \tag{1.60}$$

where C is a real number that can be positive, negative, or even 0. Since we know the direction of $\boldsymbol{b} \times \boldsymbol{c}$, i.e., perpendicular to the plane Π, all we need is the quantity C above, which can be readily recognized as the dot product of the two-dimensional vectors $\boldsymbol{E}\overline{\boldsymbol{b}}$, as given in Eq. (1.58), and $\overline{\boldsymbol{c}}$, the 2D counterpart of $\boldsymbol{c}$, i.e.,

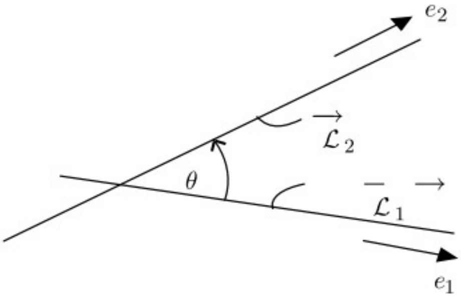
$$C = \begin{bmatrix} c_x & c_y \end{bmatrix}^T \begin{bmatrix} -b_y \\ b_x \end{bmatrix} = \overline{\boldsymbol{c}}^T \boldsymbol{E}\overline{\boldsymbol{b}} \equiv (\boldsymbol{E}\overline{\boldsymbol{b}})^T \overline{\boldsymbol{c}} = -\overline{\boldsymbol{b}}^T \boldsymbol{E}\overline{\boldsymbol{c}} \tag{1.61}$$

Therefore, the sign of C depends on whether the 3D cross product of Eq. (1.60) points toward the reader or not. C vanishes, of course, if the two factors, $\overline{\boldsymbol{b}}$ and $\overline{\boldsymbol{c}}$, are parallel.

Next we recall a concept of analytic geometry: a *directed segment* $\overrightarrow{\mathcal{L}}$ is a line $\mathcal{L}$ with a direction. In Fig. 1.17, two directed segments $\overrightarrow{\mathcal{L}}_1$ and $\overrightarrow{\mathcal{L}}_2$ are shown, each given by a line $\mathcal{L}_i$ and a unit vector $\mathbf{e}_i$, for $i = 1, 2$.

---

[5] The signed magnitude of a vector is a real number, positive, negative, or zero, whose absolute value is identical to the magnitude of the vector.



e_2
$\overrightarrow{\mathcal{L}}_2$
θ
$\overrightarrow{\mathcal{L}}_1$
e_1

Fig. 1.17 The angle between two directed segments, measured from $\overrightarrow{\mathcal{L}}_1$ to $\overrightarrow{\mathcal{L}}_2$

Now we introduce a practical application of the foregoing concepts in solving a recurrent problem of planar geometry:

Problem Given two directed segments $\overrightarrow{\mathcal{L}}_1$ and $\overrightarrow{\mathcal{L}}_2$, find the angle θ, for $0 \leq \theta \leq 2\pi$, that $\overrightarrow{\mathcal{L}}_2$ makes with $\overrightarrow{\mathcal{L}}_1$, while measuring θ ccw.

Solution Let $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ be 2D unit vectors indicating the direction of segments $\overrightarrow{\mathcal{L}}_1$ and $\overrightarrow{\mathcal{L}}_2$, respectively. Obviously, $\cos\theta$ can be derived from the scalar product P1 of $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$, namely,

$$\mathrm{P1} = \cos\theta = \boldsymbol{e}_1^T\boldsymbol{e}_2 \quad \text{or} \quad \boldsymbol{e}_1 \cdot \boldsymbol{e}_2 \tag{1.62}$$

However, the foregoing value does not determine uniquely θ, for, if $\mathrm{P1} > 0$, then θ may lie in either the first or the fourth quadrant, thus leaving us with an ambiguity. Ditto if $\mathrm{P1} < 0$, in which case θ may lie in either the second or the third quadrant.

To destroy the ambiguity, we need $\sin\theta$, which can be derived from the vector product of $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ when regarded as 3D vectors, as per Eq. (1.53). In light of the 2D form of the vector product, however, we need not work out of the plane of the two given lines. Indeed, from Eqs. (1.53), (1.60), and (1.61), we can write

$$P2 = \sin\theta = (\boldsymbol{E}\boldsymbol{e}_1)^T\boldsymbol{e}_2 \quad \text{or} \quad (\boldsymbol{E}\boldsymbol{e}_1) \cdot \boldsymbol{e}_2 \tag{1.63}$$

Obviously, if $\mathrm{P2} > 0$, then θ may lie in either the first or the second quadrant, which leaves us with an ambiguity. Ditto if $\mathrm{P2} < 0$, in which case θ may lie in either the third or the fourth quadrant.

While each of P1 and P2 does not determine *univocally* angle θ individually, both do. In fact, we can draw the rules below:

1. If $\text{P1} > 0$ and $\text{P2} > 0$, then θ lies in the first quadrant;
2. If $\text{P1} < 0$ and $\text{P2} > 0$, then θ lies in the second quadrant;
3. If $\text{P1} < 0$ and $\text{P2} < 0$, then θ lies in the third quadrant;
4. If $\text{P1} > 0$ and $\text{P2} < 0$, then θ lies in the fourth quadrant.

1.4.6 Determinants

The *determinant* is a quantity associated with an arbitrary $n \times n$ square matrix (note that the number of rows and columns must be identical). A general definition of what a determinant actually represents is rather cumbersome; luckily, we do not need it here. We can define the determinant of a $n \times n$ matrix starting with the simplest case, i.e., $n = 2$, then $n = 3$, and hence, by induction, derive a *procedure* to compute the determinant for any arbitrary value of n.

As a matter of fact, the interest in the determinant is rather theoretical; its actual computation, which is extremely costly in terms of *floating-point operations*, or *flops*, is seldom needed. The relevance of the concept lies in that the value of the determinant indicates whether or not the matrix is *singular*; if it is so, then the *solution* to the system of linear equations associated with the matrix coefficient is not unique. We are interested, in this book, only in the case in which the determinant is *non-zero*, in which case the associated system of linear equations admits one solution, which is *unique*. In this case, the matrix is said to be *invertible*, *regular* or, most commonly, *non-singular*.

A 2×2 matrix $\boldsymbol{A}$ can be *partitioned* either column-wise or row-wise, as shown below:

$$\boldsymbol{A} \equiv \begin{bmatrix} \boldsymbol{a} & \boldsymbol{b} \end{bmatrix} \equiv \begin{bmatrix} \boldsymbol{c}^T \\ \boldsymbol{d}^T \end{bmatrix} \tag{1.64}$$

where $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$, and $\boldsymbol{d}$ are all two-dimensional column vectors. Furthermore, we recall the definition of $\boldsymbol{E}$ as seen in Sect. 1.4.5. If the components of $\boldsymbol{a}$ and $\boldsymbol{b}$ are given as $\boldsymbol{a} = \begin{bmatrix} a_x & a_y \end{bmatrix}^T$ and $\boldsymbol{b} = \begin{bmatrix} b_x & b_y \end{bmatrix}^T$, then the determinant of $\boldsymbol{A}$ is defined as

$$\det(\boldsymbol{A}) = \det \begin{bmatrix} a_x & b_x \\ a_y & b_y \end{bmatrix} = a_x b_y - a_y b_x \tag{1.65}$$

which can be readily cast in the form

$$\det(\boldsymbol{A}) = \begin{bmatrix} a_x & a_y \end{bmatrix} \begin{bmatrix} b_y \\ -b_x \end{bmatrix} \equiv \begin{bmatrix} a_x & a_y \end{bmatrix} \underbrace{\left(- \begin{bmatrix} -b_y \\ b_x \end{bmatrix} \right)}_{-\boldsymbol{E}\boldsymbol{b}} \tag{1.66}$$

the first array of the foregoing product being $\boldsymbol{a}^T$, the second $-\boldsymbol{E}\boldsymbol{b}$.

3.1.3 Distance of a Point to a Plane

Given the plane Π represented by Eq. (3.3a) or, alternatively, by Eq. (3.3b), we want to compute the distance of a *given* point $Q(\xi,\ \eta,\ \zeta)$ to the plane, as illustrated in Fig. 3.1. To do this, we proceed as in Sect. 2.2.1: We first find the unit normal $\boldsymbol{n}$ to the plane. Moreover, let $\boldsymbol{p}_0$, $\boldsymbol{q}$, and $\boldsymbol{p}$ be the position vectors of P_0, Q, and $P(x,\ y,\ z)$, the latter being an arbitrary point of the plane. Since P_0 and P lie in the plane, the difference $\boldsymbol{p} - \boldsymbol{p}_0$ is perpendicular to the unit normal to the plane, $\boldsymbol{n}$, i.e.,

$$\boldsymbol{n}^T(\boldsymbol{p} - \boldsymbol{p}_0) = 0 \tag{3.7}$$

or, in expanded form,

$$\boldsymbol{n}^T\boldsymbol{p} - \boldsymbol{n}^T\boldsymbol{p}_0 = 0 \tag{3.8}$$

Now, let us divide both sides of Eq. (3.3b) by $\sqrt{A^2 + B^2 + C^2}$:

$$\frac{A}{\sqrt{A^2 + B^2 + C^2}}x + \frac{B}{\sqrt{A^2 + B^2 + C^2}}y + \frac{C}{\sqrt{A^2 + B^2 + C^2}}z + \frac{D}{\sqrt{A^2 + B^2 + C^2}} = 0 \tag{3.9}$$

Comparison of Eqs. (3.8) and (3.9) leads to

$$\boldsymbol{n} = \frac{1}{\sqrt{A^2 + B^2 + C^2}}\begin{bmatrix} A \\ B \\ C \end{bmatrix}, \quad \boldsymbol{n}^T\boldsymbol{p}_0 = -\frac{D}{\sqrt{A^2 + B^2 + C^2}} \tag{3.10}$$

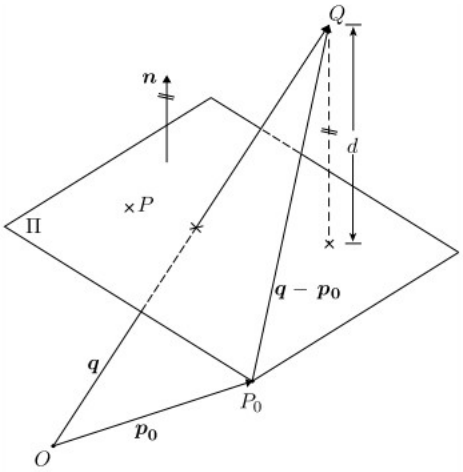


Fig. 3.1 Distance of a point to a plane

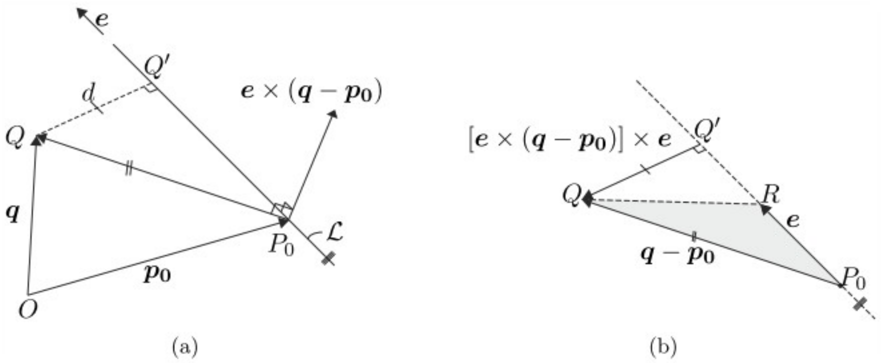

Fig. 3.2 Distance of a point to a line: **a** general layout; **b** geometric interpretation of $[\boldsymbol{e} \times (\boldsymbol{q} - \boldsymbol{p}_0)] \times \boldsymbol{e}$

From Fig. 3.1, the distance d sought is nothing but the *absolute value* of the projection of vector $\boldsymbol{q} - \boldsymbol{p}_0$ onto the unit normal $\boldsymbol{n}$, namely,

$$d = |\boldsymbol{n}^T(\boldsymbol{q} - \boldsymbol{p}_0)| \tag{3.11}$$

Interestingly, the expression for the distance of a point to a line in the 2D case, Eq. (2.9), is *formally identical* to the foregoing expression.

3.1.4 Distance of a Point to a Line

A line $\mathcal{L}$ is given by the two planes (3.6a and 3.6b). We want to find the distance of an arbitrary point $Q(\xi, \eta, \zeta)$ to $\mathcal{L}$.

First, we need a unit vector $\boldsymbol{e}$ parallel to $\mathcal{L}$ and a point P_0 of $\mathcal{L}$. If we denote by $\boldsymbol{n}_1$ and $\boldsymbol{n}_2$ the unit normal to each of the two planes that define $\mathcal{L}$, then we can obtain $\boldsymbol{e}$ as $\boldsymbol{n}_1 \times \boldsymbol{n}_2/\|\boldsymbol{n}_1 \times \boldsymbol{n}_2\|$. Moreover, $\boldsymbol{n}_1$ and $\boldsymbol{n}_2$ are produced using the expression for $\boldsymbol{n}$ displayed in Eq. (3.10):

$$\boldsymbol{n}_i = \frac{1}{\sqrt{A_i^2 + B_i^2 + C_i^2}} \begin{bmatrix} A_i \\ B_i \\ C_i \end{bmatrix}, \quad i = 1, 2 \tag{3.12}$$

We thus have the layout of Fig. 3.2a.

From Fig. 3.2a, P_0 is a point of $\mathcal{L}$, of position vector $\boldsymbol{p}_0$, while $\boldsymbol{e} \times (\boldsymbol{q} - \boldsymbol{p}_0)$ is a vector normal to the plane defined by $\mathcal{L}$ and Q, its norm $\|\boldsymbol{e} \times (\boldsymbol{q} - \boldsymbol{p}_0)\|$ being twice the area of the triangle P_0RQ depicted in Fig. 3.2b. Moreover, if we regard P_0R as the base of the triangle, d becomes its height, and hence

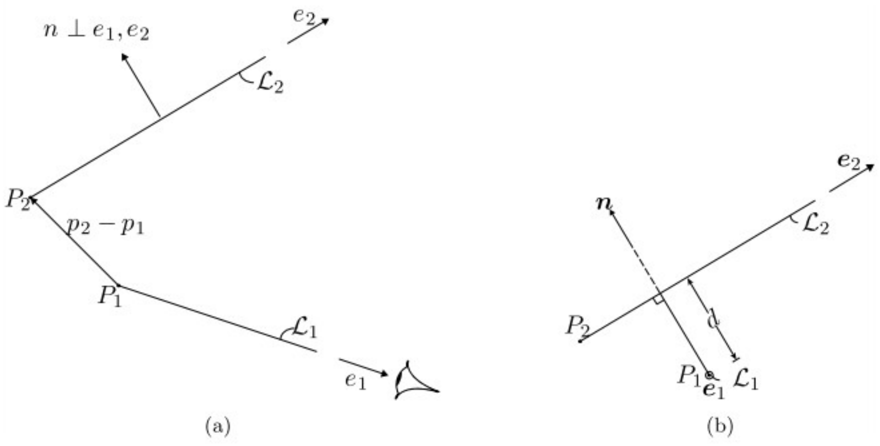

Fig. 3.3 Distance between two lines: **a** general layout; **b** view with $\mathcal{L}_1$ projected as a point, and $\boldsymbol{n}$ lying in the projection plane

$$\overline{P_0 R} d = \|\boldsymbol{e} \times (\boldsymbol{q} - \boldsymbol{p}_0)\| \tag{3.13}$$

where $\overline{P_0 R} = \|\boldsymbol{e}\| = 1$, so that

$$d = \|\boldsymbol{e} \times (\boldsymbol{q} - \boldsymbol{p}_0)\| \tag{3.14}$$

thereby computing the desired distance. Notice, moreover, that

$$\boldsymbol{q} - \boldsymbol{q}' = [\boldsymbol{e} \times (\boldsymbol{q} - \boldsymbol{p}_0)] \times \boldsymbol{e} \tag{3.15}$$

In the above equation, $\boldsymbol{q}'$ is the position vector of Q', the *orthogonal* projection of Q onto $\mathcal{L}$.

3.1.5 Distance Between Two Skew Lines

We have the general layout of Fig. 3.3, depicting two *skew* lines $\mathcal{L}_1$ and $\mathcal{L}_2$, parallel to the unit vectors $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ and passing through P_1 and P_2, respectively. If $\boldsymbol{n}$ denotes the unit normal to $\mathcal{L}_1$ and $\mathcal{L}_2$, then, apparently, the distance d between the two lines is nothing but the absolute value of the projection of $\boldsymbol{p}_2 - \boldsymbol{p}_1$ onto $\boldsymbol{n}$, i.e.,

$$d = |\boldsymbol{n}^T(\boldsymbol{p}_2 - \boldsymbol{p}_1)|, \quad \boldsymbol{n} \equiv \frac{\boldsymbol{e}_1 \times \boldsymbol{e}_2}{||\boldsymbol{e}_1 \times \boldsymbol{e}_2||} \tag{3.16}$$

The above relations are illustrated in Fig. 3.3b.

3.2 Surfaces

A surface is a two-dimensional set of points, extending in two directions that change from point to point, but has no thickness. We will study various types of surfaces, as described below.

The *plane*, introduced and defined in Sect. 3.1.1, is the simplest surface. That is, the plane is the *perpendicular bisector* of the *segment* defined by two given points. A plane can also be visualized as a set of lines passing through a given point and perpendicular to one given direction. In *computer graphics*, *solid objects* can be bounded by planes, forming *facets* of the solid, each facet being a polygon. In this case, the solid turns out to be a *polyhedron*. As a matter of fact, arbitrary surfaces, like airplane fuselages, are sometimes approximated, for certain computations pertaining to the solids that they enclose—volume, centroid location, etc.—by polyhedra. These polyhedra are the *finite elements* introduced to determine the stress and strain distribution on the fuselage of aircraft.[3]

In increasing order of *complexity*, the next surface is the *quadric*, namely, a surface defined, in a certain coordinate frame, by a *quadratic tri-variate polynomial*, namely,

$$\begin{aligned}F(x,\ y,\ z) = A_{11}x^2 + 2A_{12}xy + 2A_{13}xz + A_{22}y^2 + 2A_{23}yz\\ + A_{33}z^2 + B_1x + B_2y + B_3z + C = 0\end{aligned} \tag{3.17}$$

which can be cast in the compact form

$$F(\boldsymbol{p}) = \boldsymbol{p}^T\boldsymbol{A}\boldsymbol{p} + \boldsymbol{b}^T\boldsymbol{p} + C = 0 \tag{3.18a}$$

where

$$\boldsymbol{A} \equiv \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{12} & A_{22} & A_{23} \\ A_{13} & A_{23} & A_{33} \end{bmatrix}, \quad \boldsymbol{b} \equiv \begin{bmatrix} B_1 \\ B_2 \\ B_3 \end{bmatrix} \tag{3.18b}$$

and $\boldsymbol{p}$ defined as in Eq. (3.1), with $\boldsymbol{A}$ being *symmetric*. The above expression can be cast in *homogeneous* array form, similar to Eq. (2.16), if we introduce homogeneous coordinates, namely,

$$F(p) = \boldsymbol{p}^T\boldsymbol{R}\boldsymbol{p} = 0 \tag{3.19a}$$

where

$$\boldsymbol{p} = \begin{bmatrix} x \\ y \\ z \\ 1 \end{bmatrix}, \quad \boldsymbol{R} = \begin{bmatrix} \boldsymbol{A} & \boldsymbol{b} \\ \boldsymbol{b}^T & C \end{bmatrix} \tag{3.19b}$$

---

[3] In fact, some "advanced" finite elements are not polyhedra, but solids bounded by combinations of quadratic or higher order simple surfaces.

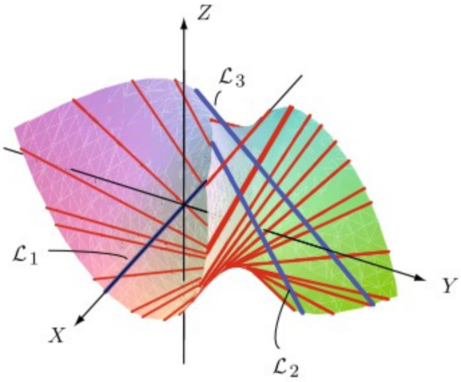

Fig. 3.4 A single-sheet hyperboloid created using three skew lines

Examples of quadrics are the *ellipsoid*, a particular case of which is the *sphere*; the *two-sheet hyperboloid*; the *single-sheet hyperboloid*; the *hyperbolic paraboloid*; and the *paraboloid*. In the same way that we have criteria based on the entries of the upper left block of matrix $\boldsymbol{R}$ of Eq. (2.17) to characterize the conics, there are criteria to characterize the quadric at hand. The reader should have noticed that matrix $\boldsymbol{R}$ of Eq. (3.19b) is *symmetric*, just like its counterpart in Eq. (2.16) in the planar case, in connection with the conic curves. The abovementioned criteria are based on matrix $\boldsymbol{A}$ of Eq. (3.19b). However, these criteria fall outside the scope of this book and will not be pursued here. The total number of quadrics[4] is 17.

Out of the foregoing surfaces, the single-sheet hyperboloid deserves special attention, as it leads, as special cases, to well-known familiar surfaces such as the cylinder and the cone. A single-sheet hyperboloid can be generated by the motion of a line constrained to intersect three given *skew lines*. Two skew lines do not intersect, which means that they do not intersect at all, not even at infinity, as do parallel lines. Shown in Fig. 3.4 is a picture of a single-sheet hyperboloid, as defined by three skew lines, $\{\mathcal{L}_i\}_1^3$.

All surfaces generated by the motion of a line belong to the class of *ruled surfaces*. The moving line generating the surface is termed the *generatrix*, which moves along a curve termed the *directrix*, the relative orientation of the generatrix with respect to the directrix being, in general, variable. Depending on the pattern of this variation, different surfaces can be obtained from the same directrix. In particular, when the orientation of the generatrix is kept constant, a *cylindrical surface* is obtained. Obviously, if the directrix is a circle and the generatrix remains normal to the plane of the circle, then a *circular cylinder* is generated. If the directrix is still a circle, but the generatrix is constrained to pass through a given point, then a *cone* is obtained. Moreover, if the given point lies on the normal to the plane of the circle passing through the center of the circle, then a *right circular cone* is generated.

Ruled surfaces are *curved* in one direction, that of the directrix, but are straight in the direction of the generatrix. For this reason, such surfaces are sometimes termed

---

[4] For the whole list, visit http://mathworld.wolfram.com/QuadraticSurface.html.

single-curve surfaces. Probably the most photographed ruled surface is the *Guggenheim Museum* in Bilbao, Spain. The architect behind this design, Frank Gehry, became well known in architects' circles because of his pioneering use of the CAD software package that was then in use for the design of aircraft fuselage. The design of the latter is much more daring in comparison, because the fuselage is a *double-curved* surface. The most general surfaces are *double curve*. The simplest examples of these are the ellipsoid and the paraboloid.

In computer graphics, certain special kinds of surfaces can be obtained from a generatrix. For example, to generate an axially symmetric surface, like the sphere, we can turn a circle around one of its diameters. Such surfaces are termed *surfaces of revolution*. Other means of generating surfaces is by *extrusion*, whereby a generatrix is translated in one fixed direction. Extrusion is studied in a more general form in Chap. 4.

A doubly curved surface is sometimes referred to as a *warped surface*. The best known example of such a surface is a horse saddle. Other occurrences are the human body, for example, and many engineering works like the aircraft fuselage mentioned above and the styled, aerodynamic shapes of sports cars.

3.3 Simple Solids

3.3.1 Cylinders

3.3.1.1 Description

A cylindrical surface is a ruled surface formed by a line segment called the cylinder *generatrix* that moves while remaining parallel to a fixed line, and touching a planar curve, called the cylinder *directrix*. Moreover, this curve lies in a plane intersecting the fixed line, called the cylinder axis, as shown in Fig. 3.5. The faces of the teeth of *spur* gears are cylindrical surfaces, as depicted in Fig. 3.6; these surfaces have a planar involute—see Fig. 2.19c—as their directrix. This is the reason why such gears are called *involute gears*, to distinguish them from other kinds, like *cycloidal gears*. The directrix of this alternative kind of gears is an *epicycloid*,[5] a curve illustrated in Fig. 2.19b.

If the above-mentioned generatrix remains perpendicular to the directrix, the cylinder is *straight*; otherwise, the cylinder is *oblique*. A right circular cylinder, whose directrix is a circle, is depicted in Fig. 3.5.

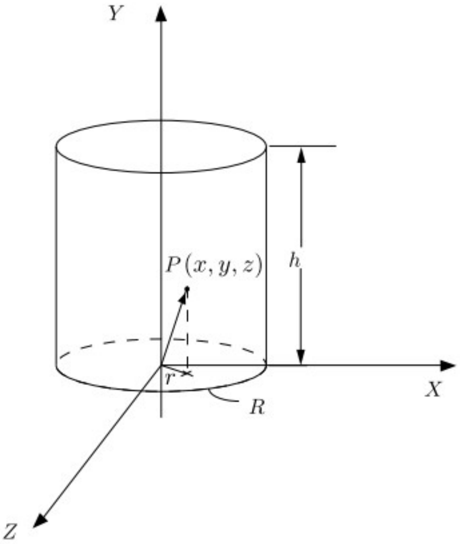
The representation of a *bounded* solid cylinder also calls, of course, for inequalities. For example, the solid cylinder of Fig. 3.5 is represented by

$$x^2 + z^2 \leq R^2, \quad 0 \leq y \leq h \tag{3.20}$$

---

[5] Only a small part of this curve is used to define the gear-tooth profile that is close to the X-axis in Fig. 2.19b.

Fig. 3.5 A bounded circular cylinder



The first inequality excludes points lying a distance greater than R from the Y-axis, which is the cylinder axis; the second inequality restricts the points inside the cylinder to lie between the X–Y-plane and the plane parallel to the former a distance h above it.

In array form, the foregoing inequality becomes

$$\begin{bmatrix} x & y & z & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -R^2 \end{bmatrix} \begin{bmatrix} x \\ y \\ z \\ 1 \end{bmatrix} \leq 0, \quad 0 \leq y \leq h \tag{3.21}$$

A pair of involute spur gears is used to transmit torque and motion between shafts of parallel axes. In order to design a spur-gear pair, two cylinders are produced with parallel axes and radii inversely proportional to the intended gear ratio. Next, an involute curve is produced around each of the bases of the circular cylinders. Now, with each of these curves as the directrix of a cylindrical surface, the flanks of the gears are generated. The reason behind the use of the involute lies in its geometric properties: upon meshing two involute profiles with a common tangent, each profile can turn about its cylinder axis, while maintaining a constant angle between the line of centers of the cylinder bases and the common normal. This angle is known as the *pressure angle*, which should be kept constant to obtain a constant gear ratio.

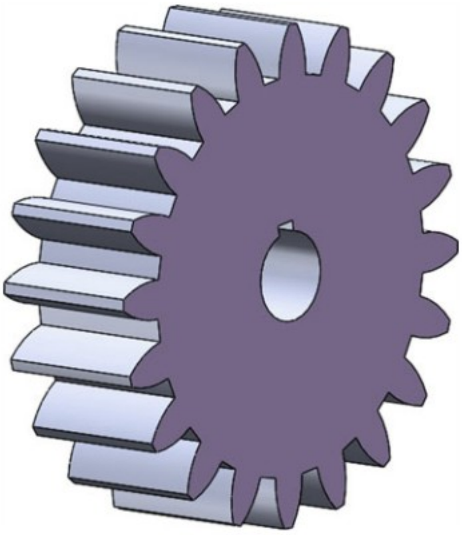


Fig. 3.6 A spur gear with its tooth flanks as instances of a cylindrical surface

3.3.2 *Cones*

3.3.2.1 Description

A conic surface is a ruled surface formed by a line, the cone *generatrix*, moving along a curved path, the cone *directrix*, such that the line always passes through one fixed point, called the *vertex*, a.k.a. the *apex*. Each position of the generatrix is called an *element* of the surface. Such surfaces, when bounded by a plane that cuts all elements, form *solid cones*. The surface defined by the teeth of a *bevel gear*, shown in Fig. 3.7, is a conic surface.

The simplest conic surfaces are those whose generatrix makes a *constant angle* with a fixed line, called its *axis*. Instances of solid cones produced from these surfaces are illustrated in Fig. 3.8, where we distinguish

- A *right cone*, shown in Fig. 3.8a, characterized by having its circular base normal to its axis.
- An *oblique cone*, as shown in Fig. 3.8b, whereby the axis is oblique to the circular base.
- A right cone to which a portion containing the apex has been cut off by means of a plane oblique to the axis gives rise to a *truncated cone*, as illustrated in Fig. 3.8c.
- A *frustum*, obtained if the foregoing cutting plane is normal to the axis, as depicted in Fig. 3.8d.

The flanks of the teeth of a bevel gear are made of conic surfaces. Commonly, the directrix of the conic surface in question is an *approximation* of the *spherical*

Congruence of Triangles:SSS

Lemma 1.3.10.1. *If points Z_1, Z_2 lie on opposite sides of a line a_{XY}, the congruences $XZ_1 \equiv XZ_2$, $YZ_1 \equiv YZ_2$ imply $\angle XYZ_1 \equiv XYZ_2$ (and $\angle YXZ_1 \equiv \angle YXZ_2$).*

Proof. $Z_1 a_{XY} Z_2 \Rightarrow \exists X'\ X' \in a_{XY} \,\&\, [Z_1X'Z_2]$. Observe that the lines a_{XY}, $a_{Z_1Z_2}$ meet only in X', because $Z_1 \notin a_{XY} \Rightarrow a_{Z_1Z_2} \neq a_{XY}$, and therefore for any Y' such that $Y' \in a_{XY}$, $Y' \in a_{Z_1Z_2}$, we have $X' \in a_{XY} \cap a_{Z_1Z_2} \,\&\, Y' \in a_{XY} \cap a_{Z_1Z_2} \overset{T1.1.1}{\Longrightarrow} Y' = X'$. [273] We also assume that $Y \notin a_{Z_1Z_2}$. [274] For the isosceles triangle $\triangle Z_1YZ_2$ the theorem T 1.3.3 gives $YZ_1 \equiv YZ_2 \Rightarrow \angle YZ_1Z_2 \equiv YZ_2Z_1$. On the other hand, $[Z_1X'Z_2] \overset{L1.2.11.15}{\Longrightarrow} Z_{1X'} = Z_{1Z_2} \,\&\, Z_{2X'} = Z_{2Z_1} \Rightarrow \angle YZ_1X' = \angle YZ_1Z_2 \,\&\, \angle YZ_2X' = \angle YZ_2Z_1$. Therefore, $\angle YZ_1Z_2 \equiv \angle YZ_2Z_1 \,\&\, \angle YZ_1X' = \angle YZ_1Z_2 \,\&\, \angle YZ_2Z = \angle YZ_2Z_1 \Rightarrow \angle YZ_1X' \equiv \angle YZ_2X'$.

Let Z_1, Z_2, X be collinear, i.e. $X \in a_{Z_1Z_2}$ (See Fig. 1.116, a)). Then we have $X \in a_{XY} \cap a_{Z_1Z_2} \Rightarrow X' = X$, and we can write $XZ_1 \equiv XZ_2 \,\&\, YZ_1 \equiv YZ_2 \,\&\, \angle YZ_1X' \equiv \angle YZ_2X' \overset{T1.3.4}{\Longrightarrow} \triangle XYZ_1 \equiv \triangle XYZ_2 \Rightarrow \angle XYZ_1 \equiv \angle XYZ_2 \,\&\, \angle YXZ_1 \equiv XYZ_2$. [275]

Now suppose neither X nor Y lie on $a_{Z_1Z_2}$. In this case $X' \in a_{XY} \,\&\, X' \neq X \neq Y \overset{T1.2.2}{\Longrightarrow} [X'XY] \vee [X'YX] \vee [XX'Y]$. Suppose $[X'XY]$ (See Fig. 1.116, b)). [276] Then $Y \in Z_{iY} \,\&\, X' \in Z_{iX'} \,\&\, X \in Z_{iX} \overset{L1.2.21.6,L1.2.21.4}{\Longrightarrow} Z_{iX} \subset Int\angle YZ_iX'$, where $i = 1, 2$. $[X'XY] \overset{L1.2.11.15}{\Longrightarrow} X'_X = X'_Y \Rightarrow \angle Z_1X'X = \angle Z_1X'Y \,\&\, \angle Z_2X'X = \angle Z_2X'Y$. Furthermore, arguing exactly as above, we see that $XZ_1X' = \angle XZ_1Z_2 \,\&\, \angle XZ_2X' = \angle XZ_2Z_1$, whence $\angle XZ_1X' \equiv \angle XZ_2X'$. Using T 1.3.9 we obtain $\angle XZ_1Y \equiv \angle XZ_2Y$, which allows us to write $XZ_1 \equiv XZ_2 \,\&\, YZ_1 \equiv YZ_2 \,\&\, \angle XZ_1Y \equiv \angle XZ_2Y \overset{T1.3.4}{\Longrightarrow} \triangle XZ_1Y \equiv \triangle XZ_2Y \Rightarrow \angle XYZ_1 \equiv XYZ_2 \,\&\, \angle YXZ_1 \equiv \angle YXZ_2$.

Finally, suppose $[XX'Y]$ (See Fig. 1.116, c)). Then $[XX'Y] \Rightarrow [YX'X] \overset{L1.2.11.15}{\Longrightarrow} Y_{X'} = Y_X \Rightarrow \angle XYZ_i \equiv \angle X'YZ_i$, where $i = 1, 2$. Together with $\angle X'YZ_1 \equiv \angle X'YZ_2$, this gives $\angle XYZ_1 \equiv \angle XYZ_2$. □

Theorem 1.3.10 (Third Triangle Congruence Theorem (SSS))**.** *If all sides of a triangle $\triangle ABC$ are congruent to the corresponding sides of a triangle $\triangle A'B'C'$, i.e. if $AB \equiv A'B'$, $BC \equiv B'C'$, $AC \equiv A'C'$, the triangle $\triangle ABC$ is congruent to the triangle $\triangle A'B'C'$. In other words, if a triangle $\triangle ABC$ is weakly congruent to a triangle $\triangle A'B'C'$, this implies that the triangle $\triangle ABC$ is congruent to the triangle $\triangle A'B'C'$.*

Proof. (See Fig. 1.117.) By hypothesis, $\triangle ABC \simeq \triangle A'B'C'$, i.e., $AB \equiv A'B'$, $BC \equiv B'C'$, $AC \equiv A'C'$. Using A 1.3.4, A 1.3.1, L 1.2.11.3, choose B'' so that $C'_{B''}C'_{B'}a_{A'C'}$, $\angle ACB \equiv \angle A'C'B''$, $BC \equiv B''C'$, and then choose B''' so that $C'_{B'''}a_{A'C'}C'_{B''}$.[277] Then we have $AC \equiv A'C' \,\&\, BC \equiv B''C' \,\&\, \angle ACB \equiv \angle A'C'B'' \overset{T1.3.4}{\Longrightarrow} \triangle ABC \equiv \triangle A'B''C' \Rightarrow AB \equiv A'B''$. $A'C' \equiv A'C' \,\&\, B''C' \equiv B'''C' \,\&\, \angle A'C'B'' \equiv \angle A'C'B''' \overset{T1.3.4}{\Longrightarrow} \triangle A'B''C' \equiv \triangle A'B'''C' \Rightarrow AB \equiv A'B''$. Since $AB \equiv A'B' \,\&\, AB \equiv A'B'' \,\&\, A'B'' \equiv A'B''' \,\&\, BC \equiv B'C' \,\&\, BC \equiv B''C' \,\&\, B''C' \equiv B'''C' \overset{T1.3.1}{\Longrightarrow} A'B''' \equiv A'B' \,\&\, A'B''' \equiv A'B'' \,\&\, B'''C' \equiv B'C' \,\&\, B'''C' \equiv B''C' \overset{T1.3.1}{\Longrightarrow} B''C' \equiv B'C'$, $B''B'a_{A'C'} \,\&\, B'''a_{A'C'}B'' \overset{L1.2.17.10}{\Longrightarrow} B'''a_{A'C'}B'$, we have $A'B''' \equiv A'B'' \,\&\, B'''C' \equiv B''C' \,\&\, B'''a_{A'C'}B'' \overset{L1.3.10.1}{\Longrightarrow} \angle A'C'B''' \equiv \angle A'C'B''$, $A'B''' \equiv A'B' \,\&\, B'''C' \equiv B'C' \,\&\, B'''a_{A'C'}B'$. Finally, $\angle A'C'B''' \equiv \angle A'C'B'' \,\&\, \angle A'C'B''' \equiv \angle A'C'B' \,\&\, C'_{B''}C'_{B'}a_{A'C'} \overset{A1.3.4}{\Longrightarrow} \angle A'C'B'' = \angle A'C'B' \Rightarrow C'_{B''} = C'_{B''}$, $C'B'' \equiv C'B' \,\&\, C'_{B''} = C'_{B'} \overset{A1.3.1}{\Longrightarrow} B'' = B'$. □

Congruence of Angles and Congruence of Paths as Equivalence Relations

Lemma 1.3.11.1. *If angles $\angle(h', k')$, $\angle(h'', k'')$ are both congruent to an angle $\angle(h, k)$, the angles $\angle(h', k')$, $\angle(h'', k'')$ are congruent to each other, i.e., $\angle(h', k') \equiv \angle(h'', k'')$ and $\angle(h'', k'') \equiv \angle(h', k')$.*

Proof. (See Fig. 1.118.) Denote O, O', O'' the vertices of the angles $\angle(h, k)$, $\angle(h', k')$, $\angle(h'', k'')$, respectively. Using A 1.3.1, choose $H \in h$, $K \in k$, $H'\ inh'$, $K' \in k'$, $H'' \in h''$ so that $OH \equiv O'H'$, $OK \equiv O'K'$, $OH \equiv O''H''$, $OK \equiv O''K''$, whence by T 1.3.1 $O'H' \equiv OH$, $O'K' \equiv OK$, $O''H'' \equiv OH$, $O''K'' \equiv OK$, and by L 1.2.21.1 $\angle HOK = \angle(h, k)$, $\angle H'O'K' = \angle(h', k')$, $\angle H''O''K'' = \angle(h'', k'')$. Then we have $O'H' \equiv OH \,\&\, O'K' \equiv OK \,\&\, \angle H'O'K' \equiv \angle HOK \,\&\, O''H'' \equiv OH \,\&\, O''K'' \equiv OK \,\&\, \angle H''O''K'' \overset{T1.3.4}{\Longrightarrow} \triangle H'O'K' \equiv \triangle HOK \,\&\, \triangle H''O''K'' \equiv \triangle HOK \Rightarrow K'H' \equiv KH \,\&\, K''H'' \equiv KH \overset{T1.3.1}{\Longrightarrow} K'H' \equiv K''H''$. Also, $O'H' \equiv OH \,\&\, O''H'' \equiv OH \,\&\, O'K' \equiv OK \,\&\, O''K'' \equiv$

---

[273] We take into account that, obviously, $[Z_1X'Z_2] \overset{L1.2.1.3}{\Longrightarrow} X' \in a_{Z_1Z_2}$.

[274] We can assume this without loss of generality - see next footnote.

[275] Observe that the seemingly useless fact that $\angle YXZ_1 \equiv YXZ_2$ allows us to avoid considering the case $Y \in a_{Z_1Z_2}$ separately. Instead, we can substitute X for Y and Y for X to obtain the desired result, taking advantage of the symmetry of the conditions of the theorem with respect to this substitution.

[276] Again, because of obvious symmetry with respect to substitution $X \to Y$, $Y \to X$, we do not need to consider the case when $[X'YX]$. Note that we could have avoided this discussion altogether if we united both cases $[X'XY]$, $[X'YX]$ into the equivalent $Y \in X'_X$, $Y \neq X$, but the approach taken here has the appeal of being more illustrative.

[277] To be more precise, we take a point B_0 such that $C'_{B''}a_{A'C'}B_0$, and then, using A 1.3.4, draw the angle $\angle A'C'B'''$ such that $C'_{B'''}B_0a_{A'C'}$, $\angle A'C'B'' \equiv \angle A'C'B'''$, $B''C' \equiv B'''C'$. We then have, of course, $C'_{B''}a_{A'C'}B_0 \,\&\, C'_{B'''}B_0a_{A'C'} \overset{L1.2.18.5}{\Longrightarrow} C'_{B'''}a_{A'C'}C'_{B''}$. Using jargon, as we did here, allows one to avoid cluttering the proofs with trivial details, thus saving the space and intellectual energy of the reader for more intricate points.

Figure 1.117: if $AB \equiv A'B'$, $BC \equiv B'C'$, $AC \equiv A'C'$, the triangle $\triangle ABC$ is congruent to the triangle $\triangle A'B'C'$ (SSS, or The Third Triangle Congruence Theorem).

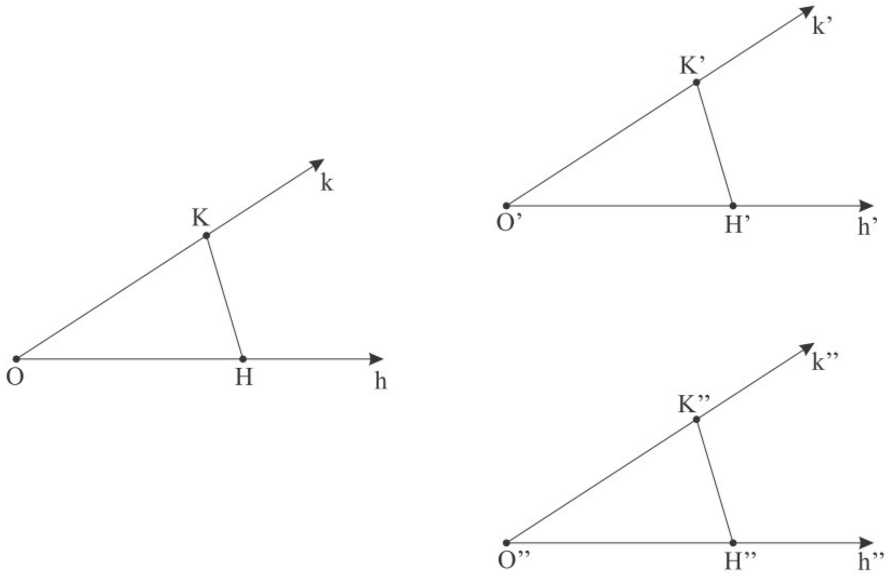

Figure 1.118: $\angle(h',k') \equiv \angle(h,k)$ and $\angle(h'',k'') \equiv \angle(h,k)$ imply $\angle(h',k') \equiv \angle(h'',k'')$ and $\angle(h'',k'') \equiv \angle(h',k')$.

$OK \overset{T1.3.1}{\Longrightarrow} O'H' \equiv O''H'' \,\&\, O'K' \equiv O''K''$. Finally, $O'H' \equiv O''H'' \,\&\, O'K' \equiv O''K'' \,\&\, K'H' \equiv K''H'' \overset{T1.3.10}{\Longrightarrow}$ $\triangle H'O'K' \equiv \triangle H''O''K'' \Rightarrow \angle H'O'K' \equiv \angle H''O''K'' \Rightarrow \angle(h',k') \equiv \angle(h'',k'')$. $\square$

Theorem 1.3.11. *Congruence of angles is a relation of equivalence on the class of all angles, i.e. it possesses the properties of reflexivity, symmetry, and transitivity.*

Proof. Reflexivity follows from A 1.3.4.

Symmetry: Let $\angle(h,k) \equiv \angle(h',k')$. Then $\angle(h',k') \equiv \angle(h',k') \,\&\, \angle(h,k) \equiv \angle(h',k') \overset{L1.3.11.1}{\Longrightarrow} \angle(h',k') \equiv \angle(h,k)$.

Transitivity: $\angle(h,k) \equiv \angle(h',k') \,\&\, \angle(h',k') \equiv \angle(h'',k'') \overset{\text{above}}{\Longrightarrow} \angle(h,k) \equiv \angle(h',k') \,\&\, \angle(h'',k'') \equiv \angle(h',k') \overset{L1.3.11.1}{\Longrightarrow}$ $\angle(h,k) \equiv \angle(h'',k'')$. $\square$

Therefore, if an angle $\angle(h,k)$ is congruent to an angle $\angle(h',k')$, we can say the angles $\angle(h,k)$, $\angle(h',k')$ are congruent (to each other).

Corollary 1.3.11.2. *Congruence of paths (in particular, of polygons) is a relation of equivalence on the class of all paths. That is, any path $A_1A_2\dots A_n$ is congruent to itself. If a path $A_1A_2\dots A_n$ is congruent to a path $B_1B_2\dots B_n$, the path $B_1B_2\dots B_n$ is congruent to the path $A_1A_2\dots A_n$. $A_1A_2\dots A_n \equiv B_1B_2\dots B_n$, $B_1B_2\dots B_n \equiv C_1C_2\dots C_n$ implies $A_1A_2\dots A_n \equiv C_1C_2\dots C_n$.*

Proof. $\square$

Again, if a path, in particular, a polygon, $A_1A_2\dots A_n$ is congruent to a path $B_1B_2\dots B_n$, we shall also say (and C 1.3.11.2 gives us the right to do so) that the paths $A_1A_2\dots A_n$ and $B_1B_2\dots B_n$ are congruent.

We are now in a position to prove theorem opposite to T 1.3.3.

Theorem 1.3.12. *If one angle, say, $\angle CAB$, of a triangle $\triangle ABC$ is congruent to another angle, say, $\angle ACB$, then $\triangle ABC$ is an isosceles triangle with $\angle ABC \equiv \angle ABC$.*

Proof. Let in a $\triangle ABC$ $\angle CAB \equiv \angle ACB$. Then by T 1.3.12 $\angle ACB \equiv \angle CAB$ and $AC \equiv \,\&\, \angle CAB \equiv \angle ACB \,\&\, \angle CAB \equiv$ $\angle ACB \overset{T1.3.11}{\Longrightarrow} \triangle CAB \equiv \triangle ACB \Rightarrow AB \equiv CB$. $\square$

Comparison of Intervals

Lemma 1.3.13.1. *For any point C lying on an open interval (AB), there are points $E, F \in (AB)$ such that $AC \equiv EF$.*

Proof. (See Fig. 1.119.) Suppose $[ACB]$. By T 1.2.1 $\exists F$ $[CFB]$. Then $[ACB] \,\&\, [CFB] \overset{L1.2.3.2}{\Longrightarrow} [ACF] \,\&\, [AFB]$. $[ACF] \,\&\, AF \equiv FA \overset{C1.3.9.2}{\Longrightarrow} \exists E\ [FEA] \,\&\, AC \equiv FE$. Finally, $[AEF] \,\&\, [AFB] \overset{L1.2.3.2}{\Longrightarrow} [AEB]$. $\square$

The following lemma is opposite, in a sense, to L 1.3.13.1

ARMSTRONG NUMBERS

Some numbers, often referred to as Armstrong numbers,[11] are each equal to the sum of their digits, each of which is taken to the power equal to the number of digits in the original number.

For example, the three-digit number 153 $=1^3+5^3+3^3$. Strangely enough, while there are no two-digit Armstrong numbers, there are four three-digit Armstrong numbers as follows (figure 1-8):

n	$100 \le n \le 999$	
153	$1^3 + 5^3 + 3^3 = 1 + 125 + 27$	= 153
370	$3^3 + 7^3 + 0^3 = 27 + 343 + 0$	= 370
371	$3^3 + 7^3 + 1^3 = 27 + 343 + 1$	= 371
407	$4^3 + 0^3 + 7^3 = 64 + 0 + 343$	= 407

Figure 1-8

There are three four-digit Armstrong numbers as seen below (figure 1-9).

n	$1{,}000 \le n \le 9{,}999$	
1,634	$1^4 + 6^4 + 3^4 + 4^4 = 1 + 1{,}296 + 81 + 256$	= 1,634
8,208	$8^4 + 2^4 + 0^4 + 8^4 = 4{,}096 + 16 + 0 + 4{,}096$	= 8,208
9,474	$9^4 + 4^4 + 7^4 + 4^4 = 6{,}561 + 256 + 2{,}401 + 256$	= 9,474

Figure 1-9

Among the five-digit numbers, there are three Armstrong numbers (figure 1-10).

n	$10{,}000 \le n \le 99{,}999$	
54,748	$5^5 + 4^5 + 7^5 + 4^5 + 8^5 = 3{,}125 + 1{,}024 + 16{,}807 + 1{,}024 + 32{,}768$	= 54,748
92,727	$9^5 + 2^5 + 7^5 + 2^5 + 7^5 = 59{,}049 + 32 + 16{,}807 + 32 + 16{,}807$	= 92,727
93,084	$9^5 + 3^5 + 0^5 + 8^5 + 4^5 = 59{,}049 + 243 + 0 + 32{,}768 + 1{,}024$	= 93,084

Figure 1-10

The only Armstrong number among the six-digit numbers is: 548,834.

$5^6 + 4^6 + 8^6 + 8^6 + 3^6 + 4^6 = 15{,}625 + 4{,}096 + 262{,}144 + 262{,}144 + 729 + 4{,}096 = 548{,}834$

---

[11] L. Deimel Jr. and M. Jones, "Finding Pluperfect Digital Invariants," *Journal of Recreational Mathematics* 42, no. 2 (1981–82): 87–107.

The following is a table (figure 1-11) that lists the Armstrong numbers of 7–10 digits.

k	**Armstrong numbers**
7	$n =$ 1,741,725; 4,210,818; 9,800,817; 9,926,315
8	$n =$ 24,678,050; 24,678,051; 88,593,477
9	$n =$ 146,511,208; 472,335,975; 534,494,836; 912,985,153
10	$n =$ 4,679,307,774

Figure 1-11

Here is a number that is 39 digits long:

115,132,219,018,763,992,565,095,597,973,971,522,401

and is equal to the sum of its digits, each of which is taken to the thirty-ninth power, thus making it an Armstrong number. Furthermore, it is the largest Armstrong number. In other words,

$$\begin{aligned}&1^{39}+1^{39}+5^{39}+1^{39}+3^{39}+2^{39}+2^{39}+1^{39}+9^{39}+0^{39}+1^{39}+8^{39}+7^{39}+6^{39}+3^{39}+9^{39}\\&\quad+9^{39}+2^{39}+5^{39}+6^{39}+5^{39}+0^{39}+9^{39}+5^{39}+5^{39}+9^{39}+7^{39}+9^{39}+7^{39}+3^{39}+9^{39}\\&\quad+7^{39}+1^{39}+5^{39}+2^{39}+2^{39}+4^{39}+0^{39}+1^{39}\\&\quad=115{,}132{,}219{,}018{,}763{,}992{,}565{,}095{,}597{,}973{,}971{,}522{,}401\\&\quad\approx 1.151322190\cdot 10^{38}\end{aligned}$$

Figure 1-12

There are no Armstrong numbers for $k = 2, 12, 13, 15, 18, 22, 26, 28, 30$, and 36 (and $k > 39$). In fact, there are only eighty-nine Armstrong numbers in the decimal system.

The following is a list of the *consecutive* Armstrong numbers:

$k = 3$: 370; 371
$k = 8$: 24,678,050; 24,678,051
$k = 11$: 32,164,049,650; 32,164,049,651
$k = 16$: 4,338,281,769,391,370; 4,338,281,769,391,371
$k = 25$: 3,706,907,995,955,475,988,644,380; 3,706,907,995,955,475,988,644,381
$k = 29$: 19,008,174,136,254,279,995,012,734,740;
19,008,174,136,254,279,995,012, 734,741
$k = 33$: 186,709,961,001,538,790,100,634,132,976,990;
186,709,961,001,538,790,100, 634,132,976,991
$k = 39$: 115,132,219,018,763,992,565,095,597,973,971,522,400
115,132,219,018,763, 992,565,095,597,973,971,522,401

Incidentally, our first Armstrong number, 153, has some other amazing properties. It is a triangular number, where

$$1 + 2 + 3 + 4 + 5 + 6 + 7 + 8 + 9 + 10 + 11 + 12 + 13 + 14 + 15 + 16 + 17 = 153$$

The number 153 is not only equal to the sum of the cubes of its digits ($1^3 + 5^3 + 3^3 = 1 + 125 + 27 = 153$) but it is also a number that can be expressed as the sum of consecutive factorials:[12] $1! + 2! + 3! + 4! + 5! = 153$.

Can you discover other properties of this ubiquitous number 153?

MORE NUMBER CURIOSITIES

As an "extension" of the Armstrong numbers, we will present numbers where the sum of the digits of the original number—each taken to the power one more or less than the number of digits in the original number—is equal to the original number. This differs from the Armstrong numbers, where the power to which each of the digits was taken was equal to the number of digits in the original number.

To begin, consider the following four-digit numbers where each of the digits is take to the fifth power and the sum is equal to the original number.

$4{,}150 = 4^5 + 1^5 + 5^5 + 0^5$
$4{,}151 = 4^5 + 1^5 + 5^5 + 1^5$

---

[12] $n!$ reads "n factorial" and equals $n\cdot(n-1)\cdot(n-2)\cdot\ldots\cdot3\cdot2\cdot1$.

The following are some other examples of non-Armstrong numbers:

$194{,}979 = 1^5 + 9^5 + 4^5 + 9^5 + 7^5 + 9^5$
$14{,}459{,}929 = 1^7 + 4^7 + 4^7 + 5^7 + 9^7 + 9^7 + 2^7 + 9^7$

Here is a forty-one-digit number[13] that is equal to the sum of the digits, each taken to the forty-second power: 36,428,594,490,313,158,783,584,452,532,870,892,261,556

$3^{42} + 6^{42} + 4^{42} + 2^{42} + 8^{42} + 5^{42} + 9^{42} + 4^{42} + 4^{42} + 9^{42} + 0^{42} + 3^{42} + 1^{42} + 3^{42} + 1^{42} + 5^{42}$
$+ 8^{42} + 7^{42} + 8^{42} + 3^{42} + 5^{42} + 8^{42} + 4^{42} + 4^{42} + 5^{42} + 2^{42} + 5^{42} + 3^{42} + 2^{42} + 8^{42} + 7^{42}$
$+ 0^{42} + 8^{42} + 9^{42} + 2^{42} + 2^{42} + 6^{42} + 1^{42} + 5^{42} + 5^{42} + 6^{42}$
$= 36{,}428{,}594{,}490{,}313{,}158{,}783{,}584{,}452{,}532{,}870{,}892{,}261{,}556$

The relationships between numbers and powers can be fascinating. Here are a few to relish.

Notice how, in these cases, quite the opposite of the previous numbers, the powers reflect the original number and the base stays the same.

$4{,}624 = 4^4 + 4^6 + 4^2 + 4^4$
$1{,}033 = 8^1 + 8^0 + 8^3 + 8^3$
$595{,}968 = 4^5 + 4^9 + 4^5 + 4^9 + 4^6 + 4^8$
$3{,}909{,}511 = 5^3 + 5^9 + 5^0 + 5^9 + 5^5 + 5^1 + 5^1$
$13{,}177{,}388 = 7^1 + 7^3 + 7^1 + 7^7 + 7^7 + 7^3 + 7^8 + 7^8$
$52{,}135{,}640 = 19^5 + 19^2 + 19^1 + 19^3 + 19^5 + 19^6 + 19^4 + 19^0$

Then there are those numbers that differ from the previous examples and lend themselves to an even more astonishing pattern: here the powers and the bases match the original digits.[14]

$3{,}435 = 3^3 + 4^4 + 3^3 + 5^5$
$438{,}579{,}088 = 4^4 + 3^3 + 8^8 + 5^5 + 7^7 + 9^9 + 0^0 + 8^8 + 8^8$

We can also find a reversal of this pattern, namely, where the bases go in the proper order and the exponents progress in the reverse order.

$48{,}625 = 4^5 + 8^2 + 6^6 + 2^8 + 5^4$
$397{,}612 = 3^2 + 9^1 + 7^6 + 6^7 + 1^9 + 2^3$

---

[13] See L. E. Deimel Jr. and M. T. Jones, *Journal of Recreational Mathematics* 14, no. 4 (1981–82): 284.

[14] Although 0^0 is undefined, we shall value it at 0 for our purposes here.

Searching through our number system reveals that there are also some entertaining patterns where consecutive exponents are used:

$$\begin{aligned}
43 &= 4^2 + 3^3\\
63 &= 6^2 + 3^3\\
89 &= 8^1 + 9^2\\
1{,}676 &= 1^5 + 6^4 + 7^3 + 6^2
\end{aligned}$$

Yet when we formalize this a bit and use the consecutive natural numbers as exponents, we have the following amazing relationships:

$$\begin{aligned}
135 &= 1^1 + 3^2 + 5^3\\
175 &= 1^1 + 7^2 + 5^3\\
518 &= 5^1 + 1^2 + 8^3\\
598 &= 5^1 + 9^2 + 8^3\\
1{,}306 &= 1^1 + 3^2 + 0^3 + 6^4\\
1{,}676 &= 1^1 + 6^2 + 7^3 + 6^4\\
2{,}427 &= 2^1 + 4^2 + 2^3 + 7^4\\
2{,}646{,}798 &= 2^1 + 6^2 + 4^3 + 6^4 + 7^5 + 9^6 + 8^7
\end{aligned}$$

You may have noticed that 1,676 appeared in both lists of consecutive exponents.

A further charming occurrence in mathematics—in the decimal system, of course—is seen with the following illustrations. Although you may find this a bit contrived, it simply highlights the notion that there are probably limitless nuggets we can cull from our numbers system.

$$\mathbf{16}^3 + \mathbf{50}^3 + \mathbf{33}^3 = 4{,}096 + 125{,}000 + 35{,}937 = \mathbf{16\ 5{,}0\ 33} = 165{,}033$$

$$\mathbf{166}^3 + \mathbf{500}^3 + \mathbf{333}^3 = 4{,}574{,}296 + 125{,}000{,}000 + 36{,}926{,}037 = \mathbf{166,\ 500,\ 333} = 166{,}500{,}333$$

$$\mathbf{588}^2 + \mathbf{2{,}353}^2 = 345{,}744 + 5{,}536{,}609 = \mathbf{5{,}88\ 2{,}353} = 5{,}882{,}353$$

MORE UNUSUAL NUMBER RELATIONSHIPS

There are a number of unusual relationships between certain numbers—as represented in the decimal system. There is not much explanation for them. So just enjoy them and see if you can find others like them.

We are going to present pairs of numbers where the product and the sum are reversals of each other (figure 1-13).

The two numbers		**their *product***	**their *sum***
9	9	81	18
3	24	72	27
2	47	94	49
2	497	994	499

Figure 1-13

Moving along to other number curiosities, consider the number 3,025. Suppose we split the number as 30 and 25, and then add these two numbers to get $30 + 25 = 55$. Then, if we square this result, we surprisingly get back to the original number: $55^2 = 3{,}025$. The question that immediately arises is "Are there other numbers for which this little procedure also works?"

Well, here are a few more such numbers:

$9{,}801 \rightarrow 98 + 01 = 99$ and $99^2 = 9{,}801$
$2{,}025 \rightarrow 20 + 25 = 45$ and $45^2 = 2{,}025$
$088{,}209 \rightarrow 088 + 209 = 297$ and $297^2 = 88{,}209$
$494{,}209 \rightarrow 494 + 209 = 703$ and $703^2 = 494{,}209$
$998{,}001 \rightarrow 998 + 001 = 999$ and $999^2 = 998{,}001$
$99{,}980{,}001 \rightarrow 9998 + 0001 = 9{,}999$ and $9{,}999^2 = 99{,}980{,}001$

Perhaps you can now find other numbers where this amazing relationship will hold.

While we are in the mode of "splitting" numbers, let's partition numbers to get some other fascinating relationships

$1{,}233 \rightarrow 12|\,33 = 12^2 + 33^2$
$8{,}833 \rightarrow 88|\,33 = 88^2 + 33^2$
$990{,}100 \rightarrow 990|\,100 = 990^2 + 100^2$
$94{,}122{,}353 \rightarrow 9412|\,2353 = 9{,}412^2 + 2{,}353^2$
$7{,}416{,}043{,}776 \rightarrow 74160|\,43776 = 74{,}160^2 + 43{,}776^2$
$116{,}788{,}321{,}168 \rightarrow 116788|\,321168 = 116{,}788^2 + 321{,}168^2$
$221{,}859 \rightarrow 22|\,18|\,59 = 22^3 + 18^3 + 59^3$
$166{,}500{,}333 \rightarrow 166|\,500|\,333 = 166^3 + 500^3 + 333^3$

You might like to verify some of the following that can be split, where the sum of the squares of the parts will equal the original number:

$10{,}100 \rightarrow 10|100 = 10^2 + 100^2$
$5{,}882{,}353 \rightarrow 588|2353 = 588^2 + 2{,}353^2$

Here are a few more such numbers: 9,901,0|09,901, 1,765,0|38,125, 2,584,0|43,776, 999,900|010,000, 123,288|328,768, and there are still more. You might want to verify this relationship. You can also find more of these numbers.

An analogous situation—this time using differences instead of sums—also produces some interesting relationships:

$48 \rightarrow 4|8 = 8^2 - 4^2$
$3{,}468 \rightarrow 34|68 = 68^2 - 34^2$
$416{,}768 \rightarrow 416|768 = 768^2 - 416^2$
$33{,}346{,}668 \rightarrow 3334|6668 = 6{,}668^2 - 3{,}334^2$

You might like to verify some of the following that can be split, where the difference of the squares of the parts will equal the original number. 16|128, 34|188, 140|400, 484|848, 530|901, 334|668, 234|1,548, and others.

AN UNUSUAL SITUATION

Sometimes numbers can be changed by accident. In a recent publication, a computer glitch dropped all the exponents to the base line. So that 8^3 was shown as 83. Would there be a value that would not be affected by such a computer failure? You can try all the possibilities and you may stumble upon $2^5 \cdot 9^2 = 2{,}592$, which is believed to be the only such case.

FRIENDLY NUMBERS

What could possibly make two numbers friendly? Your first reaction might be that this means numbers that are friendly to you. Actually, we will be inspecting numbers that are "friendly" to each other. Mathematicians have decided that two numbers are considered "friendly" (or as often used in the more sophisticated literature, "amicable") if the sum of the proper divisors[15] of one number equals the second number *and* the sum of the proper divisors of the second number equals the first number.

---

[15] *Proper divisors* of a number *n* are divisors that are smaller than the number *n*. That means 1 is a proper divisor, but *n* is not.

Sounds complicated? It's not at all difficult to understand. Let's look at the smallest pair of friendly numbers: 220 and 284.

The divisors of **220** (other than 220 itself) are 1, 2, 4, 5, 10, 11, 20, 22, 44, 55, and 110. Their sum is 1 + 2 + 4 + 5 + 10 + 11 + 20 + 22 + 44 + 55 + 110 = **284**.

The divisors of **284** (other than 284 itself) are 1, 2, 4, 71, and 142, and their sum is 1 + 2 + 4 + 71 + 142 = **220**. This shows that the two numbers are friendly numbers.

Although this pair of friendly numbers was already known to Pythagoras about 500 BCE, a second pair of friendly numbers, first discovered in 1636 by the French mathematician Pierre de Fermat (1607–1665),[16] is 17,296 and 18,416.

$17{,}296 = 2^4 \cdot 23 \cdot 47$, and $18{,}416 = 2^4 \cdot 1{,}151$

The sum of the factors of 17,296 is
1 + 2 + 4 + 8 + 16 + 23 + 46 + 47 + 92 + 94 + 184 + 188 + 368 + 376 + 752 + 1,081 + 2,162 + 4,324 + 8,648 = $\underline{18{,}416}$

The sum of the factors of 18,416 is
1 + 2 + 4 + 8 + 16 + 1,151 + 2,302 + 4,604 + 9,208 = $\underline{17{,}296}$

Thus, they, too, are truly friendly numbers!

Two years later, the French mathematician René Descartes (1596–1650) found another pair of friendly numbers: 9,363,584 and 9,437,056. By 1747, the Swiss mathematician Leonhard Euler (1707–1783) discovered sixty pairs of friendly numbers, yet he seemed to have overlooked the second smallest pair, which was discovered in 1866 by the sixteen-year-old Nicolò Paganini:

The sum of the factors of 1,184 is 1 + 2 + 4 + 8 + 16 + 32 + 37 + 74 + 148 + 296 + 592 = 1,210

And the sum of the factors of 1,210 is 1 + 2 + 5 + 10 + 11 + 22 + 55 + 110 + 121 + 242 + 605 = 1,184

We now have identified over 363,000 pairs of friendly numbers. Here are a few of these:

2,620 and 2,924
5,020 and 5,564
6,232 and 6,368
10,744 and 10,856
12,285 and 14,595
63,020 and 76,084
111,448,537,712 and 118,853,793,424

---

[16] There is evidence that Fermat's discovery was anticipated by the Morroccan mathematician Ibn al-Banna al-Marakushi al-Azdi (1256–ca. 1321).

You might want to verify the above pairs' "friendliness"!

For the experts, the following is one method for finding friendly numbers:

$$\text{Let}\quad \begin{aligned} a &= 3\cdot 2^n - 1 \\ b &= 3\cdot 2^{n-1} - 1 \\ c &= 3^2\cdot 2^{2n-1} - 1 \end{aligned}$$

where n is an integer ≥ 2 and where a, b, and c are all prime numbers, then $2^n\cdot ab$ and $2^n\cdot c$ are friendly numbers.
(Notice that for $n = 2$, 4, and 7 that a, b, and c are all prime for $n \leq 200$.)

Here is a list of friendly numbers less than 10,000,000:

	First number	Second number	Year of discovery	Discoverer
1	220	284	-	Pythagoras
2	1,184	1,210	1860	Paganini
3	2,620	2,924	1747	Euler
4	5,020	5,564	1747	Euler
5	6,232	6,368	1747	Euler
6	10,744	10,856	1747	Euler
7	12,285	14,595	1939	Brown
8	17,296	18,416	ca. 1310/1636	Ibn al-Banna/Fermat
9	63,020	76,084	1747	Euler

Chapter 4

GEOMETRY SURPRISES

The topic of geometry evokes, in many people, their high school memories of the subject. Usually, these recollections encompass the many proofs they were required to do to establish geometric relationships. Too often, the process of the proofs became the focus, overshadowing the actual relationships being proved and, unfortunately, leaving the beauty of geometry somewhat neglected. This chapter is intended to reverse that process. In order to demonstrate the beauty of geometry, we will present some truly awe-inspiring relationships—all of which (obviously) can be proved—but, so as not to disturb the "flow" of the presentation, we will merely refer you to sources where the proofs can be found. (See the bibliography for some suggested books.)

Join us now as we explore some truly amazing geometric relationships. However, before we embark on our journey through these geometric wonders, we must caution you that appearance alone can be misleading. Sometimes what appears to be true is not, and what appears impossible can be possible. This makes our journey through geometry that much more intriguing. To demonstrate that, we offer some optical illusions for your entertainment.

OPTICAL ILLUSIONS

In geometry, what you see is not always true. For example, in figure 4-1 you see two white squares. Most observers would say that the left-side white square is a bit smaller than the white square on the right. This is incorrect. They are both the same size. Their context and presentation make for an optical illusion.

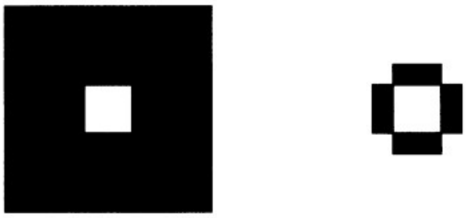

Figure 4-1

Another example to show you that your optical judgment may not be as accurate as you might think is that of figure 4-2, where the circle inscribed in the square on the left appears to be smaller than the circle circumscribed about the square on the right. Again, this is not true, since they are the same size.

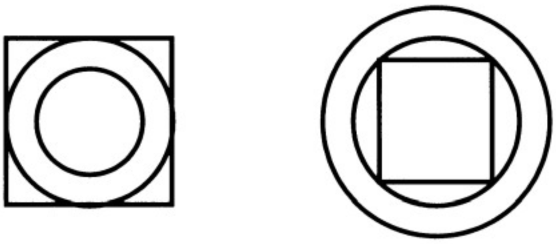

Figure 4-2

To further "upset" your sense of perception, consider the following few optical illusions. In figure 4-3, the center (black) circle on the left appears to be smaller than the center (black) circle on the right. Again, not so. They are both of equal size.

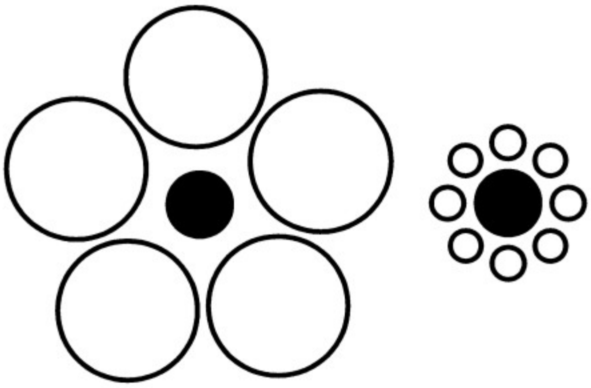

Figure 4-3

In figure 4-4, *AB* appears to be longer than *BC*, but it isn't. They are the same length.

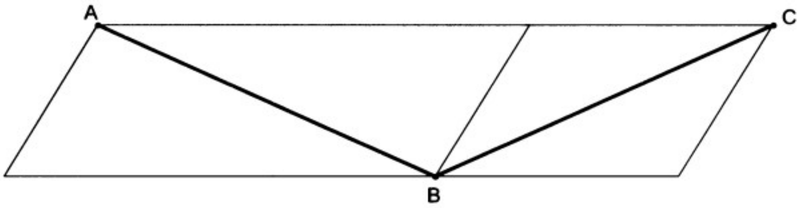

Figure 4-4

In figure 4-5, the horizontal line appears to be shorter than the vertical line, but, again, you have an optical illusion, since they are actually the same length.

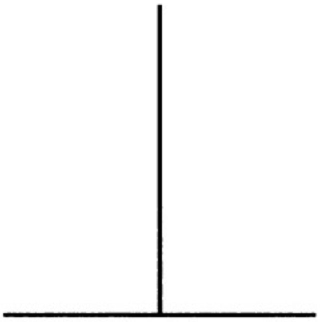

Figure 4-5

Some optical illusions are done intentionally. Take, for example, the *tribar* or *Penrose triangle* (figure 4-6). Popularized by Roger Penrose (1931–) in 1958, it was previously created in 1934 by Oscar Reutersvärd (1915–2002), a Swedish artist. It appears to be a triangle with three right angles. His invention was honored by the issuance of a postage stamp in 1982 (see figure 4-7).[1]

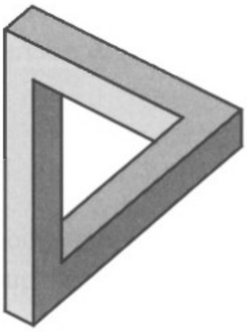

Figure 4-6

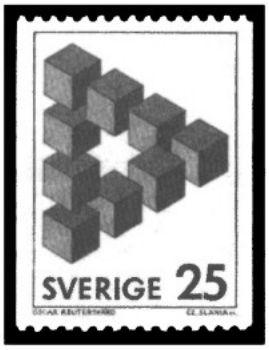

Figure 4-7

---

[1] Swedish postage stamp: 25 Öre, Sverige, February 16, 1982.

A postage stamp depicting an "irrational" cube was issued by the Republic of Austria in 1981 to commemorate the tenth International Mathematics Congress in Innsbruck (see figure 4-8).

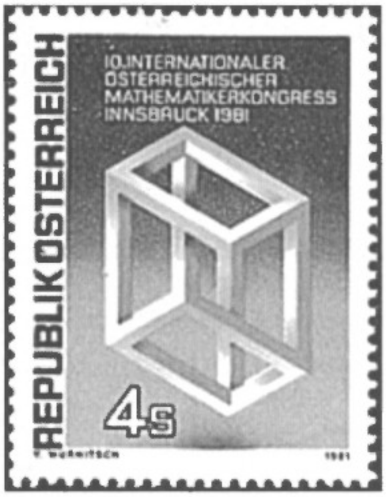

Figure 4-8

Just as there are optical illusions throughout our geometric world, so too there are "proofs" that can be fallacious, not by their errors in reasoning, but rather in their assumptions of geometric appearances.

A very popular "fallacy proof" is that every triangle can be proved to be isosceles.[2] The error in the proof is one that might have baffled Euclid, who did not properly define the concept of betweenness.[3]

Do not let these unusual optical illusions and tricks in geometry disillusion you. There is much beauty in geometry that is true. By this we are not referring to visually beautiful things, rather we are referring to amazing relationships that you would not think possible. We will present some here to rekindle your curiosity and to enhance your perception of geometry as more than just something that is optically interesting or just a series of proofs.

LOOKING AT GEOMETRY CRITICALLY

Consider the two squares in figure 4-9, where the smaller one has a side of length 3 and the larger one has a side of length 4, and where the vertex (or corner) M of square $MNPQ$ is the center of square $ABCD$.

---

[2] A triangle with two equal sides is called *isosceles*.

[3] For a complete discussion of this, see A. S. Posamentier, *Advanced Euclidean Geometry* (Hoboken, NJ: John Wiley, 2002), pp. 13–15.

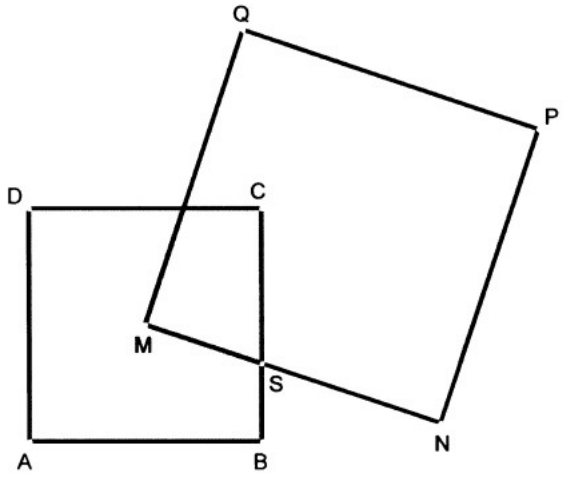

Figure 4-9

The question we raise is what is the area of the overlapping portion of the two squares? Does the exact relative position of the two squares matter? Since the exact placement of the two squares was not given—just the vertex *M*—suppose we rotate the larger square to the position shown in figure 4-10 or to that shown in figure 4-11. In either case, the "restrictions" mentioned in the original situation are still upheld, namely, that the vertex of one square is at the center of the other. From either of these new positions (figure 4-10 or 4-11), we can conclude that the overlapping portion is one-fourth of the area of the smaller square *ABCD*.

Yet this raises the question about whether this can assure us that this is not just an "extreme" case but also one that holds between the extreme or special positions.

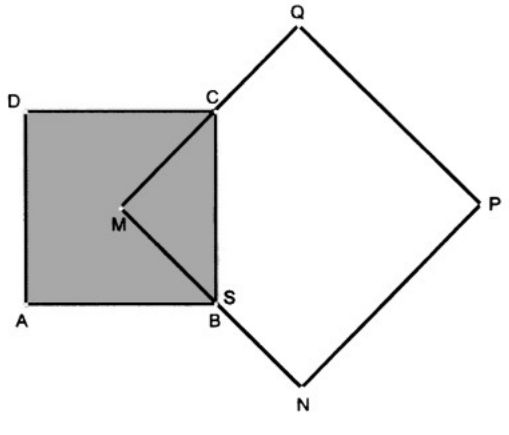

Figure 4-10

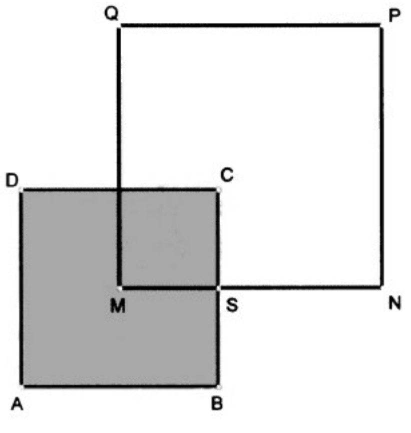

Figure 4-11

Suppose the larger square, *MNPQ*, is placed more "randomly," as shown in figure 4-12 and as it was positioned in our original question (figure 4-9). We can show (and, of course, prove) that the four regions into which square *ABCD* is partitioned all have the same area— since they can be shown to be congruent. This is a nice case of using extremes to guide us to a "conjecture" and we can then see it to be true for the random case shown in figure 4-12.

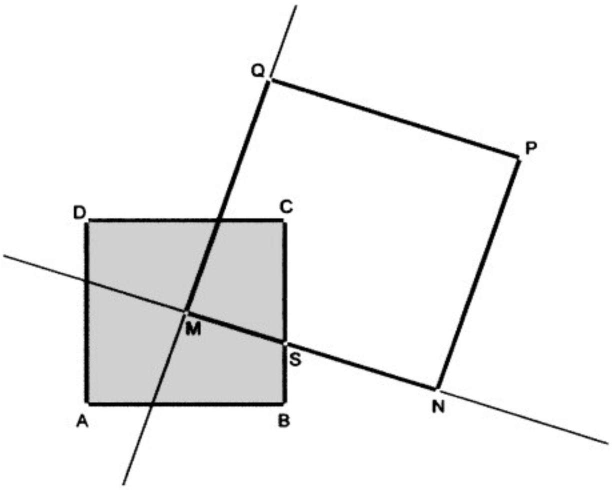

Figure 4-12

SOME TRIANGLE PROPERTIES—WITH MEDIANS

To impress you with the many wonderful, and often mind-boggling, relationships that exist in Euclidean plane geometry, we shall take you on an unfolding journey through various geometric shapes. When we refer to a triangle as being isosceles, we mean than it has two sides of equal length. A triangle with all sides of equal length is called *equilateral*. When we refer to a *scalene* triangle, it is one where all three sides are of different lengths. One way of finding some truly remarkable relationships derives from noticing that these unexpected relationships can occur in *any* triangle regardless of its shape!

We often take for granted that certain lines of a triangle behave as we would expect. For example, we know that the medians of a triangle (i.e., the lines joining a vertex with the midpoint of the opposite side) are concurrent—that is, they all go through the same point. In figure 4-13, *AF*, *BD*, and *CE* are the medians of triangle ΔABC, and *G* is their point of intersection (or the point of concurrency of the medians). This, in itself, is a fascinating reationship, since it is completely independent of the type of triangle. It holds true for *all* triangles!

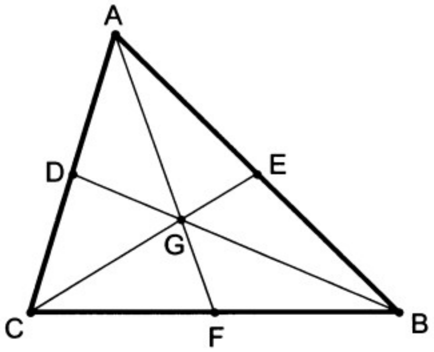

Figure 4-13

Furthermore, the medians partition the triangle into six smaller triangles, which happen to be equal in area. Again, this is true regardless of the shape of the triangle. That is, $Area\Delta ADG = Area\Delta AEG = Area\Delta BEG = Area\Delta BFG = Area\Delta CFG = Area\Delta CDG$.

We can also partition any triangle, say, ΔABC, into four congruent triangles ($\Delta ADE \cong \Delta CDF \cong \Delta FEB \cong \Delta EFD$) by using the midpoints of the three sides and joining them to form a medial triangle (see figure 4-14). Here, ΔEFD is called the *medial triangle* of ΔABC. Remember, these partitions hold true for *any* shape triangle.

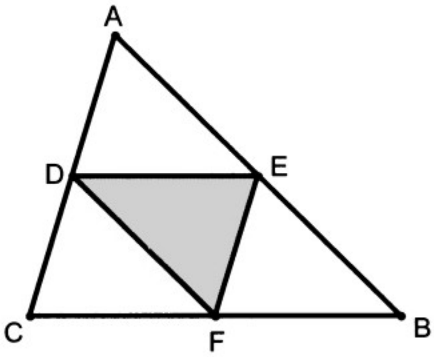

Figure 4-14

In other words, the area of triangle ΔABC is four times the area of triangle ΔEFD. That is, this relationship is a constant one that holds for all triangles.

In addition, point G (the point of intersection of the medians) is the center of gravity of the triangle, and is called the *centroid*. That is, if you want to balance a cardboard triangle on the tip of a pencil, you would need to find the centroid to place the point appropriately. We shall revisit the center of gravity a bit later. In the meantime, we can also appreciate another fascinating fact about the centroid of a triangle; namely, the centroid trisects each of the medians. In other words, in figure 4-15: $GD = \frac{1}{3}BD$, $GE = \frac{1}{3}CE$, and $GF = \frac{1}{3}AF$.

!$ (' $, ! 0

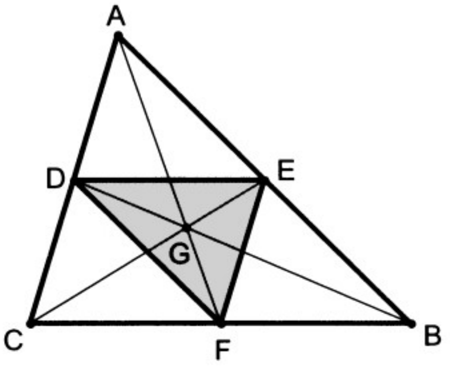

Figure 4-15

SOME QUADRILATERAL PROPERTIES

We shall now shift to inspect the quadrilateral and the midpoints of its sides. If we consecutively connect the midpoints of any quadrilateral with line segments, we always get a parallelogram (figure 4-16), which is called a *Varignon parallelogram.*[4] This is truly amazing, since it will hold true for any shape of a quadrilateral. Moreover, the Varignon parallelogram has half the area of the original quadrilateral, and its perimeter is equal to the sum of the lengths of the diagonals of the original quadrilateral. That is, in figure 4-16: the area of parallelogram *EFGH* is one-half of the area of quadrilateral *ABCD*, and the perimeter of parallelogram *EFGH* equals *AC* + *BD*.

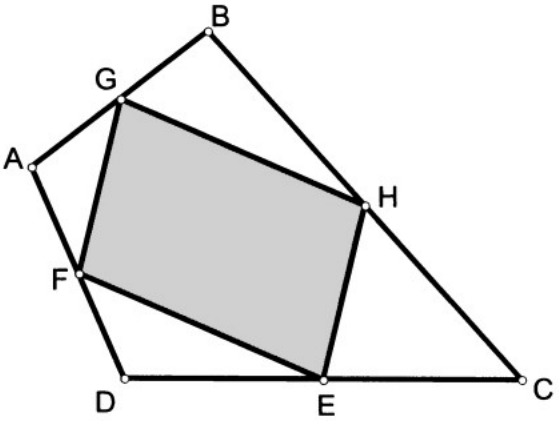

Figure 4-16

---

[4] Named for Pierre Varignon (1654–1722), a French mathematician. Although discovered in 1713, it was first published (posthumously) in 1731.

Just for curiosity's sake, let's see what happens when we reduce the length of one side of the quadrilateral, say, *AB*, to length zero. We get a triangle with one vertex having points *A*, *B*, and *G* coincide as in figure 4-17. Here, too, the resulting Varignon parallelogram still exists and is one-half the area of the original triangle (or quadrilateral with a zero-length side). You might want to relate this to our result in figure 4-14, where we found that the triangle *ABC* was partitioned into four triangles of equal area, leaving us with a similar result when we consider the parallelogram *ADFE* in figure 4-14, which is analogous to parallelogram *AFEH* in figure 4-17. The perimeter relationship (perimeter of parallelogram *EFGH* equals *AC* + *BD*) also holds true for the situation shown in figure 4-17. It is not only nice to have this consistency, it is essential!

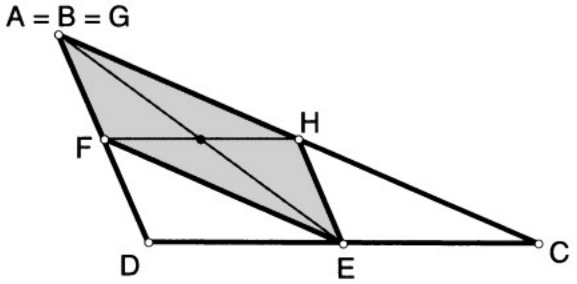

Figure 4-17

Of course, some quadrilaterals—when the midpoints of their sides are connected—will yield a special parallelogram, such as a rectangle, a square, or a rhombus (a parallelogram with all sides equal).

For example, suppose we consider a quadrilateral whose diagonals are perpendicular (see figure 4-18). When the side-midpoints of this quadrilateral are connected, a rectangle, *EFGH,* is produced.

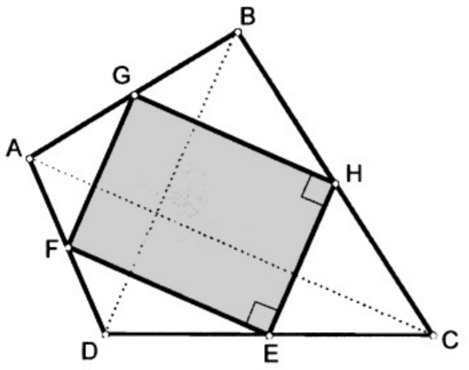

Figure 4-18

If the quadrilateral has perpendicular diagonals that are also the same length, then the quadrilateral produced by joining the side-midpoints is a special kind of rectangle that we know as a square! (See figure 4-19.)

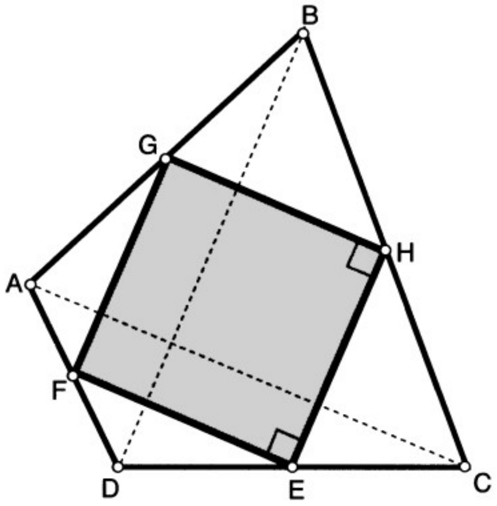

Figure 4-19

If the original quadrilateral has diagonals of equal length that are not perpendicular, then the quadrilateral formed by joining the side-midpoints will be a rhombus, as in figure 4-20.

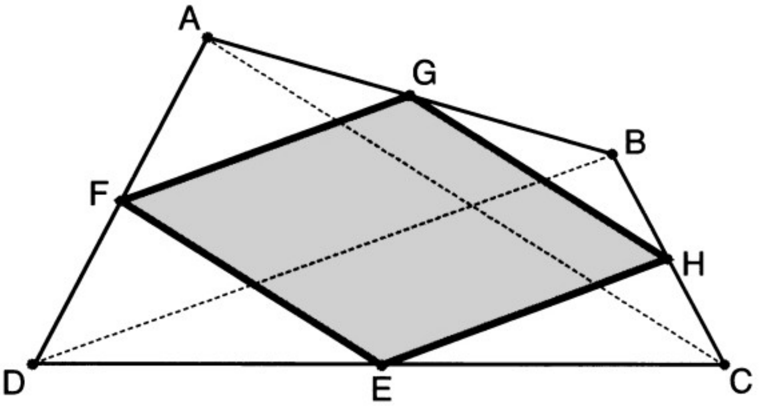

Figure 4-20

Naturally, we can continue this process of connecting consecutively the midpoints of the resulting parallelograms to get the series of parallelograms shown in figure 4-21.

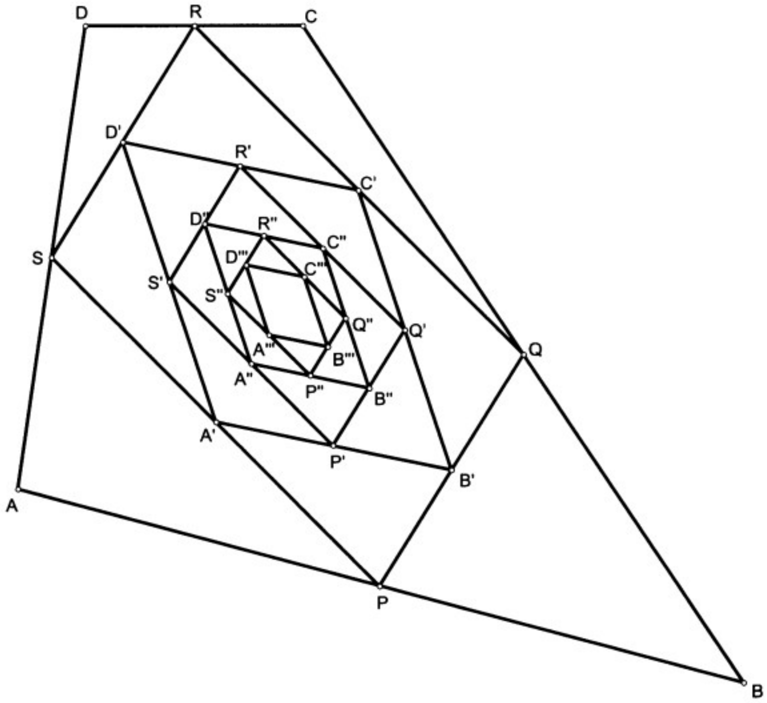

Figure 4-21

One of the prettier results from this investigation occurs when we can generate many special quadrilaterals from a randomly drawn quadrilateral. In the randomly drawn quadrilateral *ABCD* shown in figure 4-22 we connected the midpoints to form a parallelogram (*MNOP*). We then found the intersections of the bisectors of the angles of parallelogram *MNOP* to create rectangle *EFGH*. By bisecting each of the angles of this rectangle, we created the square *JKLR*. Therefore, from the randomly drawn quadrilateral *ABCD* we have created three special quadrilaterals: a parallelogram, a rectangle, and a square.

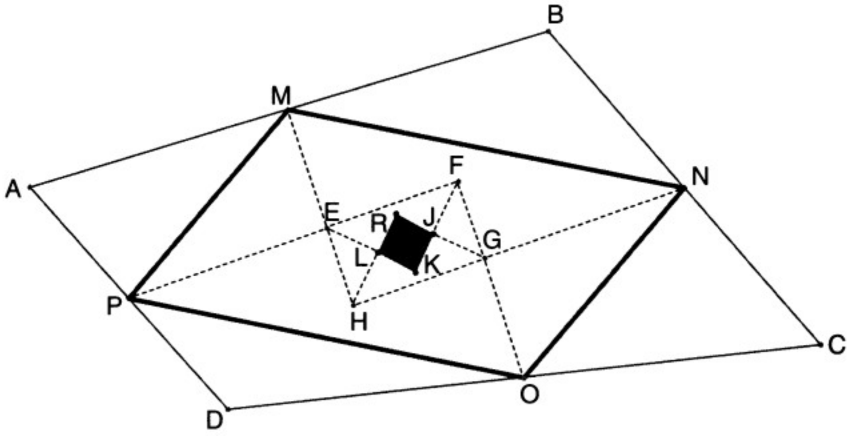

Figure 4-22

This is another example of the beauty of the geometric relationships that too often remain hidden. Their exposure is truly enlightening! You might want to try other ways of creating a square from a randomly drawn quadrilateral.

CENTER OF GRAVITY

Earlier (page 153), we located the center of gravity of a triangle (called the centroid) by finding the point of intersection of its medians. Some countries have run contests to find the "center" of their country. As you can see from figure 4-23, the contest submissions in Austria took on many creative methods. Yet the one that won the contest was for the town of Bad Aussee, where residents balanced a wooden map of the country on a point that was their town's location. Figure 4-23 is a translation of a plaque that designates the center of Austria in the town of Bad Aussee—as shown in the adjoining map (figure 4-24).

BAD AUSSEE

The geographic center in Austria
Latitude 47° 36' – Longitude 13° 47' east of border
(Dipl.-Ing. Otto Kloiber, Vienna)

MITTELPUNKT ÖSTERREICHS
BAD AUSSEE
1951

Why can Bad Aussee name itself the "Center of Austria?" Here is a brief review: In 1949 the magazine *Die Große Österreich Illustrierte* had a competition with the challenge of finding the center of Austria. Each Austrian had been invited to take part. The "winner" received a free vacation, which was a luxury then. The participants tried with different methods to find the navel of Austria. For example, the following:

THE DIAGONAL-SOLUTION:
Find the four points on the border, draw a rectangular of latitude and longitude along those points. The intersection of the diagonals would be the center.

THE CORNER-METHOD:
Find the point which is, in total length, the furthest away from the borders of Austria. The geometric solution would be the center of a circle whose circumference is tangent to the edges of other countries bordering Austria, and which reaches furthest into Austrian territory.

THE FOCAL POINT-THEORY:
Glue the map of Austria onto cardboard and cut out the map exactly along the borders. Put this Austria on the tip of a needle and move it around till the map balances.

The people of Bad Aussee started measuring and balancing and wrote to the magazine: "We are the ones!" The magazine confirmed (after a survey by the University of Vienna): "Bad Aussee is the center of Austria." The official ceremony with the actress Maria Andergast was on September 24, 1949.

In 1989 the local chamber of commerce of Bad Aussee used the 40th anniversary of the center-designation to celebrate with various festivities that the town is now the heart of Austria. As a permanent monument to remind everyone, that Bad Aussee is the center of Austria, a "center-stone" has been dedicated in the spa-gardens of the town.

The bronze plaque on the center-stone, a so-called "Omphalos" (Greek for "navel"), symbolizes the center. The inscription is in Gothic print and originated from the municipal seal of Aussee from 1505 and reads "Ause."

Furthermore, the local chamber of commerce strove to protect this title and applied to the Austrian patent office, which rendered this official designation in September 1991.

Vou explicar melhor:

Com Varignon Parallelogram poderemos obter um paralelogramma, ou seja, 2 pares de retas paralelas que foram obtidas de um quadrilátero (que nem sempre) é regular.

Desta forma nós conseguiremos obter padrões para realizar deduções de cálculos de áreas e assim,

19.04.20

inferimos a área total deste quadrilátero irregular, cujos (~~arestas~~) lados não são paralelas e os ângulos formados entre elas (~~arestas~~) (lados) são desconhecidos.

Obs: Aresta é a reta que se origina a partir da intersecção de 2 planos que formam um ângulo.
(3D do quadrilátero irregular)

Varignon parallelogram aplica-se para todos tipos de quadrilátero: regular e irregular.

(quadrado)
↳ é um paralelograma.
↳ é um polígono que reúne os características do losango e do retângulo ao mesmo tempo.
↳ os lados são congruentes (mesma medida).
↳ um quadrado também pode ser chamado de losango.

Obs: 1. Todo paralelogramo é quadrado, retângulo ou losango;
2. Todo retângulo ou losango é também um quadrado.

IMPORTANT:

rôle in crystallography; elementary crystals are close-packed and produce simple or complex space-lattices according to the different elements and different axes of symmetry. The basic configurations are the three principal systems of partition of space: cubic, hexagonal (derived from close-packed hexagonal or tetrahedral prisms) and cuboctahedric, which partakes of the two previous ones.[1] There are in all seven fundamental groups of symmetry, representing 230 possible types of point-lattices.[2] The fundamental law in crystallography is the "law of rational coefficients": the coefficients expressing (in three-dimensional analytical geometry) the relations between the different plane facets of a crystal and the directions of the three principal axes of symmetry are small integer numbers.

The different configurations of crystallized matter correspond to states of stable or relatively stable equilibrium determined by rigorous causality, the chemical reactions of the different elements being themselves explained by a tendency of the electrons to combine with each other according to more stable arrangements. The most general principle governing the states of equilibrium of physico-chemical systems is the "Criterium of Dirichlet": in order that the equilibrium of a closed system should be stable it is sufficient that its potential energy should be (or should pass through) a minimum. A corollary is Curie's Law: a body tends to take the shape presenting the minimum surface energy made possible by the directing forces. In many cases (for crystalline systems as well as for the more complex ones of organic chemistry) the minimum of superficial potential energy corresponds to the solution which for a given volume produces the smallest surface agreeing with the linking forces. (In space the sphere gives

2.1.3 Filters, Ripple Voltage, and Diode Current

If a capacitor is added in parallel with the load resistor of a half-wave rectifier to form a simple filter circuit (Figure 2.8(a)), we can begin to transform the half-wave sinusoidal output into a dc voltage. Figure 2.8(b) shows the positive half of the output sine wave, and the beginning portion of the voltage across the capacitor, assuming the capacitor is initially uncharged. If we assume that the diode forward resistance is $r_f = 0$, which means that the $r_f C$ time constant is zero, the voltage across the capacitor follows this initial portion of the signal voltage. When the signal voltage reaches its peak and begins to decrease, the voltage across the capacitor also starts to decrease, which means the capacitor starts to discharge. The only discharge current path is through the resistor. If the RC time constant is large, the voltage across the capacitor discharges exponentially with time (Figure 2.8(c)). During this time period, the diode is cut off.

A more detailed analysis of the circuit response when the input voltage is near its peak value indicates a subtle difference between actual circuit operation and the qualitative description. If we assume that the diode turns off immediately when the input voltage starts to decrease from its peak value, then the output voltage will decrease exponentially with time, as previously indicated. An exaggerated sketch of these two voltages is shown in Figure 2.8(d). The output voltage decreases at a faster rate than the input voltage, which means that at time t_1, the difference between v_I and

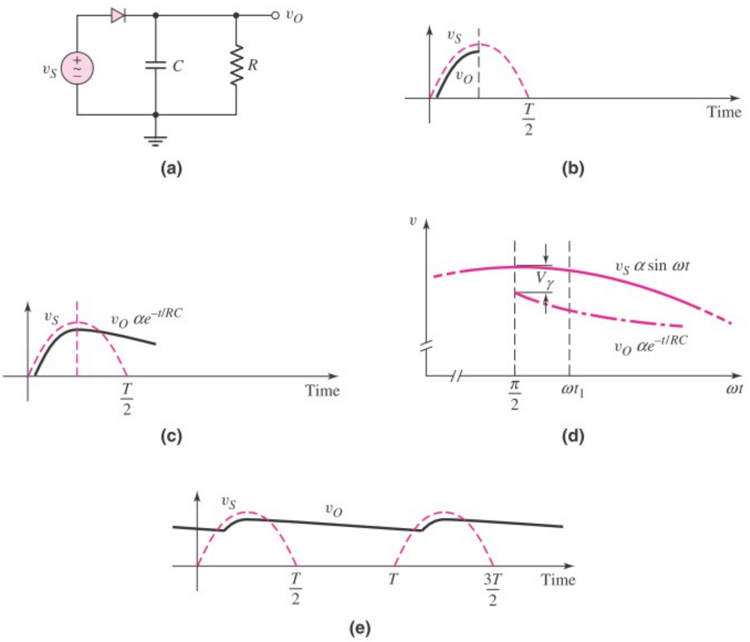

Figure 2.8 Simple filter circuit: (a) half-wave rectifier with an RC filter, (b) positive input voltage and initial portion of output voltage, (c) output voltage resulting from capacitor discharge, (d) expanded view of input and output voltages assuming capacitor discharge begins at $\omega t = \pi/2$, and (e) steady-state input and output voltages

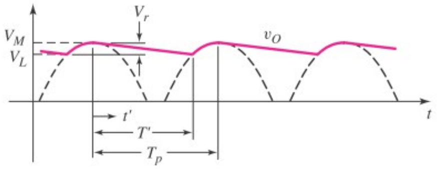

Figure 2.9 Output voltage of a full-wave rectifier with an *RC* filter showing the ripple voltage

v_O, that is, the voltage across the diode, is greater than V_γ. However, this condition cannot exist. Therefore, the diode does not turn off immediately. If the *RC* time constant is large, there is only a small difference between the time of the peak input voltage and the time the diode turns off. In this situation, a computer analysis may provide more accurate results than an approximate hand analysis.

During the next positive cycle of the input voltage, there is a point at which the input voltage is greater than the capacitor voltage, and the diode turns back on. The diode remains on until the input reaches its peak value and the capacitor voltage is completely recharged.

Since the capacitor filters out a large portion of the sinusoidal signal, it is called a **filter capacitor.** The steady-state output voltage of the *RC* filter is shown in Figure 2.8(e).

The ripple effect in the output from a full-wave filtered rectifier circuit can be seen in the output waveform in Figure 2.9. The capacitor charges to its peak voltage value when the input signal is at its peak value. As the input decreases, the diode becomes reverse biased and the capacitor discharges through the output resistance *R*. Determining the ripple voltage is necessary for the design of a circuit with an acceptable amount of ripple.

To a good approximation, the output voltage, that is, the voltage across the capacitor or the *RC* circuit, can be written as

$$v_O(t) = V_M e^{-t'/\tau} = V_M e^{-t'/RC} \tag{2.3}$$

where t' is the time after the output has reached its peak value, and *RC* is the time constant of the circuit.

The smallest output voltage is

$$V_L = V_M e^{-T'/RC} \tag{2.4}$$

where T' is the discharge time, as indicated in Figure 2.9.

The **ripple voltage** V_r is defined as the difference between V_M and V_L, and is determined by

$$V_r = V_M - V_L = V_M(1 - e^{-T'/RC}) \tag{2.5}$$

Normally, we will want the discharge time T' to be small compared to the time constant, or $T' \ll RC$. Expanding the exponential in a series and keeping only the linear terms of that expansion, we have the approximation[2]

$$e^{-T'/RC} \cong 1 - \frac{T'}{RC} \tag{2.6}$$

---

[2] We can show that the difference between the exponential function and the linear approximation given by Equation (2.6) is less than 0.5 percent for $RC = 10T'$. We need a relatively large *RC* time constant for this application.

The ripple voltage can now be written as

$$V_r \cong V_M\left(\frac{T'}{RC}\right) \qquad \textbf{(2.7)}$$

Since the discharge time T' depends on the RC time constant, Equation (2.7) is difficult to solve. However, if the ripple effect is small, then as an approximation, we can let $T' = T_p$, so that

$$V_r \cong V_M\left(\frac{T_p}{RC}\right) \qquad \textbf{(2.8)}$$

where T_p is the time between peak values of the output voltage. For a full-wave rectifier, T_p is one-half the signal period. Therefore, we can relate T_p to the signal frequency,

$$f = \frac{1}{2T_p}$$

The ripple voltage is then

$$V_r = \frac{V_M}{2fRC} \qquad \textbf{(2.9)}$$

For a half-wave rectifier, the time T_p corresponds to a full period (not a half period) of the signal, so the factor 2 does not appear in Equation (2.9). The factor of 2 shows that the full-wave rectifier has half the ripple voltage of the half-wave rectifier.

Equation (2.9) can be used to determine the capacitor value required for a particular ripple voltage.

EXAMPLE 2.3

Objective: Determine the capacitance required to yield a particular ripple voltage.

Consider a full-wave rectifier circuit with a 60 Hz input signal and a peak output voltage of $V_M = 10$ V. Assume the output load resistance is $R = 10\ \text{k}\Omega$ and the ripple voltage is to be limited to $V_r = 0.2$ V.

Solution: From Equation (2.9), we can write

$$C = \frac{V_M}{2fRV_r} = \frac{10}{2(60)(10 \times 10^3)(0.2)} \Rightarrow 41.7\ \mu\text{F}$$

Comment: If the ripple voltage is to be limited to a smaller value, a larger filter capacitor must be used. Note that the size of the ripple voltage and the size of filter capacitor are related to the load resistance R.

EXERCISE PROBLEM

Ex 2.3: Assume the input signal to a rectifier circuit has a peak value of $V_M = 12$ V and is at a frequency of 60 Hz. Assume the output load resistance is $R = 2\ \text{k}\Omega$ and the ripple voltage is to be limited to $V_r = 0.4$ V. Determine the capacitance required to yield this specification for a (a) full-wave rectifier and (b) half-wave rectifier. (Ans. (a) $C = 125\ \mu$F, (b) $C = 250\ \mu$F).

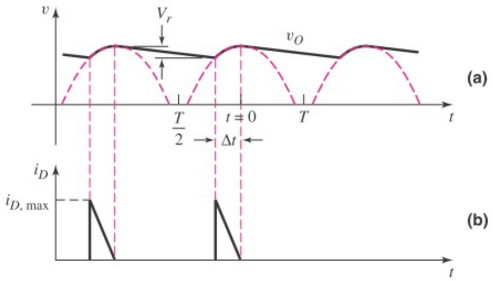

Figure 2.10 Output of a full-wave rectifier with an *RC* filter: (a) diode conduction time and (b) diode current

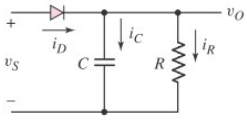

Figure 2.11 Equivalent circuit of a full-wave rectifier during capacitor charging cycle

The diode in a filtered rectifier circuit conducts for a brief interval Δt near the peak of the sinusoidal input signal. The diode current supplies the charge lost by the capacitor during the discharge time. Figure 2.10 shows the rectified output of a full-wave rectifier and the filtered output assuming ideal diodes ($V_\gamma = 0$) in the rectifier circuit. We will use this approximate model to estimate the diode current during the diode conduction time. Figure 2.11 shows the equivalent circuit of the full-wave rectifier during the charging time. We see that

$$i_D = i_C + i_R = C\frac{dv_O}{dt} + \frac{v_O}{R} \tag{2.10}$$

During the diode conduction time near $t = 0$ (Figure 2.10), we can write

$$v_O = V_M \cos \omega t \tag{2.11}$$

For small ripple voltages, the diode conduction time is small, so we can approximate the output voltage as

$$v_O = V_M \cos \omega t \cong V_M\left[1 - \frac{1}{2}(\omega t)^2\right] \tag{2.12}$$

The charging current through the capacitor is

$$i_C = C\frac{dv_O}{dt} = CV_M\left[-\frac{1}{2}(2)(\omega t)(\omega)\right] = -\omega CV_M\omega t \tag{2.13}$$

From Figure 2.10, the diode conduction occurs during the time $-\Delta t < t < 0$, so that the capacitor current is positive and is a linear function of time. We note that at $t = 0$, the capacitor current is $i_C = 0$. At $t = -\Delta t$, the capacitor charging current is at a peak value and is given by

$$i_{C,\text{peak}} = -\omega CV_M[\omega(-\Delta t)] = +\omega CV_M\omega\Delta t \tag{2.14}$$

The capacitor current during the diode charging time is approximately triangular and is shown in Figure 2.10(b).

From Equation (2.11), we can write that the voltage V_L is given by

$$V_L = V_M \cos[\omega(-\Delta t)] \cong V_M\left[1 - \frac{1}{2}(\omega\Delta t)^2\right] \tag{2.15}$$

Solving for $\omega\Delta t$, we find

$$\omega\Delta t = \sqrt{\frac{2V_r}{V_M}} \tag{2.16}$$

where $V_r = V_M - V_L$.

From Equation (2.9), we can write

$$fC = \frac{V_M}{2RV_r} \tag{2.17(a)}$$

or

$$2\pi fC = \omega C = \frac{\pi V_M}{RV_r} \tag{2.17(b)}$$

Substituting Equations (2.17(b)) and (2.16) into Equation (2.14), we have

$$i_{C,\text{peak}} = \left(\frac{\pi V_M}{RV_r}\right) V_M \left(\sqrt{\frac{2V_r}{V_M}}\right) \tag{2.18(a)}$$

or

$$i_{C,\text{peak}} = \pi \frac{V_M}{R}\sqrt{\frac{2V_M}{V_r}} \tag{2.18(b)}$$

Since the charging current through the capacitor is triangular, we have that the average capacitor current during the diode charging time is

$$i_{C,\text{avg}} = \frac{\pi}{2}\frac{V_M}{R}\sqrt{\frac{2V_M}{V_r}} \tag{2.19}$$

During the capacitor charging time, there is still a current through the load. This current is also being supplied through the diode. Neglecting the ripple voltage, the load current is approximately

$$i_L \cong \frac{V_M}{R} \tag{2.20}$$

Therefore, the peak diode current during the diode conduction time for a full-wave rectifier is approximately

$$i_{D,\text{peak}} \cong \frac{V_M}{R}\left(1 + \pi\sqrt{\frac{2V_M}{V_r}}\right) \tag{2.21}$$

and the average diode current during the diode conduction time is

$$i_{D,\text{avg}} \cong \frac{V_M}{R}\left(1 + \frac{\pi}{2}\sqrt{\frac{2V_M}{V_r}}\right) \tag{2.22}$$

The average diode current over the entire input signal period is

$$i_D(\text{avg}) = \frac{V_M}{R}\left(1 + \frac{\pi}{2}\sqrt{\frac{2V_M}{V}}\right)\frac{\Delta t}{T} \tag{2.23}$$

For the full-wave rectifier, we have $1/2T = f$, so

$$\Delta t = \frac{1}{\omega}\sqrt{\frac{2V_r}{V_M}} = \frac{1}{2\pi f}\sqrt{\frac{2V_r}{V_M}} \tag{2.24(a)}$$

Then

$$\frac{\Delta t}{T} = \frac{1}{2\pi f}\sqrt{\frac{2V_r}{V_M}}2f = \frac{1}{\pi}\sqrt{\frac{2V_r}{V_M}} \tag{2.24(b)}$$

Then the average current through the diode during the entire cycle for a full-wave rectifier is

$$i_D(\text{avg}) = \frac{1}{\pi}\sqrt{\frac{2V_r}{V_M}}\frac{V_M}{R}\left(1 + \frac{\pi}{2}\sqrt{\frac{2V_M}{V_r}}\right) \tag{2.25}$$

DESIGN EXAMPLE 2.4

Objective: Design a full-wave rectifier to meet particular specifications.

A full-wave rectifier is to be designed to produce a peak output voltage of 12 V, deliver 120 mA to the load, and produce an output with a ripple of not more than 5 percent. An input line voltage of 120 V (rms), 60 Hz is available.

Solution: A full-wave bridge rectifier will be used, because of the advantages previously discussed. The effective load resistance is

$$R = \frac{V_O}{I_L} = \frac{12}{0.12} = 100\,\Omega$$

Assuming a diode cut-in voltage of 0.7 V, the peak value of v_S is

$$v_S(\max) = v_O(\max) + 2V_\gamma = 12 + 2(0.7) = 13.4\text{ V}$$

For a sinusoidal signal, this produces an rms voltage value of

$$v_{S,\text{rms}} = \frac{13.4}{\sqrt{2}} = 9.48\text{ V}$$

The transformer turns ratio is then

$$\frac{N_1}{N_2} = \frac{120}{9.48} = 12.7$$

For a 5 percent ripple, the ripple voltage is

$$V_r = (0.05)V_M = (0.05)(12) = 0.6\text{ V}$$

The required filter capacitor is found to be

$$C = \frac{V_M}{2fRV_r} = \frac{12}{2(60)(100)(0.6)} \Rightarrow 1667\,\mu\text{F}$$

The peak diode current, from Equation (2.21), is

$$i_{D,\text{peak}} = \frac{12}{100}\left[1 + \pi\sqrt{\frac{2(12)}{0.6}}\right] = 2.50\text{ A}$$

and the average diode current over the entire signal period, from Equation (2.25), is

$$i_D(\text{avg}) = \frac{1}{\pi}\sqrt{\frac{2(0.6)}{12}}\left(\frac{12}{100}\right)\left(1 + \frac{\pi}{2}\sqrt{\frac{2(12)}{0.6}}\right) \Rightarrow 132\text{ mA}$$

Finally, the peak inverse voltage that each diode must sustain is

$$\text{PIV} = v_R(\max) = v_S(\max) - V_\gamma = 13.4 - 0.7 = 12.7\text{ V}$$

The geometrical symmetry
operations of translation and

)*+,)))-) '. * ? ? #.% !C6
)*+,)))-) '. * ? ? #.% 0!
($

Returning to symmetry transformations it is clear that the successive application of two symmetry transformations produces a third symmetry transformation, and it can be shown that the set of all symmetry transformations with this law of combination forms a group, the symmetry group of the system. For a quantum system the symmetry transformations are represented by unitary operators, and the successive application of two symmetry transformations S and T is represented by the operator product TS. From section 1.2 we see the set of symmetry transformations of a quantum system is contained in the set of all unitary operators which commute with the Hamiltonian operator of the system.

1.4. Geometrical Symmetries

An important sub-group of symmetry transformations of many dynamical systems has a geometrical origin. The space of classical physics is described by a Euclidean geometry, implying that all points of space and all directions are equivalent and only statements relating to relative position and relative orientation have a meaning independent of the coordinate system. If the Euclidean character of space is reflected in physical laws no point in space nor any directions should be distinguishable absolutely by the performance of experiments. The operations of translation and rotation applied to a physical system should therefore belong to the symmetry group of the system. Thus the geometrical character of space determines symmetries of physical laws, or, perhaps more correctly, the physical symmetries determine the geometry of space. Lorentz transformations and space reflection come also into the category of symmetries with a geometrical origin.

In practical problems often a distinction is made between a physical system and its surroundings and the effect of the surroundings is approximated by boundary conditions or by a set of known fields or forces applied from the outside. This approximate treatment may destroy the geometrical symmetries partially or completely. For example, the equations of motion of an atom in an external magnetic field are not invariant for arbitrary rotations unless the external field is also rotated.

The geometrical symmetry operations of translation and rotation can be looked at in two ways, called active and passive. In the active sense introduced above they transform one state of a system into another. A rotation actually rotates the system from one position to another. The passive approach interprets the symmetry operations as coordinate transformations, and the symmetry of the dynamical laws is expressed by stating that the equations of motion are invariant under translation or rotation of axes. Any translation or rotation of a system may, however, be induced by a coordinate transformation and the two views are equivalent. This fact can be seen most easily by considering a simple example, the rotation of a one-particle quantum system through an angle α about the z-axis. (See Fig. 1.) Rotating the system transforms its wave function to a new one so that the value of the new wave function at the point $(\phi+\alpha)$ is the same as that of the old one at the point ϕ where ϕ is the azimuthal angle. Let the original wave function be $\psi(r,\theta,\phi)$ and the rotated wave function

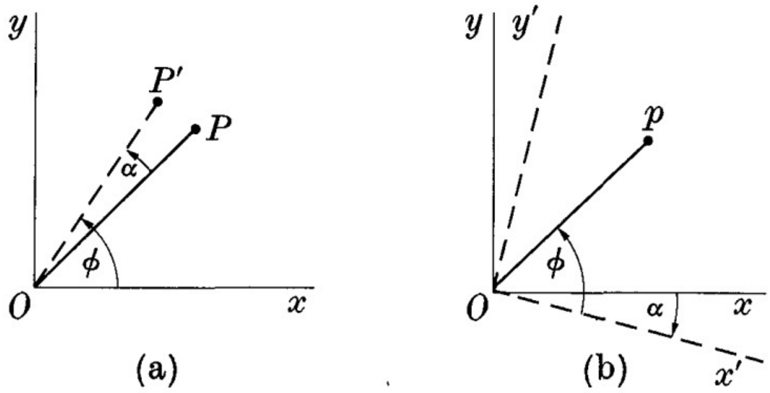

FIG. 1. (a) Represents a rotation of the system. A vector OP is carried into OP' by the rotation.
(b) Represents the equivalent rotation of axes. The vector OP remains fixed, but its coordinates are changed. The position of OP relative to the new axes in (b) is the same as that of OP' relative to the axes in (a).

$\psi' = D_\alpha \psi$ then this argument shows that

$$\psi'(r,\theta,\,\phi+\alpha) = \psi(r,\theta,\phi),$$

or

$$\psi'(r,\theta,\phi) \qquad = \psi(r,\theta,\,\phi-\alpha).$$

Thus the rotated wave function can be obtained from the original wave function by making the coordinate transformation $(r,\theta,\phi) \rightarrow (r,\theta,\phi-\alpha)$, i.e. by a rotation of the coordinate axes through an angle $-\alpha$ about the z-axis. Both these views of the rotation are important and will be used with the convention that a positive (counter clockwise) rotation refers to a positive rotation of the system, hence a negative rotation of axes.‡

1.5. Conservation Laws

There is a relation between the geometrical symmetries of a physical system and the momentum and angular momentum conservation laws, having its origin in the fact that the linear and angular momenta are respectively the generators of translations and rotations of the system. As an example consider the canonical transformation generated by L_z, the z-component of the angular momentum of a classical particle.

If F is any function of the coordinates q_i and the momenta p_i of a dynamical system and α is small then the transformation§

$$\begin{aligned} p_i' &= p_i + \alpha\{p_i, F\}, \\ q_i' &= q_i + \alpha\{q_i, F\}, \end{aligned} \tag{1.1}$$

is an infinitesimal canonical transformation in the sense that Hamilton's equations of motion retain the same form when written in terms of p_i' and q_i'. F is called the generating function of the transformation and it can be shown that if $G(p_i,\, q_i)$

---

‡ This convention agrees with Rose [54], Messiah [46]. Other authors use the opposite convention, a positive rotation referring to a positive rotation of the axes; Wigner [78], Edmonds [22]. Cf. section 2.4 and Appendix V.

§ The Poisson bracket $\{G, F\}$ of two functions of p_i and q_i is defined as

$$\{G, F\} = \sum_k \left(\frac{\partial G}{\partial q_k}\frac{\partial F}{\partial p_k} - \frac{\partial G}{\partial p_k}\frac{\partial F}{\partial q_k} \right).$$

Complex Integration

7.1 Paths and Contours

In this chapter, we consider integration along a contour in the complex plane. Recall that a path in $\mathbb{C}$ is a continuous function $\gamma : [a,b] \to \mathbb{C}$, for some $a \le b$ in $\mathbb{R}$. The set of points $\{\, z : z = \gamma(t),\ a \le t \le b \,\}$ is the trace of γ which we denote by $\operatorname{tr}\gamma$.

Example 7.1 Let $\gamma_1(t) = e^{2\pi i t}$ for $0 \le t \le 1$. Then we find that

$$\operatorname{tr}\gamma_1 = \{\, z : |z| = 1 \,\} = \text{ unit circle.}$$

Now suppose that $\gamma_2(t) = e^{-4\pi i t}$ for $0 \le t \le 1$. We see that again

$$\operatorname{tr}\gamma_2 = \{\, z : |z| = 1 \,\} = \text{ unit circle.}$$

The paths γ_1 and γ_2 have the same trace but are different paths: the path γ_1 goes round the circle anticlockwise once, whereas γ_2 goes round twice in a clockwise sense.

Remark 7.1 The convention is to take the anticlockwise sense as being positive. This is consistent with the convention that the positive direction is that with increasing polar angle.

Definition 7.1 The path $\gamma : [a,b] \to \mathbb{C}$ is said to be closed if $\gamma(a) = \gamma(b)$. The path γ is said to be simple if it does not cross itself, that is, $\gamma(s) \ne \gamma(t)$ whenever $s \ne t$ with s, t in (a,b). (The possibility that $\gamma(a) = \gamma(b)$ is allowed.)

Example 7.2 The path γ_1 in the example above is a simple closed path, whereas γ_2 is closed but not simple. The path $\gamma(t) = e^{-5\pi i t}$, $0 \le t \le 1$, has the unit circle as its trace, but γ is neither closed nor simple.

Definition 7.2 Let $\gamma : [a,b] \to \mathbb{C}$ be a path. The reverse path $\widetilde{\gamma}$ is given by $\widetilde{\gamma} : [a,b] \to \mathbb{C}$ with $\widetilde{\gamma}(t) = \gamma(a+b-t)$.

Evidently, $\widetilde{\gamma}$ is "γ in the opposite direction". Note that the parametric range for $\widetilde{\gamma}$ is the same as that for γ, namely $[a,b]$. It is also clear that $\operatorname{tr}\widetilde{\gamma} = \operatorname{tr}\gamma$.

Definition 7.3 The path $\gamma : [a,b] \to \mathbb{C}$ is smooth if the derivative $\gamma'(t)$ exists and is continuous on $[a,b]$ (with right and left derivatives at a and b, respectively). In other words, if $\gamma(t) = x(t) + iy(t)$, then γ is smooth if and only if both x and y are differentiable (real functions of a real variable) and such that the derivatives $x'(t)$ and $y'(t)$ are continuous functions of the parameter $t \in [a,b]$.

A contour is a piecewise smooth path, that is, $\gamma : [a,b] \to \mathbb{C}$ is a contour if and only if there is a finite collection $a = a_0 < a_1 < \cdots < a_n = b$ (for some $n \in \mathbb{N}$) such that each subpath $\gamma : [a_{i-1}, a_i] \to \mathbb{C}$ is smooth, $1 \le i \le n$.

We write $\gamma = \gamma_1 + \gamma_2 + \cdots + \gamma_n$, where γ_i is the restriction of γ to the subinterval $[a_{i-1}, a_i]$.

Example 7.3 According to our (reasonable) definition, the path given by $t \mapsto \gamma(t) = \cos^3(2\pi t) + i\sin^3(2\pi t)$, for $0 \le t \le 1$, is smooth. Its trace is illustrated in the figure, Fig. 7.1.

7.2 The Length of a Contour

Next, we wish to develop a means of formulating the length of a path. By way of motivation, suppose that $\gamma : [a,b] \to \mathbb{C}$ is a given smooth path. We can consider an inscribed polygon as an approximation to the path and its length will be an approximation to the length of the path. Suppose that the polygon has vertices $\{z_0, z_1, \ldots, z_n\}$. Then the length of such a polygonal path is the sum of the lengths of its straight line segments, namely, $\sum_{j=1}^{n} |z_j - z_{j-1}|$.

Suppose that the ends of the line segments correspond to values $t_0, t_1, \ldots, t_n$ of the path parameter, that is, $z_j = \gamma(t_j)$. Then

$$\begin{aligned}\sum_{j=1}^{n} |z_j - z_{j-1}| &= \sum_{j=1}^{n} |\gamma(t_j) - \gamma(t_{j-1})| \\ &= \sum_{j=1}^{n} \left| \frac{\gamma(t_j) - \gamma(t_{j-1})}{t_j - t_{j-1}} \right| (t_j - t_{j-1}),\end{aligned}$$

with $a = t_0 < t_1 < \cdots < t_n = b$. Now, the quotient $\dfrac{\gamma(t_j) - \gamma(t_{j-1})}{t_j - t_{j-1}}$ can be considered an approximation to the derivative $\gamma'(t_j)$, in which case the sum on the right hand side becomes an approximation to an integral

$$\sum_{j=1}^{n} \left| \frac{\gamma(t_j) - \gamma(t_{j-1})}{t_j - t_{j-1}} \right| (t_j - t_{j-1}) \quad \overset{\text{approx}}{\rightsquigarrow} \quad \int_a^b |\gamma'(t)| \, dt.$$

Indeed, in view of the assumed smoothness of γ, one might expect that the left hand side converges to the right hand side as $\max_j (t_j - t_{j-1}) \to 0$. Rather than prove this here, we will just take this as motivation for our definition of the length of a path, as follows.

Definition 7.4 The length of the smooth path $\gamma : [a,b] \to \mathbb{C}$ is the non-negative real number $L(\gamma)$ given by the formula

$$L(\gamma) = \int_a^b |\gamma'(t)| \, dt.$$

If $\gamma = \gamma_1 + \gamma_2 + \cdots + \gamma_n$ is a contour (with each γ_j smooth), we define the length of γ to be $L(\gamma) = L(\gamma_1) + L(\gamma_2) + \cdots + L(\gamma_n)$.

Examples 7.4

(1) Let $\gamma(t) = e^{2\pi i t}$, for $0 \le t \le 1$. We calculate

$$L(\gamma) = \int_0^1 |\gamma'(t)|\, dt = \int_0^1 \left|2\pi i e^{2\pi i t}\right|\, dt = 2\pi \int_0^1 1\, dt = 2\pi\,.$$

(2) Let $\gamma(t) = e^{-4\pi i t}$, for $0 \le t \le 1$. Then $\gamma'(t) = -4\pi i e^{-4\pi i t}$, so that

$$L(\gamma) = \int_0^1 4\pi = 4\pi\,.$$

(3) Define the path γ by

$$\gamma(t) = \begin{cases} e^{2\pi i t}, & 0 \le t < 1 \\ 1, & 1 \le t < 2 \\ e^{-2\pi i t}, & 2 \le t \le 3. \end{cases}$$

Then γ is a contour and

$$\gamma'(t) = \begin{cases} 2\pi i e^{2\pi i t}, & 0 \le t < 1 \\ 0, & 1 < t < 2 \\ -2\pi i e^{-2\pi i t}, & 2 < t \le 3. \end{cases}$$

(At $t = 1$, the left derivative is $2\pi i$, the right derivative is 0 and at $t = 2$, the left derivative is 0, the right derivative is $-2\pi i$.) We find

$$L(\gamma) = \int_0^1 2\pi\, dt + \int_1^2 0\, dt + \int_2^3 2\pi\, dt = 4\pi\,.$$

(4) Suppose that $\gamma(t) = z_0 + t(z_1 - z_0)$, $0 \le t \le 1$. Then γ is the line segment $\gamma = [z_0, z_1]$. We have $\gamma'(t) = z_1 - z_0$ and so

$$L(\gamma) = \int_0^1 |z_1 - z_0|\, dt = |z_1 - z_0|\,,$$

as it should.

Remark 7.2 We see that every contour has a well-defined length—this is because of its good behaviour. In general, paths need not have a meaningful length. For example, let $\gamma : [0,1] \to \mathbb{C}$ be the path given by

$$\gamma(t) = \begin{cases} (1-t)\, e^{2\pi i/(1-t)}, & \text{for } 0 \le t < 1 \\ 0, & \text{for } t = 1. \end{cases}$$

The path γ starts at the point $\gamma(0) = 1$ and spirals counterclockwise in towards the origin (and encircles the origin an infinite number of times). Evidently, γ is continuous at any t with $0 \le t < 1$. Furthermore, for any $0 \le t < 1$, $|\gamma(t) - \gamma(1)| = (1-t) \to 0$, as $t \uparrow 1$, and so we see that γ is also continuous at $t = 1$. Hence γ really is a path. However, for any $0 \le s < 1$, the length of γ "from 0 to s" is

$$\begin{aligned}\int_0^s |\gamma'(t)|\, dt &= \int_0^s \Big|\frac{2\pi i}{1-t} - 1\Big|\, dt \\ &\ge \int_0^s \frac{2\pi}{1-t}\, dt = 2\pi \ln\Big(\frac{1}{1-s}\Big) \to \infty\end{aligned}$$

as s increases to 1. One could say that γ has infinite length.

7.3 Integration along a Contour

One way of looking at the integral of a real function of a real variable is to think of it as the area under its graph. This is approximated by the area of suitable rectangles (typically very thin and with height determined by the values of the function at the location of the rectangle).

$$\int_a^b f(x)\, dx = \text{ area under graph } \quad \overset{\text{approx}}{=} \quad \sum f(x_i)\Delta x_i$$

where $f(x_i)\Delta x_i$ is the area (height × base) of the rectangle with height $f(x_i)$ and width Δx_i. This formula makes sense for complex variables and complex-valued functions even though the original idea of area no longer does.

Suppose $\gamma : [a,b] \to \mathbb{C}$ is a smooth path. Let $a = t_0 < t_1 < \cdots < t_n = b$ and set $z_j = \gamma(t_j)$. With the preceding comments in mind, we consider

$$\begin{aligned}\sum f(z_j)(z_j - z_{j-1}) &= \sum f(\gamma(t_j))\, \frac{\gamma(t_j) - \gamma(t_{j-1})}{t_j - t_{j-1}}\, (t_j - t_{j-1}) \\ &\overset{\text{approx ?}}{=} \int_a^b f(\gamma(t))\, \gamma'(t)\, dt\end{aligned}$$

provided that the t_js are close together. It is possible to prove convergence of such sums to integrals (provided f is continuous), but we will simply take the right hand side as our definition of the complex contour integral.

Definition 7.5 Let $\gamma : [a, b] \to \mathbb{C}$ be smooth and f a continuous complex function on $\operatorname{tr}\gamma$. The contour integral of f along γ is defined to be

$$\int_\gamma f \equiv \int_a^b f(\gamma(t))\, \gamma'(t)\, dt.$$

Sometimes the notation $\int_\gamma f(z)\, dz$ is used. If we write $f = u + iv$ and $\gamma(t) = x(t) + iy(t)$, then $\int_\gamma f$ can be written as $X + iY$, where X and Y are real integrals,

$$X = \int_a^b \{u(x(t), y(t))\, x'(t) - v(x(t), y(t))\, y'(t)\}\, dt$$

and

$$Y = \int_a^b \{u(x(t), y(t))\, y'(t) + v(x(t), y(t))\, x'(t)\}\, dt.$$

For any contour γ, we define

$$\int_\gamma f = \int_{\gamma_1} f + \int_{\gamma_2} f + \cdots + \int_{\gamma_n} f$$

where $\gamma_1, \ldots, \gamma_n$ are the smooth parts of the contour γ.

Examples 7.5

(1) Let $\gamma(t) = e^{it}$ for $a \le t \le b$, and take $f(z) = \frac{1}{z}$. Then

$$\begin{aligned}\int_\gamma f &\equiv \int_\gamma \frac{dz}{z} \\ &= \int_a^b f(e^{it})\, ie^{it}\, dt \\ &= \int_a^b \frac{1}{e^{it}}\, ie^{it}\, dt \\ &= \int_a^b i\, dt = i(b-a).\end{aligned}$$

In particular, with $a = 0$ and $b = 2\pi$, we find that $\int_\gamma \frac{dz}{z} = 2\pi i$.

(2) For given $a < b$ in $\mathbb{R}$, let $\gamma(t) = a + t(b-a)$, for $0 \le t \le 1$, that is, γ is just the line segment $[a,b]$ in $\mathbb{R}$. Then, for any f, continuous on $\operatorname{tr}\gamma$,

$$\begin{aligned}\int_\gamma f &= \int_0^1 f(\gamma(t))\,\gamma'(t)\,dt \\ &= \int_0^1 f(a+t(b-a))\,(b-a)\,dt \\ &= \int_a^b f(s)\,ds,\end{aligned}$$

by the change of variable $s = a + t(b-a)$. In particular, if f is real-valued, then $\int_{[a,b]} f$ is precisely the usual real integral $\int_a^b f(x)\,dx$.

Remark 7.3 This last observation has important consequences. Suppose that $\gamma = \gamma_1 + \cdots + \gamma_n$ is a contour where one of the smooth parts is a line segment on the real axis, $\gamma_k = [a,b]$, say, with $a < b \in \mathbb{R}$. Suppose that f is a continuous complex function on $\operatorname{tr}\gamma$ and that f is real on $\operatorname{tr}\gamma_k$, that is, f is real on the line segment $[a,b]$ on the real axis. We have

$$\int_\gamma f = \int_{\gamma_1} f + \cdots + \int_{\gamma_k} f + \cdots + \int_{\gamma_n} f$$

which expresses the real integral $\int_{\gamma_k} f = \int_a^b f(x)\,dx$ in terms of complex integrals. This may not seem much of an advance, but the point is that complex integrals can often be evaluated by general theory based only on rather general properties of the function f. This turns out to be a very powerful method for performing real integration.

Proposition 7.1 *For any contour γ and any functions, f, g, continuous on its trace* $\operatorname{tr}\gamma$*, we have*

(i) $\displaystyle\int_\gamma \alpha f + \beta g = \alpha \int_\gamma f + \beta \int_\gamma g$, *for all α, $\beta \in \mathbb{C}$;*

(ii) $\displaystyle\int_{\widetilde{\gamma}} f = -\int_\gamma f$.

Proof. The integral along a contour is given by the sum of the integrals along its smooth parts, so it is enough to consider the case of a smooth path $\gamma : [a,b] \to \mathbb{C}$. Then (i) is clear from the definition.

To prove (ii), we evaluate the left hand side.

$$\begin{aligned}\int_{\widetilde{\gamma}} f &= \int_a^b f(\widetilde{\gamma}(t))\,\widetilde{\gamma}'(t)\,dt \\ &= -\int_a^b f(\gamma(a+b-t))\,\gamma'(a+b-t)\,dt \\ &= \int_b^a f(\gamma(s))\,\gamma'(s)\,ds, \quad \text{putting } s = a+b-t, \\ &= -\int_a^b f(\gamma(s))\,\gamma'(s)\,ds \\ &= -\int_\gamma f,\end{aligned}$$

as required. □

The next result tells us that the integral along a path is somewhat insensitive to how we choose to parameterize the path.

Proposition 7.2 *The integral $\int_\gamma f$ is independent of the parametrization of the smooth path γ, i.e., if $\gamma : [a,b] \to \mathbb{C}$, $\varphi : [\alpha,\beta] \to [a,b]$ with $\varphi(\alpha) = a$, $\varphi(\beta) = b$, φ is differentiable and φ' is continuous, then*

$$\int_{\widehat{\gamma}} f = \int_\gamma f,$$

where $\widehat{\gamma}$ is the smooth path $\widehat{\gamma} = \gamma \circ \varphi : [\alpha,\beta] \to \mathbb{C}$.

Proof. This is really just a change of variable. Let $f(\gamma(t))\,\gamma'(t) = u(t) + iv(t)$, where u and v are real, and let $U(s) = \int_a^s u(t)\,dt$ and $V(s) = \int_a^s v(t)\,dt$. Put $F(s) = U(s) + iV(s)$. Then $F : [a,b] \to \mathbb{C}$ and $F'(t) = U'(t) + iV'(t) = u(t) + iv(t) = f(\gamma(t))\,\gamma'(t)$. We have

$$\begin{aligned}\int_\gamma f &= \int_a^b f(\gamma(t))\,\gamma'(t)\,dt = F(b) - F(a) = F(\varphi(\beta)) - F(\varphi(\alpha))\\ &= U(\varphi(\beta)) - U(\varphi(\alpha)) + i\big(V(\varphi(\beta)) - V(\varphi(\alpha))\big)\\ &= \int_\alpha^\beta U(\varphi(s))'\,ds + i\int_\alpha^\beta V(\varphi(s))'\,ds\\ &= \int_\alpha^\beta U'(\varphi(s))\,\varphi'(s)\,ds + i\int_\alpha^\beta V'(\varphi(s))\,\varphi'(s)\,ds\\ &= \int_\alpha^\beta F'(\varphi(s))\,\varphi'(s)\,ds = \int_\alpha^\beta f(\gamma(\varphi(s)))\,\gamma'(\varphi(s))\,\varphi'(s)\,ds\\ &= \int_\alpha^\beta f(\gamma\circ\varphi(s))\,(\gamma\circ\varphi)'(s)\,ds = \int_{\gamma\circ\varphi} f\,,\end{aligned}$$

as required. □

Example 7.6 For $0 \le t \le 1$, let $\gamma(t) = 1 + t(i-1)$, and let $\eta(t) = 1 + t^2(i-1)$. This corresponds to the reparametrization $\varphi(t) = t^2$, so that $\eta(t) = \gamma(\varphi(t))$. By way of illustration, let f be the function given by $z \mapsto f(z) = \operatorname{Re} z + 2\operatorname{Im} z$. Then

$$\begin{aligned}\int_\gamma f &= \int_0^1 (1 - t + 2t)(i-1)\,dt\\ &= i\int_0^1 (1+t)\,dt - \int_0^1 (1+t)\,dt.\end{aligned}$$

On the other hand,

$$\begin{aligned}\int_\eta f &= \int_0^1 (1 - t^2 + 2t^2)\,2t(i-1)\,dt\\ &= i\int_0^1 (1+t^2)\,2t\,dt - \int_0^1 (1+t^2)\,2t\,dt\\ &= i\int_0^1 (1+s)\,ds - \int_0^1 (1+s)\,ds, \quad \text{setting } s = t^2,\end{aligned}$$

so $\int_\eta f = \int_\gamma f$, as it should. The actual value is $\frac{3}{2}(i-1)$.

7.2. the Length of a Contour.

Polygon:

Condition:

$\gamma : [a, b] \to \mathbb{C}$ is given smooth path.

We can consider an inscribed polygon as an approximation to the path and its length will be an approximation to the length of the path.

polygon $\Rightarrow$ vertices $\{z_0, z_1, \ldots, z_n\}$.

19.04.2020

Then the length of such (de tal) a polygon path is the SUM of the lengths of its straight line segments, namely,

$$\sum_{j=1}^{n} |z_j - z_{j-1}|.$$

Suppose that the ends of the line segments correspond to values $t_0, t_1, \dots, t_n$ of the parameter, that is, $z_j = \gamma(t_j)$.

Then

$$\sum_{j=1}^{n} |z_j - z_{j-1}| = \sum_{j=1}^{n} |\gamma(t_j) - \gamma(t_{j-1})| =$$

$$\sum_{j=1}^{n} \left| \frac{\gamma(t_j) - \gamma(t_{j-1})}{t_j - t_{j-1}} \right| (t_j - t_{j-1}),$$

with $a = t_0 < t_1 < \dots < t_n = b$.

Now, the quotient $\dfrac{\gamma(t_j) - \gamma(t_{j-1})}{t_j - t_{j-1}}$ can be considered an approximation to the derivative $\gamma'(t_j)$, in which case the sum of the right hand side (lado direito) becomes an approximation to an integral.

data 19.04.2020

S T Q Q S S [✓ D]

$$\sum_{j=1}^{n}\left|\frac{\gamma(t_j)-\gamma(t_{j-1})}{t_j-t_{j-1}}\right|(t_j-t_{j-1})$$

$$\xrightarrow{\text{approx}} \int_a^b |\gamma'(t)|\,dt.$$

Indeed (de fato), in view of the assumed smoothness of γ one might expect that the left hand side converges to the right hand side as $\max_j (t_j - t_{j-1}) \to 0$.

Rather than (ao invés de) prove this here, we will just take this as motivation for our definition of the length of a path, as follows.

1.6 The Riemann Sphere and the Extended Complex Plane.

Let S^2 denote the sphere →

3.8 Polygons and Paths in $\mathbb{C}$

Definition 3.11 The line segment from z_0 to z_1 is the set

$$[z_0, z_1] = \{\, z : z = z_0 + t(z_1 - z_0),\ 0 \le t \le 1 \,\}$$

It consists of all those points in the complex plane lying on the straight line between z_0 and z_1.

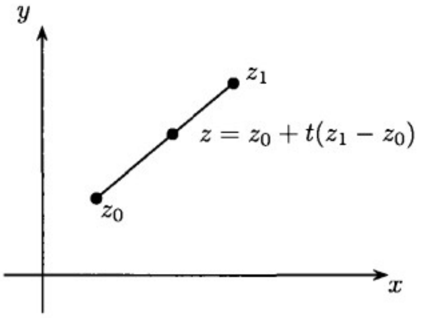

Fig. 3.5 The line segment joining z_0 to z_1.

Remark 3.12 By looking at the real and imaginary parts, we can express this in terms of (familiar) cartesian coordinates. Let $z = x+iy \in [z_0, z_1]$ and write $z_0 = x_0+iy_0$ and $z_1 = x_1+iy_1$. z can be written as $z = z_0+t(z_1-z_0)$ for some $0 \le t \le 1$, which gives the pair of equations

$$\begin{aligned} x &= x_0 + t(x_1 - x_0) \\ y &= y_0 + t(y_1 - y_0). \end{aligned}$$

Eliminating t shows that (x, y) lies on the straight line

$$y = y_0 + \frac{(y_1 - y_0)}{(x_1 - x_0)}\,(x - x_0).$$

Moreover, the restriction $0 \le t \le 1$ means that x varies between x_0 (when $t = 0$) and x_1 (when $t = 1$).

Definition 3.12 A polygon in $\mathbb{C}$ is a set of the form

$$[z_0, z_1] \cup [z_1, z_2] \cup \cdots \cup [z_{n-1}, z_n]$$

for some $n \in \mathbb{N}$ and points $z_0, z_1, \ldots, z_n$.

In other words, a polygon is a finite collection of line segments placed end to end. We say that the polygon joins the points z_0 and z_n. Notice that z_n need not be the same as z_0.

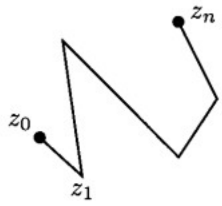

Fig. 3.6 A polygon joining z_0 to z_n.

Definition 3.13 A path in $\mathbb{C}$ is a continuous function $\varphi : [a, b] \to \mathbb{C}$, where $[a, b]$ is some closed interval in $\mathbb{R}$. We say that φ joins its initial point, $\varphi(a)$, to its final point, $\varphi(b)$. The points $\varphi(a)$ and $\varphi(b)$ are its endpoints. The trace (also called the track, or the impression) of the path φ is defined to be the set $\{ z : z = \varphi(t), t \in [a, b] \}$ and is denoted by $\operatorname{tr}\varphi$. (Note that, by definition, a map ψ from a subset S of $\mathbb{R}$ to $\mathbb{C}$ is continuous at the point $x_0 \in S$ if for any given $\varepsilon > 0$ there is $\delta > 0$ such that $|x - x_0| < \delta$, with $x \in S$, implies that $|\psi(x) - \psi(x_0)| < \varepsilon$. ψ is said to be continuous on S if it is continuous at each point of S. This is the natural definition of continuity of a complex-valued function of a real variable.)

So a path is a continuous complex-valued function of a real variable, defined on some closed interval in $\mathbb{R}$, and its track is just its range in $\mathbb{C}$.

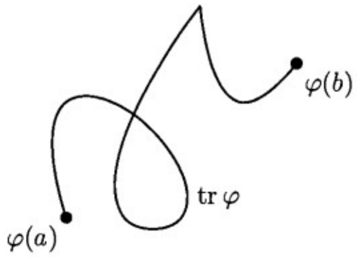

Fig. 3.7 A path joining $\varphi(a)$ to $\varphi(b)$.

Remark 3.13 A polygon can be thought of as a path, as follows. For given points (vertices) $z_0, \ldots, z_n \in \mathbb{C}$, define $\varphi : [0, n] \to \mathbb{C}$ by $\varphi(n) = z_n$ and

$$\varphi(t) = z_k + (t - k)(z_{k+1} - z_k) \quad \text{for } k \le t < k + 1$$

for $k = 0, 1, 2, \ldots, n - 1$. Then as t increases from k to $k + 1$, $\varphi(t)$ moves along the line segment $[z_k, z_{k+1}]$ from z_k towards z_{k+1}. Evidently, the trace of φ is given by $\operatorname{tr} \varphi = [z_0, z_1] \cup [z_1, z_2] \cup \cdots \cup [z_{n-1}, z_n]$.

Remark 3.14 Let $\varphi : [a, b] \to \mathbb{C}$ be a given path. Since φ is continuous, it follows that $\operatorname{tr} \varphi$ is compact in $\mathbb{C}$. To see this, let (z_n) be any sequence in $\operatorname{tr} \varphi$. Then $z_n = \varphi(t_n)$ for some $t_n \in [a, b]$. But (t_n) has a convergent subsequence $t_{n_k} \to \tau$, say, as $k \to \infty$, with $\tau \in [a, b]$. The continuity of φ implies that $\varphi(t_{n_k}) \to \varphi(\tau)$. Thus, $z_{n_k} = \varphi(t_{n_k}) \to \varphi(\tau) \in \operatorname{tr} \varphi$, as $k \to \infty$ and so $\operatorname{tr} \varphi$ is compact. We note, in particular, that any line segment $[z_0, z_1]$ is compact in $\mathbb{C}$.

Remark 3.15 Suppose that $\varphi : [a, b] \to \mathbb{C}$ and $\psi : [c, d] \to \mathbb{C}$ are paths with $\varphi(b) = \psi(c)$, i.e., ψ starts where φ ends. We can join these together into a single path as follows. Define $\gamma : [a, b + d - c] \to \mathbb{C}$, by the formula

$$\gamma(t) = \begin{cases} \varphi(t), & a \le t < b \\ \psi(c + t - b), & b \le t \le b + d - c. \end{cases}$$

We see that γ is a path starting from $\varphi(a)$ and ending at $\psi(d)$. If $c = b$, then γ is equal to φ on the subinterval $[a, b]$ of $[a, d]$ and equal to ψ on $[b, d]$. In any event, we shall write $\gamma = \varphi + \psi$.

3.9 Connectedness

Definition 3.14 A subset $S \subseteq \mathbb{C}$ is said to be pathwise connected if for any pair of points z_0, z_1 in S there is some path, φ, say, lying entirely in S (i.e., such that $\operatorname{tr} \varphi \subseteq S$) and joining z_0 to z_1

Definition 3.15 A set A in $\mathbb{C}$ is said to be polygonally connected if and only if for any two points $z', z'' \in A$ there is some polygon lying entirely within A which joins z' and z''.

Definition 3.16 A set A in $\mathbb{C}$ is said to be stepwise connected if and only if for any two points $z', z'' \in A$ there is some polygon with line segments parallel to either the real or the imaginary axes which lies entirely within A and which joins z' and z''.

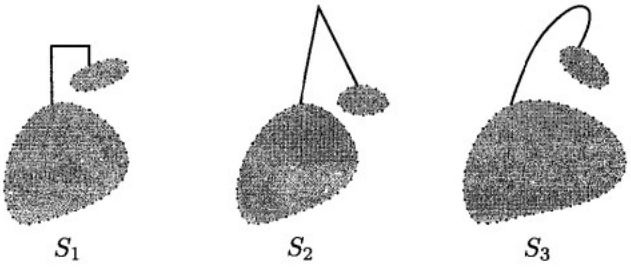

Fig. 3.8 Stepwise, polygonally and pathwise connected sets.

Figure 3.8 illustrates these three notions of connectedness. (Each set comprises two "blobs" (without their boundary) attached by a line.) Notice that S_3 is not polygonally connected, and S_2 is not stepwise connected.

Remark 3.16 The notion of connectedness is supposed to convey the idea of a set being "all in one piece". Clearly, the circle $\{ z : |z| = 1 \}$ is "all one piece" and so should qualify as being connected. However, evidently it is *not* polygonally connected—because it contains no line segments at all (it is everywhere curved!). One could therefore wonder at the usefulness of the notion of polygonal connectedness. It turns out that this is very convenient in the consideration of open sets—which is of special importance in complex analysis. (The precise point here is that pathwise connectedness is equivalent to polygonal connectedness for open sets in $\mathbb{C}$, as we will soon show.)

There is a further notion of connectedness as follows.

Definition 3.17 A subset S of $\mathbb{C}$ is said to be disconnected if there are disjoint open sets A and B (so $A \cap B = \varnothing$) such that $A \cap S \neq \varnothing$, $B \cap S \neq \varnothing$ and $S \subseteq A \cup B$. A set is said to be connected if it is not disconnected.

For open sets, the situation is a little less complicated, as the following proposition shows.

Proposition 3.8 *Let G be an open subset of $\mathbb{C}$. Then G is disconnected if and only if there are non-empty disjoint open sets G_1 and G_2, say, such that $G = G_1 \cup G_2$.*

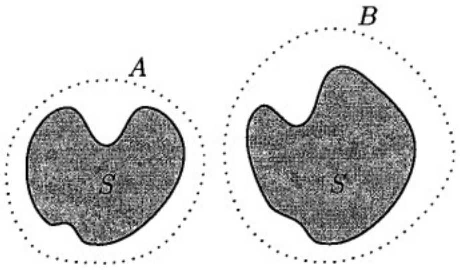

Fig. 3.9 The set S (shaded) is disconnected (the open sets A and B are dotted).

Proof. If G_1 and G_2 exist as stated, then by definition, G is disconnected.

Conversely, suppose that G is disconnected; $G \subseteq A \cup B$, with A, B disjoint, open sets such that $A \cap G \neq \varnothing$ and $B \cap G \neq \varnothing$. Setting $G_1 = A \cap G$ and $G_2 = B \cap G$ gives the open sets required. □

The next result is geometrically obvious, but nevertheless, requires proof. It rests on the completeness property of the real number system (which plays a central role in the Intermediate Value Theorem).

Theorem 3.6 *Suppose that A is a proper non-empty subset of $\mathbb{C}$. Then any path joining a point of A to a point not in A contains a point of the boundary of A. In other words, for a path to "escape" from a set, it must cross its boundary.*

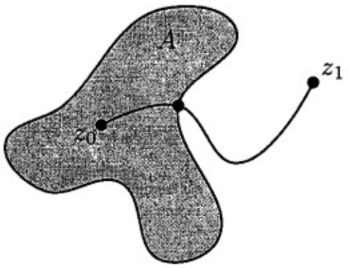

Fig. 3.10 The path must cross the boundary of A.

Proof. Suppose that $\varphi : [a, b] \to \mathbb{C}$ is a path joining $z_0 \in A$ to $z_1 \notin A$.

Let $g : [a, b] \to \mathbb{R}$ be the function

$$g(t) = \begin{cases} 0, & \varphi(t) \in A \\ 1, & \varphi(t) \notin A \,. \end{cases}$$

The function g maps $[a, b]$ onto the points $\{0, 1\}$ and so, by the Intermediate Value Theorem, g cannot be continuous. We will show that g is continuous at every point s in $[a, b]$ for which $\varphi(s) \notin \partial A$. If φ did not meet ∂A then g would be continuous on the whole of $[a, b]$, which we know to be false.

To proceed, then, suppose that $s \in [a, b]$ and that $\varphi(s) \notin \partial A$. Suppose first that $\varphi(s) \in A$, so that $g(s) = 0$. Since $\varphi(s) \notin \partial A$, there is $r > 0$ such that $D(\varphi(s), r) \subseteq A$. By continuity of φ, there is $\delta > 0$ such that

$$|t - s| < \delta, \quad t \in [a, b] \implies \varphi(t) \in D(\varphi(s), r) \subseteq A,$$

that is, $g(t) = 0 = g(s)$. Hence, for any given $\varepsilon > 0$,

$$|g(t) - g(s)| = |0 - 0| = 0 < \varepsilon$$

whenever $|t - s| < \delta$, $t \in [a, b]$. In other words, g is continuous at s.

Now suppose that $\varphi(s) \notin A$. Then $g(s) = 1$. Arguing just as before, we conclude that there is $r' > 0$ such that $D(\varphi(s), r') \subseteq \mathbb{C} \setminus A$ and that there is some $\delta' > 0$ such that

$$\varphi(t) \in D(\varphi(s), r') \subseteq \mathbb{C} \setminus A$$

whenever $|t - s| < \delta'$, $t \in [a, b]$. In other words, $g(t) = 1$ whenever we have $|t - s| < \delta'$, $t \in [a, b]$, which again shows that g is continuous at s.

We have shown that g is continuous at every point s in $[a, b]$ such that $\varphi(s) \notin \partial A$. As we have already noted, the Intermediate Value Theorem implies that g cannot be continuous on the whole of the interval $[a, b]$ and so we conclude that there must be some s for which $\varphi(s) \in \partial A$. In other words, $\operatorname{tr} \varphi \cap \partial A \neq \varnothing$ and the proof is complete. □

We can now prove the equivalence, for open sets, of the various notions of connectedness.

Theorem 3.7 *Let G be an open set. The following are equivalent.*

(i) *G is stepwise connected.*
(ii) *G is polygonally connected.*
(iii) *G is pathwise connected.*
(iv) *G is connected.*

Proof. If $G = \varnothing$ there is nothing to prove, since $\varnothing$ is "connected" in each of the four senses anyway.

Suppose that $G \neq \varnothing$. Clearly, (i) $\Longrightarrow$ (ii) $\Longrightarrow$ (iii). We first show that (iii) $\Longrightarrow$ (iv). Suppose then, that G is a non-empty pathwise connected open set in $\mathbb{C}$.

By way of contradiction, suppose that G is not connected, i.e., that G is disconnected. Then by proposition 3.8 there are disjoint, non-empty open sets A and B such that $G = A \cup B$. Let $z_0 \in A$ and suppose that $z_1 \in B$. By hypothesis, there is a path φ joining z_0 to z_1 in G. Since $z_1 \notin A$, the path φ passes through the boundary of A. That is, there is some $z^* \in \operatorname{tr} \varphi$ with $z^* \in \partial A$. Since A is open, $z^* \notin A$ and therefore $z^* \in B$. But then $D(z^*, r) \subseteq B$ for some $r > 0$. In particular, $D(z^*, r) \cap A = \varnothing$, which contradicts $z^* \in \partial A$. We deduce that G is connected, as required.

Notice that by replacing "path" by "step-path" or by "polygonal path", respectively, it follows that (iv) is a direct consequence of any one of the properties (i), (ii) or (iii).

To show that (iv) $\Longrightarrow$ (i), and hence complete the proof, suppose that G is open and connected. Let z_0 and z_1 belong to G and set

$$A = \{\, \zeta \in G : \zeta \text{ is stepwise connected to } z_0 \text{ in } G \,\}$$
$$B = G \setminus A.$$

We shall show that A is open and non-empty. Since G is open, there is $r > 0$ such that $D(z_0, r) \subseteq G$. Evidently, $D(z_0, r) \subseteq A$, so $A \neq \varnothing$.

Let $w \in A$. Then $w \in G$ and so $D(w, \rho) \subseteq G$ for some $\rho > 0$. Now, any point in $D(w, \rho)$ is stepwise connected to z_0, via w, and so $D(w, \rho) \subseteq A$ and it follows that A is open.

Next we show that B is also open (in fact, we will see that B is empty). If $z' \in B$, then $z' \in G$ and so $D(z', r') \subseteq G$, for some $r' > 0$. Any point w, say, in $D(z', r')$ is stepwise connected to z'. If w were stepwise connected to z_0, then z' would be as well (via w). We conclude that no point of $D(z', r')$ can be stepwise connected to z_0, i.e., $D(z', r') \subseteq B$, showing that B is open. But $G = A \cup B$ and G is connected, by hypothesis. It follows that $B = \varnothing$. Hence $G = A$ and the proof is complete. □

What's going on? The equivalence of these various notions of a set being all in one piece is only claimed to hold for *open* sets in $\mathbb{C}$. They are not the same in general. However, our main concern will be with open sets, so we can appeal to whichever version we find appropriate at any particular time, to suit our own convenience.

We can now easily answer the question "which sets are both open and closed"?

Theorem 3.8 *The only subsets of $\mathbb{C}$ which are simultaneously open and closed are $\varnothing$ and $\mathbb{C}$ itself.*

Proof. By way of contradiction, suppose that A is a non-empty proper subset of $\mathbb{C}$ and that A is both open and closed. It follows, in particular, that $\mathbb{C} \setminus A$, the complement of A, is open. But then we can write $\mathbb{C}$ as the disjoint union of two open sets A and $B = \mathbb{C} \setminus A$, $\mathbb{C} = A \cup B$. Since A is a proper subset of $\mathbb{C}$ it follows that B is non-empty. This means that $\mathbb{C}$ is disconnected.

However, $\mathbb{C}$ is open and evidently polygonally connected (indeed, $[z_0, z_1]$ joins the points z_0 and z_1). But this means that $\mathbb{C}$ is also connected, by theorem 3.7. This gives a contradiction and we deduce that no such non-empty proper subset A exists. □

3.10 Domains

Definition 3.18 An open connected set is called a domain (also sometimes known as a region).

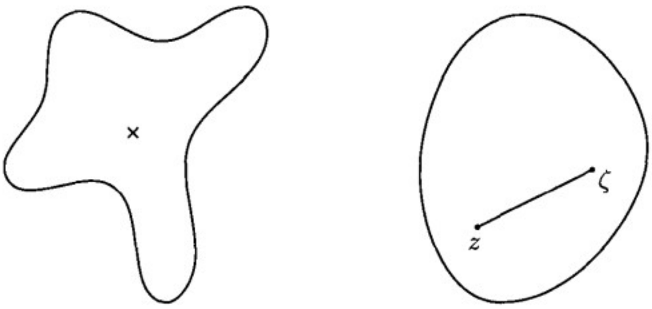

Fig. 3.11 Examples of a star-domain and a convex domain.

Definition 3.19 A domain D is (star-like or) a star-domain if there is some $z_0 \in D$ such that for each $z \in D$ the line segment $[z_0, z]$ lies in D. Any such point z_0 is called a star-centre.

What's going on? We might worry about simply asserting that $i^2 = -1$ without having said precisely what i was in the first place. However, it turns out to be all right. We can just go ahead and write any complex number as $a + ib$, where $i^2 = -1$ and not worry. It can all be justified. (But we still need to sort out square roots.)

Remark 1.5 The set of real numbers has a notion of order, defined in terms of positivity. For any real number x, precisely one of the following three statements is true; $x = 0$, $x > 0$, $-x > 0$. A property of positivity is that if $x > 0$ and $y > 0$, then $xy > 0$. It follows that $1 > 0$. (To see this, first we note that, clearly, $1 \neq 0$ (otherwise, $x = 1\,x$ would be 0 for all $x \in \mathbb{R}$). Hence either $1 > 0$ or $-1 > 0$, but not both. If $-1 > 0$ were true, then we would have $(-1)(-1) > 0$. But $(-1)(-1) = 1^2 = 1$ so that also $1 > 0$. Both $-1 > 0$ and $1 > 0$ is not allowed, so we conclude that $-1 > 0$ is false and therefore $1 > 0$.)

Is there such a notion for complex numbers which extends that for the real numbers? If this were possible then, for example, we would have either $i > 0$ or $-i > 0$ (since $i \neq 0$). If $i > 0$ were true, we would have $-1 = i^2 > 0$, which is false. Hence $-i > 0$ must be true. But then, again, this would imply $-1 = (-i)^2 > 0$, which is false. We must concede that there is no generalization of positivity extending from the real numbers to the set of complex numbers.

For real numbers x and y, the inequality $x > y$ is just a way of writing $x - y > 0$. This latter does not make sense, in general, for complex numbers, so it follows that inequalities, such as $z > \zeta$, do not make sense for complex numbers.

What's going on? Try as we might, we cannot make (useful) sense of inequalities between complex numbers.

1.6 The Riemann Sphere and the Extended Complex Plane

Let S^2 denote the sphere $\{(x, y, z) \in \mathbb{R}^3 : x^2 + y^2 + z^2 = 1\}$ in $\mathbb{R}^3$ and let N denote the point $(0, 0, 1)$, the "north pole" of S^2. Think of $\mathbb{C}$ as the plane $\{(x, y, z) : z = 0\}$, containing the equator of S^2. Then given any point P in this plane, the straight line through P and N cuts the sphere S^2 in a unique point, P', say. As P varies over the plane, the corresponding point P' varies over $S^2 \setminus \{N\}$. This sets up a one-one correspondence between $\mathbb{C}$ and $S^2 \setminus \{N\}$.

We note that points far from the origin in $\mathbb{C}$ are mapped into points near the north pole (and points close to the origin are mapped into points close to the south pole of S^2, i.e., the point $(0,0,-1)$). Notice too that if (P_n) is a sequence of points in $\mathbb{C}$ which converges to some point P in $\mathbb{C}$, then the images P'_n of P_n converge in S^2 to the image P' of P. We also see that if (z_n) is a sequence in $\mathbb{C}$ such that $|z_n| \to \infty$, then the sequence (P'_n) of their images converges to N in S^2 (and vice versa). The point N is called the "point at infinity".

The extended complex plane, $\mathbb{C}_\infty$, is defined to be $\mathbb{C}$ together with one additional element, that is, $\mathbb{C}_\infty \equiv \mathbb{C} \cup \{\infty\}$, where $\{\infty\}$ is a singleton set with $\infty \notin \mathbb{C}$. It does not matter what ∞ actually is, as long as it is not already a member of the set $\mathbb{C}$. For example, we could take ∞ to be $\varnothing$, which is certainly not a complex number. (Note that a and $\{\,a\,\}$ are different mathematical objects, so, in particular, $\varnothing$ is not the same as $\{\,\varnothing\,\}$. Indeed, the objects $\{\,\varnothing\,\}$, $\{\,\varnothing, \{\,\varnothing\,\}\,\}$ and $\{\,\varnothing, \{\,\varnothing, \{\,\varnothing\,\}\,\}\,\}$ are different, as different as the numbers $1, 2, 3$.)

What's going on? The issue is how to augment a given set to give it just one new element. That is, given a set A, how does one construct a new set B such that $B \setminus A$ is a singleton set? In the case above, $A = \mathbb{C}$ and $B = \mathbb{C}_\infty$ is the set we seek. If it does not matter what the new element is, as in the case here, then the explicit construction above is just one of many possibilities.

There is then a one-one correspondence between $\mathbb{C}_\infty$ and S^2 given by $\infty \longleftrightarrow N$ together with the correspondence between $\mathbb{C}$ and $S^2 \setminus \{N\}$, as introduced above. The extended complex plane, $\mathbb{C}_\infty$, viewed in this way is referred to as the Riemann sphere.

This gives a sensible realization of "infinity". For example, the mapping $z \mapsto 1/z$ is not *a priori* defined at $z = 0 \in \mathbb{C}$. However, if we consider the extended complex plane, or the Riemann sphere, then in addition to the mapping $z \mapsto 1/z$ for $z \in \mathbb{C} \setminus \{\,0\,\}$, we can define $0 \mapsto N$ and $N \mapsto 0$, (or, in more suggestive notation, $0 \mapsto \infty$ $(1/0 \equiv \infty)$ and $\infty \mapsto 0$ $(1/\infty \equiv 0)$). This defines the map $z \mapsto 1/z$ as a mapping from $\mathbb{C}_\infty \to \mathbb{C}_\infty$. This construction is reasonable in that if $z_n \to z$, then $1/z_n \to 1/z$ even if z or any z_n is equal to 0 or to ∞.

The point here is to notice that by studying $\mathbb{C}_\infty$, rather than just $\mathbb{C}$, we can sometimes handle singularities just as ordinary points—after all, one point on a sphere is much the same as any other.

In real analysis, one considers the limits $x \to \infty$ and $x \to -\infty$. Whilst it must be stressed at the outset that this is just shorthand symbolism, nevertheless, it does invoke a kind of image of two infinities—one positive and the other negative. In view of the picture of complex numbers as points in the plane, one might wonder if it might be worth considering some kind of collection of "complex infinities", each being somewhere off in some given direction (perhaps corresponding to some "end of the rainbow" at the "end" of the ray $r(\cos\theta + i\sin\theta)$ as r becomes very large). The view of $\mathbb{C}$ as being wrapped around a sphere, as developed above, suggests that we can bundle all these "infinities" into just a single "point at infinity", namely, the north pole.

It should be stressed that whilst $\mathbb{C}$ is a field (so one can do arithmetic), this is no longer true of $\mathbb{C}_\infty$. There is no attempt to assign any meaning whatsoever to expressions such as $\infty + \infty$ or $0 \times \infty$. The operations of addition and multiplication are simply not directly applicable when ∞ is involved.

data 19.04.2020

$$\sum_{j=1}^{n} \left| \frac{\gamma(t_j)-\gamma(t_{j-1})}{t_j-t_{j-1}} \right| (t_j-t_{j-1})$$

$$\xrightarrow{\text{approx}} \int_a^b |\gamma'(t)|\,dt.$$

Indeed (de fato), in view of the assumed smoothness of γ one might expect that the left hand side converges to the right hand side as $\max_j (t_j - t_{j-1}) \to 0$.

Rather than (ao invés de) prove this here, we will just take this as motivation for our definition of the length of a path, as follows.

4.4 Cauchy-Riemann Equations

We can relate complex-valued functions of a complex variable to real-valued functions of two real variables by looking at the real and imaginary parts:

$$\begin{aligned} z = x + iy \quad &\longleftrightarrow \quad (x, y) \in \mathbb{R}^2 \\ f(x+iy) &= \operatorname{Re} f(x+iy) + i \operatorname{Im} f(x+iy) \\ &\equiv u(x,y) + iv(x,y). \end{aligned}$$

That is, given $f(z)$, we define $u, v : \mathbb{R}^2 \to \mathbb{R}$ by $u(x,y) = \operatorname{Re} f(x+iy)$ and $v(x,y) = \operatorname{Im} f(x+iy)$.

Conversely, given two functions $u(x,y)$ and $v(x,y)$, we can construct the function $f(z) = u(x,y) + iv(x,y)$, where $z = x + iy$.

The complex differentiability of f implies that u and v, the real and imaginary parts of f, are not completely independent of each other, as we shall now discuss.

Suppose that f is differentiable at $z_0 = x_0 + iy_0$. Then we know that the quotient $(f(z) - f(z_0))/(z - z_0) \to f'(z_0)$ as $z \to z_0$.

We consider two cases, the first where $z = z_0 + s$, with $s \in \mathbb{R}$. To say that $z \to z_0$ is to say that $s \to 0$. Then

$$\begin{aligned} \frac{f(z) - f(z_0)}{z - z_0} &= \frac{u(x_0 + s, y_0) - u(x_0, y_0) + i(v(x_0 + s, y_0) - v(x_0, y_0))}{s} \\ &\to f'(z_0), \end{aligned}$$

as $s \to 0$, with $s \neq 0$. This means that the real and imaginary parts of the left hand side separately have limits, which is to say that the partial derivatives u_x and v_x exist at (x_0, y_0) and, moreover,

$$u_x(x_0, y_0) + iv_x(x_0, y_0) = f'(z_0).$$

Next, consider $z = z_0 + it$ with $t \in \mathbb{R}$. Once again, we know that

$$\begin{aligned} \frac{f(z) - f(z_0)}{z - z_0} &= \frac{u(x_0, y_0 + t) - u(x_0, y_0) + i(v(x_0, y_0 + t) - v(x_0, y_0))}{it} \\ &\to f'(z_0), \end{aligned}$$

as $t \to 0$, with $t \neq 0$. Again, this means that the real and imaginary parts of the left hand side separately have limits. Hence the partial derivatives u_y and v_y exist at (x_0, y_0) and

$$-iu_y(x_0, y_0) + v_y(x_0, y_0) = f'(z_0).$$

Equating these two expressions for $f'(z_0)$ leads to the following relations.

$$\left.\begin{aligned} u_x(x_0,y_0) &= v_y(x_0,y_0) \\ u_y(x_0,y_0) &= -v_x(x_0,y_0) \end{aligned}\right\} \qquad \textbf{Cauchy-Riemann equations}$$

If we denote complex differentiation by D_z, then the discussion above tells us that

$$D_z = \partial_x = -i\partial_y$$

where it is understood that D_z is applied to $f(z)$ and the partial derivatives are applied to $u(x,y) + iv(x,y)$. Thus

$$\begin{aligned} \partial_x u + i\,\partial_x v &= D_z f = f' \\ &= -i\,\partial_y(u+iv) = \partial_y v - i\,\partial_y u. \end{aligned}$$

Equating real and imaginary parts gives the Cauchy-Riemann equations. We have proved the following theorem.

Theorem 4.1 *If the function f is differentiable at $z_0 = x_0 + iy_0$ then f satisfies the Cauchy-Riemann equations at (x_0, y_0).*

Remark 4.3 If f does *not* satisfy the Cauchy-Riemann equations at some point (x_0,y_0), then certainly f fails to be differentiable at $z_0 = x_0 + iy_0$.

Example 4.2 We have already seen that the function $f(z) = \overline{z}$ is nowhere differentiable. Let us consider the Cauchy-Riemann equations for this f.

We have $f(z) = \overline{z} = x - iy$ and so $u(x,y) = x$ and $v(x,y) = -y$. Evidently both u and v possess partial derivatives everywhere in $\mathbb{R}^2$, but $u_x = 1$, $u_y = 0$, $v_x = 0$ and $v_y = -1$. We see that u_x is never equal to v_y and so the Cauchy-Riemann equations are never valid. We can therefore conclude that f is nowhere differentiable (as we already knew).

Remark 4.4 Is the converse of this last theorem true, that is, if f satisfies the Cauchy-Riemann equations at some point (x_0,y_0), is it true that f is differentiable at $z = x_0 + iy_0$? The answer, in general, is no!

Example 4.3 Let f be the function $f(x+iy) = |xy|^{1/2}$. Then we see that $u(x,y) = |xy|^{1/2}$, $v(x,y) = 0$, and

$$u_x(0,0) = u_y(0,0) = 0 = v_x(0,0) = v_y(0,0).$$

(For example, $u_x(0,0) = \lim_{s\to 0} \dfrac{u(s,0) - u(0,0)}{s} = 0$.) From this, it follows that the Cauchy-Riemann equations hold for f at $(0,0)$.

However, consider $s + is$ as $s \to 0$. We have, for $s \neq 0$,

$$\frac{f(s+is)-f(0)}{s+is} = \frac{|s|}{s+is} = \frac{|s|\,(s-is)}{2s^2} = \frac{|s|\,(1-i)}{2s}$$
$$\to \begin{cases} \frac{1}{2}(1-i), & \text{if } s \to 0 \text{ through positive values,} \\ -\frac{1}{2}(1-i), & \text{if } s \to 0 \text{ through negative values.} \end{cases}$$

We conclude that f is not differentiable at $z = 0$ even though f satisfies the Cauchy-Riemann equations there.

Under continuity conditions on the partial derivatives, we can prove the converse. We shall use the following result from the theory of real functions of two real variables.

Lemma 4.1 *Suppose that $\psi(x, y)$ is defined in some disc around the point $(x_0, y_0) \in \mathbb{R}^2$ and has continuous partial derivatives in this disc. Then, for all sufficiently small h and k in $\mathbb{R}$*

$$\psi(x_0 + h, y_0 + k) - \psi(x_0, y_0) = h\,\psi_x(x_0, y_0) + k\,\psi_y(x_0, y_0) + R,$$

where $|R|/\sqrt{h^2+k^2} \to 0$ as $h, k \to 0$ (with $h^2 + k^2 \neq 0$).

Proof. The idea is to find an expression for R and then use the Mean Value Theorem to obtain the required estimate. Indeed, we have

$$\begin{aligned} &\psi(x_0 + h, y_0 + k) - \psi(x_0, y_0) \\ &\qquad = \psi(x_0 + h, y_0 + k) - \psi(x_0 + h, y_0) + \psi(x_0 + h, y_0) - \psi(x_0, y_0) \\ &\qquad = k\,\psi_y(x_0 + h, y_0 + \theta k) + \psi(x_0 + h, y_0) - \psi(x_0, y_0) \end{aligned}$$

for some $0 \leq \theta \leq 1$, by the Mean Value Theorem applied to the function $y \mapsto \psi(x_0 + h, y)$ for y between y_0 and $y_0 + k$,

$$= h\,\psi_x(x_0, y_0) + k\,\psi_y(x_0, y_0) + R$$

where $R = \alpha_1 + \alpha_2$ with

$$\alpha_1 = k\,(\psi_y(x_0 + h, y_0 + \theta k) - \psi_y(x_0, y_0))$$

and

$$\alpha_2 = \psi(x_0 + h, y_0) - \psi(x_0, y_0) - h\,\psi_x(x_0, y_0).$$

Now, if $h, k \to 0$, with $h^2 + k^2 \neq 0$, then

$$\Big|\frac{\alpha_1}{\sqrt{h^2+k^2}}\Big| = \underbrace{\Big|\frac{k}{\sqrt{h^2+k^2}}\Big|}_{\leq 1}\underbrace{\Big|\psi_y(x_0+h, y_0+\theta k) - \psi_y(x_0, y_0)\Big|}_{\to 0}$$

by continuity of ψ_y. Also $\alpha_2/\sqrt{h^2+k^2} = 0$ if $h = 0$, otherwise (i.e., $h \neq 0$)

$$\Big|\frac{\alpha_2}{\sqrt{h^2+k^2}}\Big| = \underbrace{\Big|\frac{h}{\sqrt{h^2+k^2}}\Big|}_{\leq 1}\Big|\underbrace{\frac{\psi(x_0+h, y_0) - \psi(x_0, y_0)}{h}}_{\to \psi_x(x_0,y_0)} - \psi_x(x_0, y_0)\Big|$$

$$\to 0$$

as $h, k \to 0$, with $h \neq 0$. The result follows. □

Theorem 4.2 *Let $f = u + iv$ and suppose that the partial derivatives u_x, u_y, v_x and v_y exist for all (x, y) with $x + iy$ in some open disc around $x_0 + iy_0$ and that these partial derivatives are continuous at (x_0, y_0). Suppose further, that f satisfies the Cauchy-Riemann equations at (x_0, y_0). Then f is complex differentiable at the point $z_0 = x_0 + iy_0$.*

Proof. Let $\lambda = u_x(x_0, y_0) = v_y(x_0, y_0)$ and $\mu = -u_y(x_0, y_0) = v_x(x_0, y_0)$. By lemma 4.1, we can write

$$u(x_0 + h, y_0 + k) - u(x_0, y_0) = h\lambda - k\mu + R_1$$

and

$$v(x_0 + h, y_0 + k) - v(x_0, y_0) = h\mu + k\lambda + R_2$$

for small h, k and where $R_1/\sqrt{h^2+k^2}$ and $R_2/\sqrt{h^2+k^2}$ tend to zero as $h, k \to 0$ (not both zero). Hence, with $\zeta = h + ik \neq 0$,

$$\begin{aligned}\frac{f(z_0+\zeta) - f(z_0)}{\zeta} &= \frac{h\lambda - k\mu + i(h\mu + k\lambda) + R_1 + iR_2}{h + ik} \\ &= \frac{(h+ik)(\lambda + i\mu) + R_1 + iR_2}{h + ik} \\ &= \lambda + i\mu + \underbrace{\frac{R_1 + iR_2}{h + ik}}_{\to 0 \text{ as } h+ik \to 0}.\end{aligned}$$

It follows that f is differentiable at $z_0 = x_0 + iy_0$ and that its derivative is given by $f'(z_0) = \lambda + i\mu$. □

$\{(x,y,z) \in \mathbb{R}^3 : x^2+y^2+z^2=1\}$ in $\mathbb{R}^3$ and let N denote the point $(0,0,1)$, the "north pole" of S^2.

Think of $\mathbb{C}$ as the plane $\{(x,y,z) : z=0\}$, containing the equator of S^2.

Then given any point P in this plane, the straight line through P and N cuts the sphere S^2 in a unique place, P' say. As P varies over the plane, the corresponding point P' varies over $S^2 \setminus \{N\}$.

This sets up a one-one correspondence between $\mathbb{C}$ and $S^2 \setminus \{N\}$.

Chapter 5 →

(%. ## . 8 *00 GGG

Corollary 5.4 *For any* $t \in \mathbb{R}$, $|\exp(it)| = 1$.

Proof. We have $\exp(it) = \cos t + i \sin t$. Both $\cos t$ and $\sin t$ are real if t is, and therefore $|\exp(it)|^2 = \cos^2 t + \sin^2 t = 1$. □

Remark 5.5 For real x, $\sin x$ and $\cos x$ are also real, and so the relation $\sin^2 x + \cos^2 x = 1$ shows that $|\sin x| \le 1$ and also $|\cos x| \le 1$. These inequalities do not extend to the complex case. For example, if $z = it$, with $t \in \mathbb{R}$, then $\sin z = \sin it = (\exp(-t) - \exp t)/2i$. If t is large (and positive), then $\exp t$ is large, $\exp(-t)$ is small and so $|\sin it|$ is large. A similar remark applies to $\cos z$.

5.6 The Appearance of π

We wish to discuss various properties of $\sin x$ and $\cos x$ for real x. In particular, we would like to introduce the number π.

Theorem 5.2 *If* $x \in (0, 2)$, *then* $\sin x > 0$.

Proof. Suppose that $0 < x \le 1$. Then

$$\begin{aligned} \cos x &= 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots \\ &> 1 - \frac{x^2}{2!} - \frac{x^4}{4!} - \frac{x^6}{6!} - \dots \\ &> 1 - \frac{1}{2} - \frac{1}{2^3} - \frac{1}{2^5} - \dots, \end{aligned}$$

since $\dfrac{x^2}{2!} \le \dfrac{1}{2}$, $\dfrac{x^4}{4!} \le \dfrac{1}{4.3.2} < \dfrac{1}{2^3}, \dots$ etc.,

$$= 1 - \frac{\frac{1}{2}}{(1 - \frac{1}{4})} = \tfrac{1}{3}\,.$$

Hence $\sin' x = \cos x > \frac{1}{3}$ on $[0, 1]$ and so (by the Mean Value Theorem), $\sin x$ is strictly increasing on $[0, 1]$. But $\sin 0 = 0$ and therefore $\sin x > 0$ for $0 < x \le 1$. It follows that

$$\sin x = 2 \sin \tfrac{x}{2} \cos \tfrac{x}{2} > 0$$

whenever $0 < x \le 2$, since, in this case, $\sin \frac{x}{2} > 0$ and $\cos \frac{x}{2} > \frac{1}{3}$. □

Corollary 5.5 *The function* $\cos x$ *is strictly decreasing on* $[0, 2]$.

Proof. We have $\cos' x = -\sin x$ which is strictly negative on $(0, 2)$, by the theorem. By the Mean Value Theorem, it follows that the function $\cos x$ is strictly decreasing on $[0, 2]$. □

Theorem 5.3 $\sin 4 < 0$.

Proof. From the definition of $\sin x$,

$$\begin{aligned}\sin 4 = 4 - \frac{4^3}{3!} + \frac{4^5}{5!} - \frac{4^7}{7!} + \frac{4^9}{9!} \\ - \frac{4^{11}}{11!}\left(1 - \frac{4^2}{12.13}\right) - \frac{4^{15}}{15!}\left(1 - \frac{4^2}{16.17}\right) \\ - \frac{4^{19}}{19!}\left(1 - \frac{4^2}{20.21}\right) - \cdots \\ < 4 - \frac{4^3}{3!} + \frac{4^5}{5!} - \frac{4^7}{7!} + \frac{4^9}{9!} = -\tfrac{268}{405}\end{aligned}$$

and the result follows. □

Theorem 5.4 *There is a unique real number* π *satisfying* $0 < \pi < 4$ *such that* $\sin \pi = 0$. *Furthermore,* $\cos \frac{\pi}{2} = 0$, $\sin \frac{\pi}{2} = 1$ *and* $\cos \pi = -1$.

Proof. We have seen that $\sin x > 0$ for $x \in (0, 2)$ and so, in particular, $\sin 1 > 0$. We have also shown that $\sin 4 < 0$. Now, the map $x \mapsto \sin x$ is continuous on $\mathbb{R}$, and so, by the Intermediate Value Theorem, there is some real number, which we will denote by π, with $1 < \pi < 4$ and such that $\sin \pi = 0$.

We must now show that π is the only value in $(0, 4)$ obeying $\sin \pi = 0$. To this end, suppose that $\sin \alpha = 0$ with $0 < \alpha < 4$. Then

$$0 = \sin \alpha = 2 \sin \tfrac{\alpha}{2} \cos \tfrac{\alpha}{2}.$$

Hence either $\sin \frac{\alpha}{2} = 0$ or $\cos \frac{\alpha}{2} = 0$ (they cannot both vanish because the sum of their squares is equal to 1). But if $0 < \alpha < 4$, then $0 < \frac{\alpha}{2} < 2$ and we know that $\sin x > 0$ on $(0, 2)$, so $\sin \frac{\alpha}{2}$ cannot be zero. Hence, we must have that $\cos \frac{\alpha}{2} = 0$. In particular, $\cos \frac{\pi}{2} = 0$. However, $\cos x$ is strictly decreasing on $[0, 2]$ and so there can be at most one solution to $\cos x = 0$ in this interval. Hence $\frac{\alpha}{2} = \frac{\pi}{2}$ so that $\alpha = \pi$, and the uniqueness is established.

Next, $\sin^2 z + \cos^2 z = 1$ implies that $\sin^2 \frac{\pi}{2} = 1$, since $\cos \frac{\pi}{2} = 0$. Hence $\sin \frac{\pi}{2} = 1$ because $\sin \frac{\pi}{2} > 0$ (since $0 < \frac{\pi}{2} < 2$).

Finally, we have $\cos \pi = 2 \cos^2 \frac{\pi}{2} - 1 = -1$. □

What's going on? We have defined the trigonometric functions, out of the blue as it were, by means of power series. This approach avoids any appeal to geometry and right-angled triangles. However, having chosen this route, we must stick with it. In particular, it is necessary to get to π via these definitions rather than by drawing triangles or circles. As we have seen, this is all perfectly possible. Our view here is that the trigonometric functions are as we have defined them. Any results must be deduced as consequences of these power series definitions.

Remark 5.6 Numerical investigation yields $\pi = 3.14159\ldots$. It is known that π is irrational (in fact, transcendental). It is something of a sport (involving some fascinating numerical analysis) to calculate the value of π to a large number of decimal places and this has been done to over a million decimal places. Such programs have been used to test the computational integrity of supercomputers by checking to see whether they get these digits correct or not.

Theorem 5.5 *For any $z \in \mathbb{C}$ and $n \in \mathbb{Z}$,*

$$\begin{aligned}\sin(z + n\pi) &= (-1)^n \sin z \\ \cos(z + n\pi) &= (-1)^n \cos z.\end{aligned}$$

Proof. We use the trigonometric formulae;

$$\begin{aligned}\sin(z + \pi) &= \sin z \cos \pi + \cos z \sin \pi \\ &= -\sin z + 0,\end{aligned}$$

and

$$\begin{aligned}\cos(z + \pi) &= \cos z \cos \pi - \sin z \sin \pi \\ &= -\cos z - 0.\end{aligned}$$

For $n > 0$, the result now follows by induction. Substituting $z = w - n\pi$, the result then follows for $n < 0$. □

Remark 5.7 Particular cases of the above formulae deserve mention. If we set $z = 0$, then we see that $\sin(n\pi) = 0$ and $\cos(n\pi) = (-1)^n$, for any $n \in \mathbb{Z}$. The functions sin and cos are periodic (with period 2π). In particular, for any $x \in \mathbb{R}$ and any $n \in \mathbb{Z}$,

$$\begin{aligned}\sin(x + 2n\pi) &= \sin x \quad \text{and} \\ \cos(x + 2n\pi) &= \cos x.\end{aligned}$$

If we piece together all the information gained above, we recover the familiar picture of $\sin x$ and $\cos x$, for $x \in \mathbb{R}$, as periodic 'wavy' functions. In fact, $\sin x$ is an odd function, so it is determined by its values on $x \geq 0$. It is periodic, so it is determined by its values on $[0, 2\pi]$. But, $\sin(x + \pi) = \sin x \cos \pi + \cos x \sin \pi = -\sin x$ and so $\sin x$ is determined by its values on the interval $[0, \pi]$. Now,

$$\sin\left(\tfrac{\pi}{2} \pm x\right) = \sin \tfrac{\pi}{2} \cos x \pm \cos \tfrac{\pi}{2} \sin x = \cos x,$$

so we see that $\sin x$ is symmetric about $x = \frac{\pi}{2}$. It follows that $\sin x$ is completely determined by its values on $[0, \frac{\pi}{2}]$.

Furthermore, $\sin(x + \frac{\pi}{2}) = \cos x$ and so the graph of $\cos x$ is got by translating the graph of $\sin x$ by $\frac{\pi}{2}$ to the left.

5.7 Inverse Trigonometric Functions

From the analysis above, we see that $\sin x$ is strictly increasing on the interval $[-\frac{\pi}{2}, \frac{\pi}{2}]$, $\cos x$ is strictly decreasing on the interval $[0, \pi]$ and is strictly increasing on the interval $[-\pi, 0]$. In particular, this means that sin is a one-one map of $[-\frac{\pi}{2}, \frac{\pi}{2}]$ onto $[-1, 1]$, cos is a one-one map of $[0, \pi]$ onto $[-1, 1]$ and also of $[-\pi, 0]$ onto $[-1, 1]$. For $t \in [-1, 1]$, let $\phi(t)$ be the unique element of $[-\frac{\pi}{2}, \frac{\pi}{2}]$ such that $\sin \phi(t) = t$, let $\psi(t)$ be the unique element of $[0, \pi]$ such that $\cos \psi(t) = t$ and let $\rho(t)$ be the unique element of $[-\pi, 0]$ with $\cos \rho(t) = t$. Thus, ϕ is the inverse of $\sin : [-\frac{\pi}{2}, \frac{\pi}{2}] \to [-1, 1]$, ψ is the inverse of $\cos : [0, \pi] \to [-1, 1]$ and ρ is the inverse of $\cos : [-\pi, 0] \to [-1, 1]$.

The standard inverse trigonometric functions $\sin^{-1}$ and $\cos^{-1}$ are given by $\sin^{-1}(t) = \phi(t)$ and $\cos^{-1}(t) = \psi(t)$ for $t \in [-1, 1]$ so that $\sin^{-1}$ takes values in $[-\frac{\pi}{2}, \frac{\pi}{2}]$ whilst $\cos^{-1}$ takes values in $[0, \pi]$.

Theorem 5.6 *Suppose that $f : [a, b] \to [c, d]$ is a strictly increasing (or decreasing) continuous map from $[a, b]$ onto $[c, d]$. Then the inverse map $f^{-1} : [c, d] \to [a, b]$ is continuous.*

Proof. The idea of the proof is straightforward, but it is a nuisance having to consider the end-points c and d of $[c, d]$ and the interior (c, d) separately. To avoid this, we shall first consider the case of $f : \mathbb{R} \to \mathbb{R}$. Suppose, then, that $f : \mathbb{R} \to \mathbb{R}$ is, say, strictly increasing and maps $\mathbb{R}$ onto $\mathbb{R}$. Let $y_0 \in \mathbb{R}$ and $\varepsilon > 0$ be given. Let $x_0 \in \mathbb{R}$ be the unique point such that $f(x_0) = y_0$, thus, $x_0 = f^{-1}(y_0)$. Set $y_1 = f(x_0 - \varepsilon)$ and $y_2 = f(x_0 + \varepsilon)$,

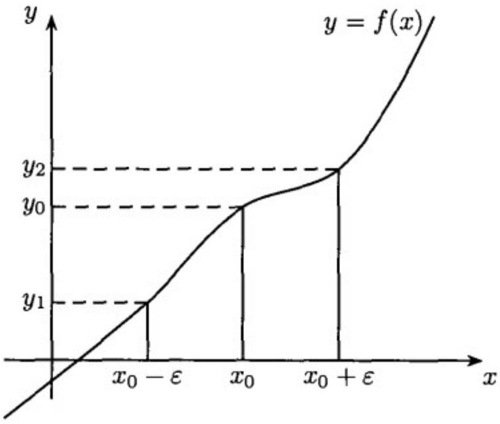

Fig. 5.1 Continuity of the inverse function.

as shown in Fig. 5.1. Then $y_1 < y_0 < y_2$. Furthermore, if $y_1 < y < y_2$, then $x_0 - \varepsilon < f^{-1}(y) < x_0 + \varepsilon$. Putting $\delta = \min\{y_0 - y_1, y_2 - y_0\}$ we see that $|y - y_0| < \delta$ implies that $\left|f^{-1}(y) - f^{-1}(y_0)\right| < \varepsilon$. That is, f^{-1} is continuous at y_0 and therefore on all of $\mathbb{R}$.

The case where f is strictly decreasing is similarly proved. Alternatively, one can note that $f^{-1}(y) = (-f)^{-1}(-y)$ and that $-f$ is increasing if f is decreasing.

Returning now to the case where f is strictly increasing and maps $[a, b]$ onto $[c, d]$, we simply extend f to the whole of $\mathbb{R}$. Define $F : \mathbb{R} \to \mathbb{R}$ by

$$F(x) = \begin{cases} x + f(a) - a, & x < a \\ f(x), & a \leq x \leq b \\ x + f(b) - b, & b < x. \end{cases}$$

Then F maps $\mathbb{R}$ onto $\mathbb{R}$, is strictly increasing, and is equal to f on $[a, b]$. As above, we see that F^{-1} is continuous. In particular, $F^{-1} = f^{-1}$ is continuous on $[c, d]$. □

Theorem 5.7 *Each of the functions ϕ, ψ, and ρ is continuous.*

Proof. This follows immediately from the preceding theorem. □

0132777622.pdf

for all $z \in \mathbb{C}$. Evidently, $\exp 0 = 1$, $\sin 0 = 0$ and $\cos 0 = 1$. Furthermore, sin is an odd function and cos is an even function, that is, $\sin(-z) = -\sin z$, and $\cos(-z) = \cos z$, for all $z \in \mathbb{C}$. If x is real, then each of $\exp x$, $\sin x$ and $\cos x$ is also real. The relationship between these three functions is not particularly transparent in the real context, but direct substitution shows that, for any $z \in \mathbb{C}$,

$$\exp iz = \cos z + i \sin z\,.$$

From this it follows that

$$\cos z = \frac{\exp iz + \exp(-iz)}{2} \quad \text{and} \quad \sin z = \frac{\exp iz - \exp(-iz)}{2i}\,.$$

5.2 Complex Hyperbolic Functions

Definition 5.2 The complex hyperbolic sine and cosine functions are defined as the series

$$\sinh z = \sum_{n=0}^{\infty} \frac{z^{2n+1}}{(2n+1)!} = z + \frac{z^3}{3!} + \frac{z^5}{5!} + \frac{z^7}{7!} + \dots$$

$$\cosh z = \sum_{n=0}^{\infty} \frac{z^{2n}}{(2n)!} = 1 + \frac{z^2}{2!} + \frac{z^4}{4!} + \frac{z^6}{6!} + \dots\,.$$

We see that

$$\sinh z = \tfrac{1}{2}\big(\exp z - \exp(-z)\big) \quad \text{and} \quad \cosh z = \tfrac{1}{2}\big(\exp z + \exp(-z)\big)$$

and, moreover, that $\sinh z = -i \sin(iz)$ and $\cosh z = \cos(iz)$. Thus, in the complex variable context, the properties of the hyperbolic functions can be readily obtained from those of the complex trigonometric functions, which shows that this is really the natural context for these functions. This is in sharp contrast to the real variable situation, where the behaviour of the hyperbolic functions on the one hand, and that of the real trigonometric functions on the other, are quite distinct. It is the extension from a real to a complex variable that exposes the otherwise hidden connections.

5.3 Properties of $\exp z$

The basic properties of the complex exponential function are given in the following proposition.

Proposition 5.1 *The exponential function has the following properties:*

(i) $\exp 0 = 1$,
(ii) $\exp(z+w) = \exp z \, \exp w$, *for any* $z, w \in \mathbb{C}$,
(iii) $\exp z \neq 0$, *for all* $z \in \mathbb{C}$,
(iv) $\exp(-z) = 1/\exp z$, *for all* $z \in \mathbb{C}$,
(v) $\exp(x+iy) = \exp x\,(\cos y + i \sin y)$, *for* $x, y \in \mathbb{C}$ *(and, in particular, for any* $x, y \in \mathbb{R}$*).*

Proof. Setting $z = 0$ immediately gives (i). To prove (ii), fix $w \in \mathbb{C}$ and set $f(z) = \exp(z+w)\,\exp(-z)$. Then we find that, for any $z \in \mathbb{C}$,

$$\begin{aligned} f'(z) &= \big(\exp(z+w)\big)'\,\exp(-z) + \exp(z+w)\,\big(\exp(-z)\big)' \\ &= \exp(z+w)\,\exp(-z) - \exp(z+w)\,\exp(-z) \\ &= 0. \end{aligned}$$

It follows that f is constant, and therefore $f(z) = f(0) = \exp w$, that is,

$$\exp w = \exp(z+w)\,\exp(-z).$$

Now set $w = a + b$ and $z = -b$. Then we obtain

$$\exp(a+b) = \exp a \, \exp b,$$

for any $a, b \in \mathbb{C}$, as required.

Using (ii) with $w = -z$, we find that

$$\exp z \, \exp(-z) = \exp 0 = 1, \text{ by (i)},$$

and so (iii) follows, and so does (iv).

To prove (v), let $z = x + iy$ and then apply (ii) to obtain

$$\begin{aligned} \exp z = \exp(x+iy) &= \exp x \, \exp(iy) \\ &= \exp x\,(\cos y + i \sin y). \end{aligned}$$

This holds for any $x, y \in \mathbb{C}$ and so, in particular, also for real x, y. □

Corollary 5.1 *Let e be the real number given by*

$$e = 1 + 1 + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \ldots = \exp 1.$$

Then $\exp n = e^n$ *for any* $n \in \mathbb{Z}$.

Proof. For each $n \in \mathbb{Z}$, let $P(n)$ be the statement that $\exp n = e^n$. For $n \in \mathbb{N}$, we shall prove the claim by induction. By definition, $\exp 1 = e$ and so $P(1)$ is true. Now let $n \in \mathbb{N}$ and suppose that $P(n)$ is true. Then

$$\begin{aligned}\exp(n+1) &= \exp n \, \exp 1, \text{ by the previous proposition,}\\ &= e^n \exp 1, \text{ by induction hypothesis,}\\ &= e^n e, \text{ since } \exp 1 = e,\\ &= e^{n+1}\end{aligned}$$

so that $P(n+1)$ is true. By induction, $P(n)$ is true for all $n \in \mathbb{N}$.

Clearly $P(0)$ is true, since both $\exp 0$ and e^0 are equal to 1 ($e^0 = 1$, by definition). Now let $n = -m$ with $m \in \mathbb{N}$. Then $\exp m = e^m$ and

$$\exp n = \exp(-m) = \frac{1}{\exp m} = \frac{1}{e^m} = e^{-m} = e^n \,,$$

as required. □

Remark 5.1 It is because of this relationship that one writes e^z for $\exp z$. This notation is often very convenient.

Remark 5.2 Suppose f is entire and satisfies $f'(z) = f(z)$ for all z and $f(0) = 1$. Then $f(z) = \exp z$. To see this, we consider the entire function $g(z) = f(z)\exp(-z)$. We see that $g'(z) = 0$ for all $z \in \mathbb{C}$ and so g is constant, $g(z) = g(0) = 1$. But then we find that $f(z) = \exp z$, as required.

For $z = x + iy$, let $f(z) = e^x(\cos y + i \sin y)$ so that $\operatorname{Re} f(x+iy) = e^x \cos y$ and $\operatorname{Im} f(x+iy) = e^x \sin y$. These functions have continuous partial derivatives throughout $\mathbb{R}^2$ and obey the Cauchy-Riemann equations and so $f(z)$ is analytic at every $z \in \mathbb{C}$. Furthermore, we know that its derivative is given by

$$f'(x+iy) = \partial_x \operatorname{Re} f(x+iy) + i\partial_x \operatorname{Im} f(x+iy) = e^x \cos y + ie^x \sin y = f(x+iy)\,.$$

Since $f(0) = 1$ we conclude that $f(z) = \exp z$.

Sometimes this approach is used to *define* the complex exponential function—assuming that the real functions e^t, $\sin\theta$ and $\cos\theta$ are somehow already known.

Proposition 5.2 *The number e is irrational.*

Proof. For any $k \in \mathbb{N}$, the power series expression for $e = \exp 1$ implies that

$$\sum_{j=0}^{k} \frac{1}{j!} < e = \sum_{j=0}^{k} \frac{1}{j!} + \frac{1}{k!}\Big(\frac{1}{k+1} + \frac{1}{(k+1)(k+2)} + \dots\Big).$$

Since $1/(k+1)(k+2)\dots(k+m) < 1/2^m$ for any $m \in \mathbb{N}$, $m > 1$, we see that the term in brackets on the right hand side above is bounded above by $\sum_{m=1}^{\infty} 1/2^m = 1$ and so

$$\sum_{j=0}^{k} \frac{1}{j!} < e < \sum_{j=0}^{k} \frac{1}{j!} + \frac{1}{k!}$$

for any $k \in \mathbb{N}$. Multiplying through by $k!$ and rearranging, we get

$$0 < k!\Big(e - \sum_{j=0}^{k} \frac{1}{j!}\Big) < 1$$

for any $k \in \mathbb{N}$. If e were rational, then we could write e as $e = p/q$ for some $p, q \in \mathbb{N}$. Setting k in the inequality above to be any integer greater than q and then taking $k!$ inside the bracket, we see that the middle expression is a positive integer strictly less than 1, which is impossible. We conclude that e is irrational. □

Remark 5.3 In fact, it is known that e is transcendental (that is, it is not a root of any real polynomial with integer coefficients, unlike $\sqrt{2}$, for example). Numerical considerations give $e = 2.71828\dots$.

5.4 Properties of $\sin z$ and $\cos z$

We turn now to basic properties of the complex trigonometric functions, sin and cos. These must be established from their power series definitions as given above.

For real α, β, we have that $\exp i(\alpha + \beta) = \cos(\alpha + \beta) + i \sin(\alpha + \beta)$. However,

$$\begin{aligned}
\exp i(\alpha + \beta) &= \exp i\alpha \, \exp i\beta \\
&= (\cos\alpha + i \sin\alpha)\,(\cos\beta + i \sin\beta) \\
&= \cos\alpha\cos\beta - \sin\alpha\sin\beta + i(\sin\alpha\cos\beta + \cos\alpha\sin\beta).
\end{aligned}$$

Equating real and imaginary parts leads to the addition rules

$$\sin(\alpha+\beta)=\sin\alpha\cos\beta+\cos\alpha\sin\beta$$

and

$$\cos(\alpha+\beta)=\cos\alpha\sin\beta-\sin\alpha\sin\beta,$$

for any $\alpha,\beta\in\mathbb{R}$. It is natural to ask whether these relationships are also valid for complex α and β. In fact they are, as we now show.

5.5 Addition Formulae

Theorem 5.1 (Addition Formulae) *For any* $a,b\in\mathbb{C}$,

$$\begin{aligned}\sin(a+b)&=\sin a\,\cos b+\cos a\,\sin b\\ \cos(a+b)&=\cos a\,\cos b-\sin a\,\sin b.\end{aligned}$$

Proof. The easiest way of proving these relations is to write the right hand sides in terms of the exponential function and do a bit of algebra. We find

$$\begin{aligned}\sin a\cos b+{}&\cos a\sin b\\ &=\frac{(e^{ia}-e^{-ia})}{2i}\,\frac{(e^{ib}+e^{-ib})}{2}\\ &\qquad+\frac{(e^{ia}+e^{-ia})}{2}\,\frac{(e^{ib}-e^{-ib})}{2i}\\ &=\frac{(e^{ia}e^{ib}+e^{ia}e^{-ib}-e^{-ia}e^{ib}-e^{-ia}e^{-ib})}{4i}\\ &\qquad+\frac{(e^{ia}e^{ib}-e^{ia}e^{-ib}+e^{-ia}e^{ib}-e^{-ia}e^{-ib})}{4i}\\ &=\frac{(e^{i(a+b)}+e^{i(a-b)}-e^{-i(a-b)}-e^{-i(a+b)})}{4i}\\ &\qquad+\frac{(e^{i(a+b)}-e^{i(a-b)}+e^{-i(a-b)}-e^{-i(a+b)})}{4i}\\ &=\frac{(e^{i(a+b)}-e^{-i(a+b)})}{2i}\\ &=\sin(a+b).\end{aligned}$$

Similarly, we calculate

$$\begin{aligned}\cos a\cos b+\sin a\sin b&=\frac{(e^{ia}+e^{-ia})}{2}\,\frac{(e^{ib}+e^{-ib})}{2}\\&\qquad+\frac{(e^{ia}-e^{-ia})}{2i}\,\frac{(e^{ib}-e^{-ib})}{2i}\\&=\frac{(e^{i(a+b)}+e^{-i(a+b)})}{2}\\&=\cos(a+b),\end{aligned}$$

as required. ☐

Corollary 5.2 *For any* $z\in\mathbb{C}$, $(\sin z)^2+(\cos z)^2=1$.

Proof. The identity $\cos(a+b)=\cos a\cos b-\sin a\sin b$, with $a=z$ and $b=-z$, gives

$$\begin{aligned}\cos 0&=\cos z\cos(-z)-\sin z\sin(-z)\\&=\cos z\cos z+\sin z\sin z,\end{aligned}$$

where we have used $\cos(-z)=\cos z$ and $\sin(-z)=-\sin z$. The result now follows since $\cos 0=1$. ☐

Remark 5.4 An alternative proof is to set $\psi(z)=\sin^2 z+\cos^2 z$ and then to calculate $\psi'(z)$. One finds that $\psi'(z)=0$, for all $z\in\mathbb{C}$, and so it follows that ψ is constant. Therefore $\psi(z)=\psi(0)=1$, as required.

In the same spirit, we can prove the addition formulae by considering the functions

$$f(z)=\sin(w-z)\cos z+\cos(w-z)\sin z$$

and

$$g(z)=\cos(w-z)\cos z-\sin(w-z)\sin z\,.$$

One finds that $f'(z)=0$ and $g'(z)=0$ for all z, so that both f and g are constant: $f(z)=f(0)=\sin w$ and $g(z)=g(0)=\cos w$. Letting $w=a+b$ and setting $z=b$, we get the required formulae.

Corollary 5.3 *For any* $z\in\mathbb{C}$, *we have*

$$\begin{aligned}&\sin 2z=2\sin z\cos z\quad\textit{and}\\&\cos 2z=\cos^2 z-\sin^2 z=2\cos^2 z-1=1-2\sin^2 z.\end{aligned}$$

Proof. We simply put $a=b=z$ in the addition formulae above and use the identity $\sin^2 z+\cos^2 z=1$. ☐

Corollary 5.4 *For any* $t \in \mathbb{R}$, $|\exp(it)| = 1$.

Proof. We have $\exp(it) = \cos t + i \sin t$. Both $\cos t$ and $\sin t$ are real if t is, and therefore $|\exp(it)|^2 = \cos^2 t + \sin^2 t = 1$. □

Remark 5.5 For real x, $\sin x$ and $\cos x$ are also real, and so the relation $\sin^2 x + \cos^2 x = 1$ shows that $|\sin x| \le 1$ and also $|\cos x| \le 1$. These inequalities do not extend to the complex case. For example, if $z = it$, with $t \in \mathbb{R}$, then $\sin z = \sin it = (\exp(-t) - \exp t)/2i$. If t is large (and positive), then $\exp t$ is large, $\exp(-t)$ is small and so $|\sin it|$ is large. A similar remark applies to $\cos z$.

5.6 The Appearance of π

We wish to discuss various properties of $\sin x$ and $\cos x$ for real x. In particular, we would like to introduce the number π.

Theorem 5.2 *If* $x \in (0, 2)$, *then* $\sin x > 0$.

Proof. Suppose that $0 < x \le 1$. Then

$$\begin{aligned}\cos x &= 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots \\ &> 1 - \frac{x^2}{2!} - \frac{x^4}{4!} - \frac{x^6}{6!} - \dots \\ &> 1 - \frac{1}{2} - \frac{1}{2^3} - \frac{1}{2^5} - \dots,\end{aligned}$$

since $\dfrac{x^2}{2!} \le \dfrac{1}{2}$, $\dfrac{x^4}{4!} \le \dfrac{1}{4.3.2} < \dfrac{1}{2^3}$, ... etc.,

$$= 1 - \frac{\frac{1}{2}}{(1 - \frac{1}{4})} = \tfrac{1}{3}.$$

Hence $\sin' x = \cos x > \frac{1}{3}$ on $[0, 1]$ and so (by the Mean Value Theorem), $\sin x$ is strictly increasing on $[0, 1]$. But $\sin 0 = 0$ and therefore $\sin x > 0$ for $0 < x \le 1$. It follows that

$$\sin x = 2 \sin \tfrac{x}{2} \cos \tfrac{x}{2} > 0$$

whenever $0 < x \le 2$, since, in this case, $\sin \frac{x}{2} > 0$ and $\cos \frac{x}{2} > \frac{1}{3}$. □

Streamlines for ideal fluid flow around a cylinder

(a)

Fluid flows faster within a narrow streamtube

Fig. 3–6

3.3 Graphical Descriptions of Fluid Flow

Several graphical methods have been devised to visualize the behavior of a flow. For analysis, these include using streamlines or streamtubes, and for experimental work, pathlines and streaklines, and optical methods are often used. We will now give each of these separate treatment.

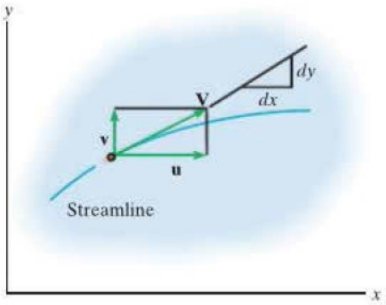
Streamlines. A ***streamline*** is a curve that is drawn through the fluid in such a manner that it indicates the direction of the velocity of particles located on it at a particular *instant of time*. Specifically, the velocity of any particle is always *tangent* to the streamline along which it is traveling at that instant. Consequently, no fluid can flow across a streamline, only *along* the streamline. For example, the streamlines for the steady flow of an *ideal fluid* around a cylinder enclosed within a rectangular duct are shown in Fig. 3–6*a*. In particular, notice the streamline at the center of the flow field. It intersects the cylinder at A. This point is called a ***stagnation point,*** because here the velocity of any particle is *momentarily* reduced to zero when it strikes the cylinder's surface.

It is important to keep in mind that streamlines are used to represent the flow field during each *instant of time*. In the example just given, the direction of the streamlines is *maintained* as time passes and fluid particles move along them; however, sometimes the streamlines can be a function of *both* space and time. For example, this occurs when fluid flows through a rotating pipe. Here the streamlines *change position* from one instant to the next, and so the fluid particles do not move along any streamline that is fixed in position.

Since the particle's velocity is *always tangent* to its streamline, then if the velocity is known, the equation that defines a streamline at a particular instant can always be determined. For example, in the case of two-dimensional flow, the particle's velocity will have two components, u in the x direction and v in the y direction. As noted in Fig. 3–7, we require

$$\boxed{\frac{dy}{dx} = \frac{v}{u}} \qquad (3\text{–}3)$$

Integrating this equation will give the *equation of the streamlines*, $y = f(x) + C$. To find the streamline that passes through a particular point (x_0, y_0), we can substitute these coordinates into this equation to evaluate the constant C. This process is demonstrated in Examples 3.1 and 3.2.



The velocity is always tangent to the streamline

Fig. 3–7

Streamtubes. For some types of analysis, it is convenient to consider a *bundle of streamlines* that surround a region of flow, Fig. 3–8. Such a circumferential grouping is called a ***streamtube***. Here the fluid flows through the streamtube as if it were contained within a curved conduit.

In two dimensions, streamtubes can be formed between any two streamlines. For example, consider the streamtube in Fig. 3–6*b* for flow around the cylinder. Notice that a small element of fluid traveling along this streamtube will move *slower* when the streamlines are *farther apart* (or the streamtube is wider), and move *faster* when they are *closer together* (or the streamtube is narrow). This is a consequence of the conservation of mass, something we will discuss in the next chapter.

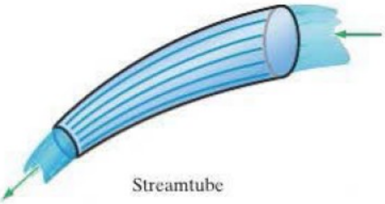


Fig. 3–8

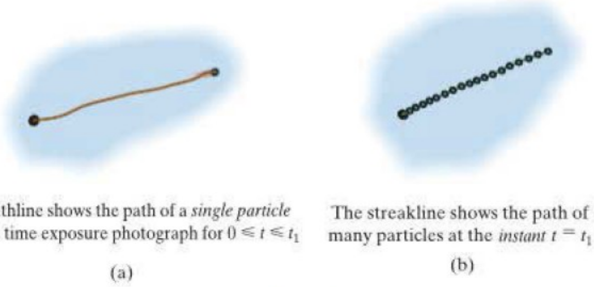


The pathline shows the path of a *single particle* using a time exposure photograph for $0 \leq t \leq t_1$

(a)

The streakline shows the path of many particles at the *instant* $t = t_1$

(b)

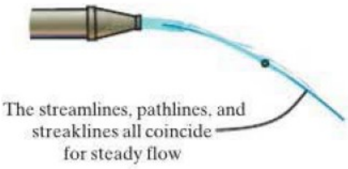
Fig. 3–9

This photo shows the streaklines of water particles ejected from a water sprinkler at a given instant.

Pathlines. The ***pathline*** for a fluid particle defines the "path" the particle travels over a *period of time*. To obtain the pathline experimentally, a neutrally buoyant *single particle* can be released within the flow stream and a *time-exposed photograph* taken. The line on the photograph then represents the pathline for this particle, Fig. 3–9*a*.

Streaklines. If smoke is released continuously in a gas, or colored dye is released in a liquid, a "trace" of *all the particles* will be carried along with the flow. This resulting succession of marked particles that have all come from the same point of origin is called a ***streakline***. It can be identified by taking an *instantaneous photograph* of the trace, or "streak," of *all the particles*, Fig. 3–9*b*.

As long as the flow is *steady*, the streamlines, pathlines, and streaklines will all *coincide*. For example, this occurs for the steady flow of water ejected from the *fixed* nozzle, Fig. 3–10. Here a streamline will maintain its same direction from one instant to the next, and so *every particle* coming from the nozzle will follow this same streamline, thereby producing a coincident pathline and streakline.



The streamlines, pathlines, and streaklines all coincide for steady flow

Fig. 3–10

Optical Methods. If the fluid is transparent, such as air and water, then the flow can be visualized indirectly using a shadowgraph. Simply put, a ***shadowgraph*** is the result of refracted or bent light rays that interact with the fluid and then cast a shadow on a screen in close proximity. Perhaps you have noticed the shadow of a heated air plume rising from a candle, or the shadow of the exhaust from a jet engine cast against a surface. In both of these cases the heat being produced changes the local density of the air, and the light passing through this air is bent. The greater the change in the fluid density, the more the light rays are bent. Shadowgraphs have been used in industry to visualize the air flow around jet aircraft and rockets, as well as to study the flow around devices that produce heat.

One other optical technique that is used to visualize the flow of a transparent fluid is **schlieren photography**. It also is based on detecting the density gradients within a fluid produced by the flow. In this case, a collimated or parallel beam of light shines on the object. The light is focused with a lens, and a knife edge is placed perpendicular to the beam at its focal point. This blocks about half the light and the fluid causes a distortion in the beam due to the density variations within the fluid. The distortion will cast light and dark regions on a nearby background surface. An example is shown in the accompanying photo of a heated source generating a flow of hot air used to suspend a ball. Schlieren photography has been used extensively in aeronautical engineering to visualize the formation of shockwaves and expansion waves formed around jet aircraft and missiles. For further details on these two optical techniques, see Ref. [5].

Computational Fluid Dynamics. Although the experimental techniques just discussed have played an important role in studying complicated flow patterns, they have been increasingly replaced with numerical techniques that apply the laws of fluid dynamics using high-speed computers. This is referred to as **computational fluid dynamics** (CFD). There are many types of commercially available CFD programs, and with some of them the engineer can extend an analysis to include heat transfer and multiphase changes within the fluid. Generally the output includes a plot of the streamlines or pathlines, with the velocity field displayed in a color-coded fashion. Digital printouts of steady flow can be made, or if the flow is unsteady, then a video can be produced. We will discuss this important field in greater length in Sec. 7.12.

Important Points

- There are two ways to describe the motion of fluid particles within a flow. A *Lagrangian description*, or system approach, has limited use since it requires tracking the location of *each particle* in the flow and reporting its motion. A *Eulerian description*, or control volume approach, is more practical, since it considers a specific region or point in the flow, and measures the motion of any fluid particles passing through this region or point.
- Fluid flow can be described in various ways. It can be classified as the result of viscous friction, which is, either laminar, transitional, or turbulent. It can be classified as nondimensional, or as one-, two-, or three-dimensional. And finally, for a space–time classification, the flow is *steady* if it does not vary with time, and *uniform* if it does not vary with location.
- A *streamline* contains particles that have velocities that are tangent to the streamline at each instant of time. If the flow is steady, then the particles move along fixed streamlines. However, if unsteady flow causes the direction of the streamlines to change, then the particles will move along streamlines that have a different orientation from one instant to the next.
- Experimentally, the flow of a *single* marked particle can be visualized using a *pathline*, which shows the path taken by the particle using a time-lapse photograph. *Streaklines* are formed when smoke or colored dye is released into the flow from the same point, and an instantaneous photo is taken of the trace of *many* particles.
- Optical methods, such as shadowgraphs and schlieren photographs, are useful for observing flow in transparent fluids caused by heat, or to visualize shock and expansion waves created in high speed flows.
- Computational fluid dynamics uses numerical analysis to apply the laws of fluid dynamics, and thereby produces data to visualize complex flow.

EXAMPLE 3.1

The velocity for the two-dimensional flow shown in Fig. 3–11 is defined by $\mathbf{V} = \{6y\mathbf{i} + 3\mathbf{j}\}\,\text{m/s}$, where y is in meters. Determine the equation of the streamline that passes through point (1 m, 2 m).

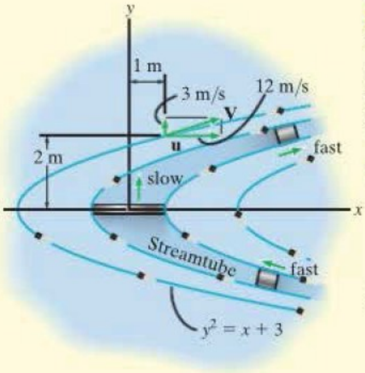

Fig. 3–11

SOLUTION

Fluid Description. This is a Eulerian description since the velocity is reported in terms of its spatial coordinates. In other words, the description reports the velocity of particles that pass through a control volume located at point (x, y) within the flow. Since time is not involved, we have steady flow, where $u = (6y)\,\text{m/s}$ and $v = 3\,\text{m/s}$.

Analysis. To find the equations of the streamlines, we must use Eq. 3–3,

$$\frac{dy}{dx} = \frac{v}{u} = \frac{3}{6y}$$

Separating the variables and integrating yields

$$\int 6y\,dy = \int 3\,dx$$

$$3y^2 = 3x + C$$

This is the equation for a parabola. Each selected constant C will produce a unique streamline. For the one passing through the point (1 m, 2 m), we require $3(2)^2 = 3(1) + C$, or $C = 9$. Therefore,

$$y^2 = x + 3 \qquad \textit{Ans.}$$

A plot of this equation (streamline) is shown in Fig. 3–11. Here particles that pass through a differential size control volume located at the point (1 m, 2 m) will have the velocity $\mathbf{V} = \{12\mathbf{i} + 3\mathbf{j}\}$ m/s, as indicated. By selecting other points to evaluate the integration constant C, we can establish the graphical representation of the entire flow field, a portion of which is also shown in Fig. 3–11. Once this is established notice how the fluid element constrained in the selected streamtube travels fast, slows down as it passes the x axis, and then speeds up again.

NOTE: If the velocity were also a function of time, then unsteady flow would occur, and the streamlines may change location from one instant to the next. To obtain them, we would first have to evaluate $\mathbf{V}$ at a particular instant of time, and then apply Eq. 3–3 in the same manner as explained here to establish the streamlines or flow field for this instant.

EXAMPLE 3.2

The velocity components of a particle in the flow field are defined by $u = 3\text{ m/s}$ and $v = (6t)\text{ m/s}$, where t is in seconds. Plot the pathline for the particle if it is released from the origin when $t = 0$. Also draw the streamline for this particle when $t = 2\text{ s}$.

SOLUTION

Fluid Description. Since the velocity is only a function of time, this is a Lagrangian description of the particle's motion. We have nonuniform flow.

Pathline. The pathline describes the location of the particle at various times. Since the particle is at (0, 0) when $t = 0$, then

$$u = \frac{dx}{dt} = 3 \qquad\qquad v = \frac{dy}{dt} = 6t$$

$$\int_0^x dx = \int_0^t 3\,dt \qquad\qquad \int_0^y dy = \int_0^t 6t\,dt$$

$$x = (3t)\text{ m} \qquad\qquad y = \left(3t^2\right)\text{ m} \tag{1}$$

Eliminating the time between these two parametric equations, we obtain our result

$$y = 3\left(\frac{x}{3}\right)^2 \quad \text{or} \quad y = \frac{1}{3}x^2 \qquad \textit{Ans.}$$

The pathline or path taken by the particle is a parabola, shown in Fig. 3–12.

Streamline. The streamline shows the direction of the velocity of a particle at a particular instant of time. At the instant $t = 2\text{s}$, using Eq. 1, the particle is located at $x = 3(2) = 6\text{m}$, $y = 3(2)^2 = 12\text{m}$. Also it has velocity components of $u = 3\text{ m/s}$, $v = 6(2) = 12\text{ m/s}$, Fig 3–12. Applying Eq. 3–3 to obtain the equation of the streamline at this instant, we have

$$\frac{dy}{dx} = \frac{v}{u} = \frac{12}{3} = 4$$

$$\int dy = \int 4\,dx$$

$$y = 4x + C$$

Since $x = 6\text{m}$ and $y = 12\text{m}$, then $C = -12\text{ m}$. Therefore

$$y = 4x - 12$$

This streamline is shown in Fig. 3–12. Note that both the streamline and pathline have the same slope at (6 m, 12 m). This is to be expected since both must give the same direction for the velocity when $t = 2\text{ s}$. At another instant, the particle moves along the pathline, and has another streamline (tangent).

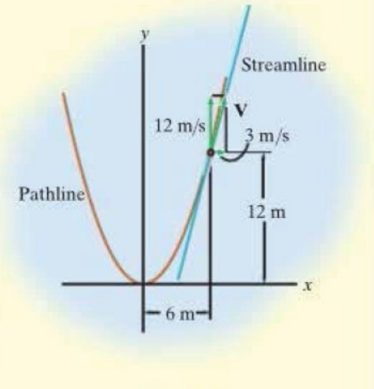

Fig. 3–12

EXAMPLE 3.3

The velocity of gas particles flowing along the center of the pipe in Fig. 3–13 is defined for $x \geq 1\,\text{m}$, by the velocity field $V = (t/x)\,\text{m/s}$, where t is in seconds and x is in meters.* If a particle is at $x = 1\,\text{m}$ when $t = 0$, determine its velocity when it is at $x = 2\,\text{m}$.

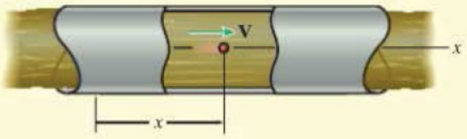

Fig. 3–13

SOLUTION

Fluid Description. Because the velocity is a function of time, the flow is unsteady, and because it is a function of position, it is nonuniform. This flow field $V = V(x, t)$ is a Eulerian description. Here *all particles* passing the location x have a velocity that changes with time, and it is measured as $V = (t/x)$.

Analysis. To find the velocity at $x = 2$ m, we must first find the time for the particle to travel from $x = 1$ m to $x = 2$ m, that is, we must find $x = x(t)$. This is a Lagrangian description since we must follow the motion of a single particle.

The particle's position can be determined from the velocity field, by realizing that for a Lagrangian description, Eq. 3–1 gives

$$V = \frac{dx}{dt} = \frac{t}{x}$$

Separating the variables and integrating yields

$$\int_1^x x\,dx = \int_0^t t\,dt$$

$$\frac{x^2}{2} - \frac{1}{2} = \frac{1}{2}t^2$$

$$x = \sqrt{t^2 + 1} \qquad (1)$$

---

*Notice that substituting t in seconds and x in meters gives units of s/m; however, here there must be a constant $1\,\text{m}^2/\text{s}^2$ (not shown) that converts these units to velocity, m/s, as stated.

The Lagrangian description of the velocity of the particle can now be determined. Here the velocity must only be a function of time.

$$V = \frac{dx}{dt} = \frac{1}{2}\left(t^2 + 1\right)^{-1/2}(2t)$$

$$= \frac{t}{\sqrt{t^2 + 1}} \qquad (2)$$

Using these results, we are now able to follow the particle as it moves along the path during each instant of time. Its position at any instant is determined from Eq. 1, and its velocity at this instant is determined from Eq. 2. Therefore, when the particle is located at $x = 2$ m, the time is

$$2 = \sqrt{t^2 + 1}$$
$$t = 1.732 \text{ s}$$

And at this time, the particle is traveling at

$$V = \frac{1.732}{\sqrt{(1.732)^2 + 1}}$$

$$V = 0.866 \text{ m/s} \qquad \textit{Ans.}$$

We can check this result, using the Eulerian description. Since we require the particle to be located at $x = 2$ m, when $t = 1.732$ s its velocity is

$$V = \frac{t}{x} = \frac{1.723}{2} = 0.866 \text{ m/s} \qquad \textit{Ans.}$$

as expected.

NOTE: In this example the velocity field has only one component, $V = u = t/x, v = 0, w = 0$. In other words, it is one-dimensional flow, and so the streamline does not change direction, rather it remains in the x direction.

3.4 Fluid Acceleration

Once the velocity field $\mathbf{V} = \mathbf{V}(x, y, z, t)$ is established, then it is possible to determine the acceleration field for the flow. One reason for doing this is to apply Newton's second law of motion, $\Sigma\mathbf{F} = m\mathbf{a}$, to relate the acceleration of the fluid particles to the forces produced by the flow. Since the velocity field is a function of *both* space and time (Eulerian description), the *time* rate of change of velocity (acceleration) must account for the changes made in *both* its space and time variables. To show how to obtain these changes, let us consider the unsteady, nonuniform flow of a fluid through the nozzle in Fig. 3–14. For simplicity, we will study the motion of a single particle as it moves through a control volume. Here the velocity is defined by $V = V(x, t)$ along the center streamline. When the particle is at position x, where the first open control surface to the control volume is located, it will have a velocity that will be *smaller* than when it is at position $x + \Delta x$, where it exits the control volume's other open control surface. This is because the nozzle constricts the flow and therefore causes the particle to have a greater speed at $x + \Delta x$. Thus the velocity of the particle will change due to its *change* Δx *in position* (nonuniform flow). If the valve is opened then the velocity of the particle can *also change within* the control volume due to a *change in time* Δt (unsteady flow). As a result, the total change in $V = V(x, t)$ will be

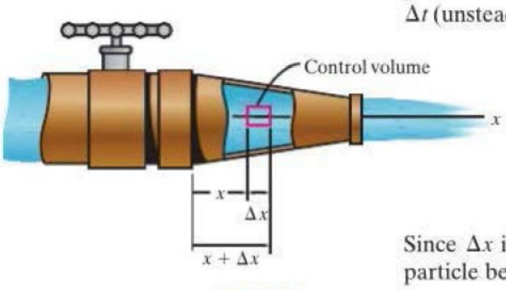

Fig. 3–14

$$\Delta V = \underbrace{\frac{\partial V}{\partial t}\Delta t}_{\substack{\text{Change of } V\\ \text{with time}\\ \text{(unsteady flow)}}} + \underbrace{\frac{\partial V}{\partial x}\Delta x}_{\substack{\text{Change of } V\\ \text{with position}\\ \text{(nonuniform flow)}}}$$

Since Δx is the distance covered in the time Δt, the acceleration of the particle becomes

$$a = \lim_{\Delta t \to 0} \frac{\Delta V}{\Delta t} = \frac{\partial V}{\partial t} + \frac{\partial V}{\partial x}\frac{dx}{dt}$$

Another way to determine this result is to use the *chain rule* of calculus. Since $V = V(x, t)$, we must use partial derivatives to find each change in V, that is, $a = \partial V/\partial t(dt/dt) + \partial V/\partial x(dx/dt)$. Realizing that $dx/dt = V$, in either case, we get

$$\boxed{a = \frac{DV}{Dt} = \underbrace{\frac{\partial V}{\partial t}}_{\substack{\text{Local}\\ \text{accel.}}} + \underbrace{V\frac{\partial V}{\partial x}}_{\substack{\text{Convective}\\ \text{accel.}}}} \qquad (3\text{–}4)$$

The notation $D(\,)/Dt$ is referred to as a ***material derivative,*** because it gives the time rate of change of a fluid property (in this case the velocity) as the fluid particle (material) passes through the control volume. Let's summarize our result.

2/6 Polar Coordinates (r-θ)
2/7 Space Curvilinear Motion
2/8 Relative Motion (Translating Axes)
2/9 Constrained Motion of Connected Particles
2/10 Chapter Review

2/1 INTRODUCTION

Kinematics is the branch of dynamics which describes the motion of bodies without reference to the forces which either cause the motion or are generated as a result of the motion. Kinematics is often described as the "geometry of motion." Some engineering applications of kinematics include the design of cams, gears, linkages, and other machine elements to control or produce certain desired motions, and the calculation of flight trajectories for aircraft, rockets, and spacecraft. A thorough working knowledge of kinematics is a prerequisite to kinetics, which is the study of the relationships between motion and the corresponding forces which cause or accompany the motion.

Particle Motion

We begin our study of kinematics by first discussing in this chapter the motions of points or particles. A particle is a body whose physical dimensions are so small compared with the radius of curvature of its path that we may treat the motion of the particle as that of a point. For example, the wingspan of a jet transport flying between Los Angeles and New York is of no consequence compared with the radius of curvature of its flight path, and thus the treatment of the airplane as a particle or point is an acceptable approximation.

We can describe the motion of a particle in a number of ways, and the choice of the most convenient or appropriate way depends a great deal on experience and on how the data are given. Let us obtain an overview of the several methods developed in this chapter by referring to Fig. 2/1, which shows a particle P moving along some general path in space. If the particle is confined to a specified path, as with a bead sliding along a fixed wire, its motion is said to be *constrained*. If there are no physical guides, the motion is said to be *unconstrained*. A small rock tied to the end of a string and whirled in a circle undergoes constrained motion until the string breaks, after which instant its motion is unconstrained.

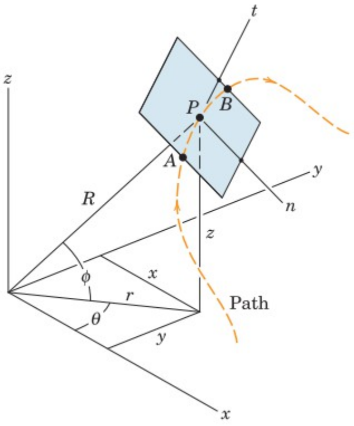

Figure 2/1

Choice of Coordinates

The position of particle P at any time t can be described by specifying its rectangular coordinates* x, y, z, its cylindrical coordinates r, θ, z, or its spherical coordinates R, θ, ϕ. The motion of P can also be described by measurements along the tangent t and normal n to the curve. The direction of n lies in the local plane of the curve.† These last two measurements are called *path variables*.

The motion of particles (or rigid bodies) can be described by using coordinates measured from fixed reference axes (*absolute-motion* analysis) or by using coordinates measured from moving reference axes (*relative-motion* analysis). Both descriptions will be developed and applied in the articles which follow.

With this conceptual picture of the description of particle motion in mind, we restrict our attention in the first part of this chapter to the case of *plane motion* where all movement occurs in or can be represented as occurring in a single plane. A large proportion of the motions of machines and structures in engineering can be represented as plane motion. Later, in Chapter 7, an introduction to three-dimensional motion is presented. We begin our discussion of plane motion with *rectilinear motion*, which is motion along a straight line, and follow it with a description of motion along a plane curve.

2/2 RECTILINEAR MOTION

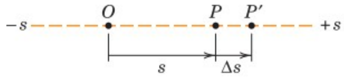

Figure 2/2

Consider a particle P moving along a straight line, Fig. 2/2. The position of P at any instant of time t can be specified by its distance s measured from some convenient reference point O fixed on the line. At time $t + \Delta t$ the particle has moved to P' and its coordinate becomes $s + \Delta s$. The change in the position coordinate during the interval Δt is called the *displacement* Δs of the particle. The displacement would be negative if the particle moved in the negative s-direction.

---

*Often called *Cartesian* coordinates, named after René Descartes (1596–1650), a French mathematician who was one of the inventors of analytic geometry.

†This plane is called the *osculating* plane, which comes from the Latin word *osculari* meaning "to kiss." The plane which contains P and the two points A and B, one on either side of P, becomes the osculating plane as the distances between the points approach zero.

Figure 2/1 Choice of Coordinates

rectangular coordinates x, y, z

its cylindrical coordinates r, θ, z, or

its spherical coordinates R, θ, ϕ.

the motion of P can also be described by measurements along the tangent t and the normal n to the curve.

the direction of n lies in the local plane of the curve.

these last two measurements are called path variables.

Motion Particles { absolute-motion analysis
{ relative-motion analysis

this plane is called the osculating plane, which the plane contains P and two points A and B, one on either side of P, becomes the osculating plane as the distances between the points approach zero.

These rules are the same as for the differentiation of scalar quantities, except for the case of the cross product where the order of the terms must be preserved. These rules are covered in Art. C/7 of Appendix C and should be reviewed at this point.

Three different coordinate systems are commonly used for describing the vector relationships for curvilinear motion of a particle in a plane: rectangular coordinates, normal and tangential coordinates, and polar coordinates. An important lesson to be learned from the study of these coordinate systems is the proper choice of a reference system for a given problem. This choice is usually revealed by the manner in which the motion is generated or by the form in which the data are specified. Each of the three coordinate systems will now be developed and illustrated.

2/4 RECTANGULAR COORDINATES (x-y)

This system of coordinates is particularly useful for describing motions where the x- and y-components of acceleration are independently generated or determined. The resulting curvilinear motion is then obtained by a vector combination of the x- and y-components of the position vector, the velocity, and the acceleration.

Vector Representation

The particle path of Fig. 2/5 is shown again in Fig. 2/7 along with x- and y-axes. The position vector $\mathbf{r}$, the velocity $\mathbf{v}$, and the acceleration $\mathbf{a}$ of the particle as developed in Art. 2/3 are represented in Fig. 2/7 together with their x- and y-components. With the aid of the unit vectors $\mathbf{i}$ and $\mathbf{j}$, we can write the vectors $\mathbf{r}$, $\mathbf{v}$, and $\mathbf{a}$ in terms of their x- and y-components. Thus,

$$\boxed{\begin{aligned}\mathbf{r} &= x\mathbf{i} + y\mathbf{j}\\ \mathbf{v} = \dot{\mathbf{r}} &= \dot{x}\mathbf{i} + \dot{y}\mathbf{j}\\ \mathbf{a} = \dot{\mathbf{v}} = \ddot{\mathbf{r}} &= \ddot{x}\mathbf{i} + \ddot{y}\mathbf{j}\end{aligned}} \qquad \mathbf{(2/6)}$$

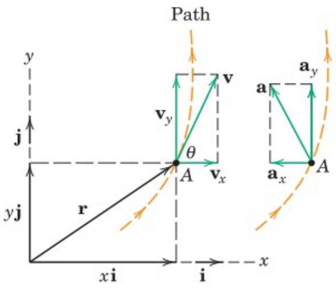

Figure 2/7

As we differentiate with respect to time, we observe that the time derivatives of the unit vectors are zero because their magnitudes and directions remain constant. The scalar values of the components of $\mathbf{v}$ and $\mathbf{a}$ are merely $v_x = \dot{x}$, $v_y = \dot{y}$ and $a_x = \dot{v}_x = \ddot{x}$, $a_y = \dot{v}_y = \ddot{y}$. (As drawn in Fig. 2/7, a_x is in the negative x-direction, so that $\ddot{x}$ would be a negative number.)

As observed previously, the direction of the velocity is always tangent to the path, and from the figure it is clear that

$$v^2 = {v_x}^2 + {v_y}^2 \qquad v = \sqrt{{v_x}^2 + {v_y}^2} \qquad \tan\theta = \frac{v_y}{v_x}$$

$$a^2 = {a_x}^2 + {a_y}^2 \qquad a = \sqrt{{a_x}^2 + {a_y}^2}$$

If the angle θ is measured counterclockwise from the x-axis to $\mathbf{v}$ for the configuration of axes shown, then we can also observe that $dy/dx = \tan\theta = v_y/v_x$.

If the coordinates x and y are known independently as functions of time, $x = f_1(t)$ and $y = f_2(t)$, then for any value of the time we can combine them to obtain $\mathbf{r}$. Similarly, we combine their first derivatives $\dot{x}$ and $\dot{y}$ to obtain $\mathbf{v}$ and their second derivatives $\ddot{x}$ and $\ddot{y}$ to obtain $\mathbf{a}$. On the other hand, if the acceleration components a_x and a_y are given as functions of the time, we can integrate each one separately with respect to time, once to obtain v_x and v_y and again to obtain $x = f_1(t)$ and $y = f_2(t)$. Elimination of the time t between these last two parametric equations gives the equation of the curved path $y = f(x)$.

From the foregoing discussion we can see that the rectangular-coordinate representation of curvilinear motion is merely the superposition of the components of two simultaneous rectilinear motions in the x- and y-directions. Therefore, everything covered in Art. 2/2 on rectilinear motion can be applied separately to the x-motion and to the y-motion.

Projectile Motion

An important application of two-dimensional kinematic theory is the problem of projectile motion. For a first treatment of the subject, we neglect aerodynamic drag and the curvature and rotation of the earth, and we assume that the altitude change is small enough so that the acceleration due to gravity can be considered constant. With these assumptions, rectangular coordinates are useful for the trajectory analysis.

For the axes shown in Fig. 2/8, the acceleration components are

$$a_x = 0 \qquad a_y = -g$$

Integration of these accelerations follows the results obtained previously in Art. 2/2*a* for constant acceleration and yields

$$\begin{aligned} v_x &= (v_x)_0 & v_y &= (v_y)_0 - gt \\ x &= x_0 + (v_x)_0 t & y &= y_0 + (v_y)_0 t - \tfrac{1}{2}gt^2 \end{aligned}$$

$$v_y{}^2 = (v_y)_0{}^2 - 2g(y - y_0)$$

In all these expressions, the subscript zero denotes initial conditions, frequently taken as those at launch where, for the case illustrated,

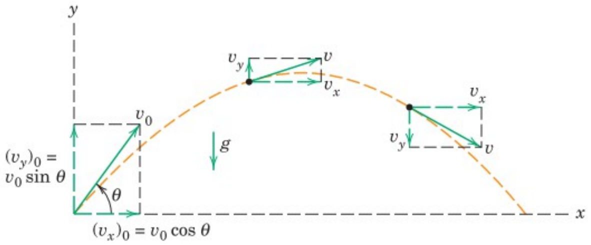

Figure 2/8

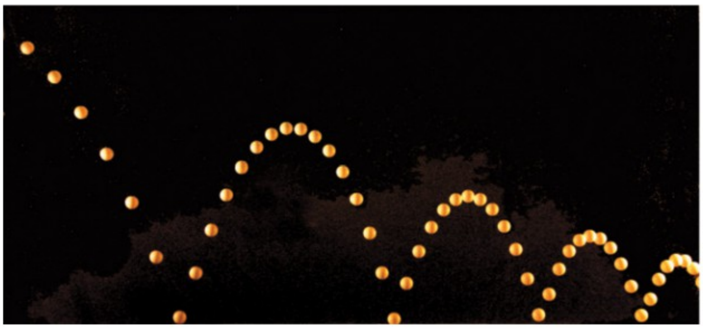
$x_0 = y_0 = 0$. Note that the quantity g is taken to be positive throughout this text.

We can see that the x- and y-motions are independent for the simple projectile conditions under consideration. Elimination of the time t between the x- and y-displacement equations shows the path to be parabolic (see Sample Problem 2/6). If we were to introduce a drag force which depends on the speed squared (for example), then the x- and y-motions would be coupled (interdependent), and the trajectory would be nonparabolic.

When the projectile motion involves large velocities and high altitudes, to obtain accurate results we must account for the shape of the projectile, the variation of g with altitude, the variation of the air density with altitude, and the rotation of the earth. These factors introduce considerable complexity into the motion equations, and numerical integration of the acceleration equations is usually necessary.



Andrew Davidhazy

This stroboscopic photograph of a bouncing ping-pong ball suggests not only the parabolic nature of the path, but also the fact that the speed is lower near the apex.

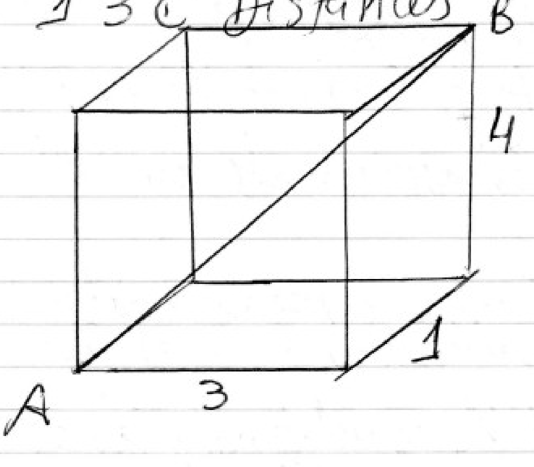
13C Distances



$$\vec{AB} = \begin{pmatrix} 3 \\ 1 \\ 4 \end{pmatrix}$$

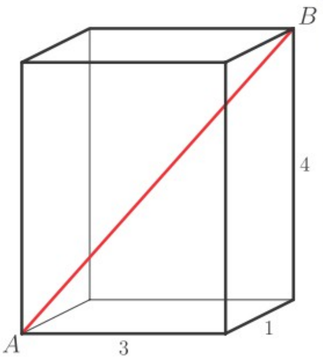
$$AB = \sqrt{3^2+1^2+4^2} = \sqrt{26}$$

this quantity is called the MAGNITUDE of $\vec{AB}$, and written as $|\vec{AB}|$.

The magnitude of a vector, $a = \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix}$, is $|a| = \sqrt{a_1^2 + a_2^2 + a_3^2}$.

The distance between points with position vector a and b is $|b-a|$

13C Distances



Geometry problems often involve finding distances between points. In this section we will see how to use vectors to do this.

Consider two points, A and B such that the displacement $\overrightarrow{AB} = \begin{pmatrix} 3 \\ 1 \\ 4 \end{pmatrix}$. The distance AB can be found by using Pythagoras' theorem in three dimensions: $AB = \sqrt{3^2 + 1^2 + 4^2} = \sqrt{26}$. This quantity is called the **magnitude** of $\overrightarrow{AB}$, and written as $\left|\overrightarrow{AB}\right|$.

To find the distance between A and B, using their position vectors, we first need to find the displacement vector $\overrightarrow{AB}$ and then calculate its magnitude.

Worked example 13.6

Points A and B have position vectors $\boldsymbol{a} = \begin{pmatrix} 2 \\ -1 \\ 5 \end{pmatrix}$ and $\boldsymbol{b} = \begin{pmatrix} 5 \\ 2 \\ 3 \end{pmatrix}$. Find the exact distance AB.

The distance is the magnitude of the displacement vector, so find $\overrightarrow{AB}$ first

$$\overrightarrow{AB} = \underline{b} - \underline{a}$$

$$= \begin{pmatrix} 5 \\ 2 \\ 3 \end{pmatrix} - \begin{pmatrix} 2 \\ -1 \\ 5 \end{pmatrix} = \begin{pmatrix} 3 \\ 3 \\ -2 \end{pmatrix}$$

Now use the formula for the magnitude

$$\left|\overrightarrow{AB}\right| = \sqrt{3^2 + 3^2 + 2^2} = \sqrt{22}$$

KEY POINT 13.4

The magnitude of a vector, $\boldsymbol{a} = \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix}$, is $|\boldsymbol{a}| = \sqrt{a_1^2 + a_2^2 + a_3^2}$.

The distance between points with position vectors $\boldsymbol{a}$ and $\boldsymbol{b}$ is $|\boldsymbol{b} - \boldsymbol{a}|$.

EXAM HINT

Don't forget that squaring a negative number gives a positive value.

The symbol $\gtreqless$ means 'greater than, equal to or less than'. This may appear to be a useless symbol, but it highlights an important idea in vectors – they cannot be put into order. So while it is correct to say that $|v| \gtreqless |u|$ it is not possible to say the same about the vectors themselves.

We saw in Section 13B that multiplying a vector by a scalar produces a vector in the same direction but of different magnitude. In more advanced applications of vectors it is useful to be able to use vectors of length 1, called **unit vectors**. The base vectors ***i***, ***j*** and ***k*** are examples of unit vectors.

Worked example 13.7

(a) Find the unit vector in the same direction as $\boldsymbol{a} = \begin{pmatrix} 2 \\ -2 \\ 1 \end{pmatrix}$.

(b) Find a vector of magnitude 5 parallel to ***a***.

(a) Call the required unit vector $\hat{a}$.

To produce a vector in the same direction but of different magnitude as ***a***, we need to multiply ***a*** by a scalar. We need to find the value of the scalar

Then $\hat{a} = k\hat{a}$ and $\hat{a} = 1$

$|k\underline{a}| = k|\underline{a}| = 1$

$\Rightarrow k = \dfrac{1}{|\underline{a}|}$

$|\underline{a}| = \sqrt{2^2 + 2^2 + 1^2} = 3$

$\therefore k = \dfrac{1}{3}$

Find the vector $\hat{\boldsymbol{a}}$

The unit vector is

$$\hat{a} = \frac{1}{3}\begin{pmatrix} 2 \\ -2 \\ 1 \end{pmatrix} = \begin{pmatrix} \frac{2}{3} \\ \frac{-2}{3} \\ \frac{1}{3} \end{pmatrix}$$

To get a vector of magnitude 5 we need to multiply the unit vector by 5

(b) Let $\underline{b}$ be parallel to $\underline{a}$ and $|\underline{b}| = 5$

Then $\underline{b} = 5\hat{a}$

$$\therefore \underline{b} = \begin{pmatrix} \frac{10}{3} \\ \frac{-10}{3} \\ \frac{5}{3} \end{pmatrix}$$

EXAM HINT

Note that part (b) has two possible answers, as ***b*** could be in the opposite direction. To get the second answer we would take the scalar to be –5 instead of 5.

The last example showed the general method for finding the unit vector in a given direction.

KEY POINT 13.5

The unit vector in the same direction as $\boldsymbol{a}$ is $\hat{\boldsymbol{a}} = \dfrac{1}{|\boldsymbol{a}|}\boldsymbol{a}$.

Exercise 13C

1. Find the magnitude of the following vectors in two dimensions.

$\boldsymbol{a} = \begin{pmatrix} 4 \\ 2 \end{pmatrix}$ $\quad \boldsymbol{b} = \begin{pmatrix} -1 \\ 5 \end{pmatrix}$ $\quad \boldsymbol{c} = 2\boldsymbol{i} - 4\boldsymbol{j}$ $\quad \boldsymbol{d} = -\boldsymbol{i} + \boldsymbol{j}$

2. Find the magnitude of the following vectors in three dimensions.

$\boldsymbol{a} = \begin{pmatrix} 4 \\ 1 \\ 2 \end{pmatrix}$ $\quad \boldsymbol{b} = \begin{pmatrix} 1 \\ -1 \\ 0 \end{pmatrix}$ $\quad \boldsymbol{c} = 2\boldsymbol{i} - 4\boldsymbol{j} + \boldsymbol{k}$ $\quad \boldsymbol{d} = \boldsymbol{j} - \boldsymbol{k}$

3. Find the distance between the following pairs of points in the plane.

(a) (i) $A\,(1, 2)$ and $B\,(3, 7)$ (ii) $C\,(2, 1)$ and $D\,(1, 2)$

(b) (i) $P\,(-1, -5)$ and $Q\,(-4, 2)$ (ii) $M\,(1, 0)$ and $N\,(0, -2)$

4. Find the distance between the following pairs of points in three dimensions.

(a) (i) $A\,(1, 0, 2)$ and $B\,(2, 3, 5)$

(ii) $C\,(2, 1, 7)$ and $D\,(1, 2, 1)$

(b) (i) $P\,(3, -1, -5)$ and $Q\,(-1, -4, 2)$

(ii) $M\,(0, 0, 2)$ and $N\,(0, -3, 0)$

5. Find the distance between the points with the given position vectors.

(a) $\boldsymbol{a} = 2\boldsymbol{i} + 4\boldsymbol{j} - 2\boldsymbol{k}$ and $\boldsymbol{b} = \boldsymbol{i} - 2\boldsymbol{j} - 6\boldsymbol{k}$

(b) $\boldsymbol{a} = \begin{pmatrix} 3 \\ 7 \\ -2 \end{pmatrix}$ and $\boldsymbol{b} = \begin{pmatrix} 1 \\ -2 \\ -5 \end{pmatrix}$

$|a| = \sqrt{a_1^2 + a_2^2 + a_3^2}$.

The distance between points with position vector a and b is $|b-a|$

)*+,)))-) '/ ## .% 0!
('.. ! 6 ! 3
1 2

On a non-calculator paper we would proceed as follows.
From the trigonometrical identities we have:

$\cos 4x = \cos^2 2x - \sin^2 2x$

and $\cos^2 2x + \sin^2 2x = 1$,

giving $\cos^2 2x = 1 - \sin^2 2x$

So $\cos 4x = 1 - \sin^2 2x - \sin^2 2x$

$\Rightarrow \cos 4x = 1 - 2\sin^2 2x$

$\Rightarrow \sin^2 2x = \dfrac{1 - \cos 4x}{2}$

Hence

$$V = \pi\int_0^{\pi}\left(\frac{1 - \cos 4x}{2}\right)\mathrm{d}x$$

$$\Rightarrow V = \frac{\pi}{2}\int_0^{\pi}(1 - \cos 4x)\,\mathrm{d}x$$

$$\Rightarrow V = \frac{\pi}{2}\left[x - \frac{\sin 4x}{4}\right]_0^{\pi}$$

$$\Rightarrow V = \frac{\pi}{2}\left[\left(\pi - \frac{\sin 4\pi}{4}\right) - \left(0 - \frac{\sin 0}{4}\right)\right]$$

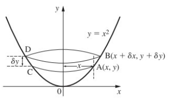
$$\Rightarrow V = \frac{\pi}{2}[(\pi - 0) - (0 - 0)]$$

$$\Rightarrow V = \frac{\pi^2}{2}\text{ units}^3$$

It is possible to rotate curves around a variety of different lines, but for the purposes of this syllabus it is only necessary to know how to find the volumes of solids of revolution formed when rotated about the *x*- or the *y*-axes.

Volumes of solids of revolution when rotated about the *y*-axis

The method is identical to finding the volume of the solid formed when rotating about the *x*-axis. Consider the curve $y = x^2$.



Look at the element ABCD where A is on the curve and has coordinates (x, y). If $y = x^2$, then $x = y^{\frac{1}{2}}$. Hence the coordinates of A are $(y^{\frac{1}{2}}, y)$. ABCD is approximately a cylinder with radius *x* and whose "height" is δy.

Therefore the volume of ABCD $\approx \pi x^2\,\delta y$

and the volume *V* of the entire solid $\approx \displaystyle\sum_{y=a}^{y=b}\pi x^2\,\delta y$.

The smaller δy becomes, the closer this approximation is to *V*,

i.e. $V = \lim_{\delta y \to 0}\displaystyle\sum_{y=a}^{y=b}\pi x^2\,\delta y$

$$V = \pi\int_a^b x^2\,\mathrm{d}y$$

This is the formula for a full revolution about the *y*-axis.

In this case $x = y^{\frac{1}{2}}$. To find the volume of the solid formed when the part of the curve between $y = 0$ and $y = 2$ is rotated about the *y*-axis, we proceed as follows.

$$V = \pi\int_0^2 x^2\,\mathrm{d}y$$

$$\Rightarrow V = \pi\int_0^2 y\,\mathrm{d}y$$

$$\Rightarrow V = \pi\left[\frac{y^2}{2}\right]_0^2$$

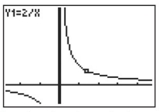
$$\Rightarrow V = \pi\left[\frac{4}{2} - 0\right]$$

$$\Rightarrow V = 2\pi$$

Example

Find the volume of the solid of revolution formed when the area bounded by the curve $xy = 2$ and the lines $x = 0, y = 3, y = 6$ is rotated about the *y*-axis.

As before, plotting the curve on a calculator or drawing a diagram first is a good idea.



As the rotation is taking place about the *y*-axis, the required formula is:

$$V = \pi\int_3^6 x^2\,\mathrm{d}y$$

Since $xy = 2$, then $x = \dfrac{2}{y}$

So we have:

$$V = \pi\int_3^6\left(\frac{2}{y}\right)^2\mathrm{d}y$$

$$\Rightarrow V = \pi\int_3^6\frac{4}{y^2}\,\mathrm{d}y$$

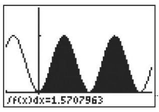
$$\Rightarrow V = \pi\int_3^6 4y^{-2}\,\mathrm{d}y$$

$$\Rightarrow V = \pi\left[\frac{4y^{-1}}{-1}\right]_3^6$$

$$\Rightarrow V = \pi\left[\left(\frac{-4}{6}\right) - \left(\frac{-4}{3}\right)\right]$$

$$\Rightarrow V = \frac{2\pi}{3}$$

The calculator display is shown below.

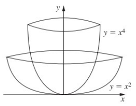


```
∫f(x)dx=1.5707963
```

Remember that this answer will need to be multiplied by π.

Hence $V = 2.09$ units^3.

Up until now it appears that volumes of solids of revolution are a theoretical application of integration. However, this is not the case. In the field of computer-aided design, volumes of solids of revolution are important. If, for example, we wanted to design a wine glass, then we could rotate the curve $y = x^2$ around the *y*-axis to give a possible shape. If we wanted a thinner wine glass, then we could rotate the curve $y = x^4$. Because this can be all modelled on a computer, and a three-dimensional graphic produced, designers can work out the shape that they want.



Exercise 6

1 Find the volumes generated when the following areas are rotated through 2π radians about the *x*-axis.

- **a** The area bounded by the curve $y = 3x + 2$, the *x*-axis, the *y*-axis and the line $x = 2$.
- **b** The area bounded by the curve $y = 4x - x^2$ and the *x*-axis.
- **c** The area bounded by the curve $y = x^3$, the *x*-axis and the line $x = 2$.
- **d** The area bounded by the curve $y = 1 + \sqrt{x}$, the *x*-axis, the *y*-axis and the line $x = 1$.
- **e** The area bounded by the curve $y = x^2 - 1$, the *x*-axis and the line $x = 3$.
- **f** The area bounded by the curve $y = \frac{1}{3}(2x - 1)^2$, the *x*-axis and the line $x = 5$.
- **g** The area bounded by the curve $y = 9x - x^2 - 14$ and the *x*-axis.
- **h** The area bounded by the curve $y = \sin 4x$, the *x*-axis and the lines $x = 0$ and $x = \frac{\pi}{4}$.
- **i** The area bounded by the curve $y = \tan 2x$, the *x*-axis and line $x = \frac{\pi}{6}$.
- **j** The area bounded by the curve $y = \mathrm{e}^{2x}\sin x$, the *x*-axis and the lines $x = 0.5$ and $x = 1.5$.

2 Find the volumes generated when the following areas are rotated through 2π radians about the *y*-axis.

- **a** The area bounded by the curve $y = 4 - x^2$ and the *x*-axis.
- **b** The area bounded by the curve $y = x^3$, the *y*-axis and the line $y = 2$.
- **c** The area bounded by the curve $y = \mathrm{e}^x$, the *y*-axis and the line $y = 2$.
- **d** The area bounded by the curve $y = \sin x$, the *y*-axis and the lines $y = 0.2$ and $y = 0.8$.
- **e** The area bounded by the curve $y = x^2 - 4x$, the *y*-axis, the *x*-axis and the line $y = 2$.
- **f** The area bounded by the curve $y = \sin^{-1} x$, the *y*-axis and the line $y = \frac{\pi}{3}$.
- **g** The area bounded by the curve $y = \ln(x + 1)$, the *y*-axis and the line $y = 1.5$.

3 Find a general formula for the volume generated when the area bounded by the curve $y = x^2$, the x axis and the line $x = a$ is rotated through 2π radians about the *x*-axis.

4 Find the volume obtained when the region bounded by the curve $y = 3 + \frac{4}{x}$, the *x*-axis and the lines $x = 3$ and $x = 6$ is rotated through 360° about the *x*-axis.

5 Consider the curve $y = x^{\frac{1}{2}}$. The part of the curve between $y = 2$ and $y = 5$ is rotated through 2π radians about the *y*-axis. Find the volume of the solid of revolution formed.

6 Find the volume generated when the area bounded by the curve $y = \ln x$, the *x*-axis, the *y*-axis and the line $y = 2$ is rotated through 360° about the *y*-axis.

7 Consider the curve $y = \frac{1}{5}x^2$. A volume is formed by revolving this curve through 360° about the *y*-axis. The radius of the rim of this volume is 5 cm. Find the depth of the shape and its volume.

8 Sketch the curve $y = |x^2 - 1|$ and shade the area that is bounded by the curve and the *x*-axis. This area is rotated through 2π radians about the *x*-axis. Find the volume generated. What is the volume when it is rotated through 2π radians about the *y*-axis?

9 The parabola $y = 8x^2$ is rotated through 360° about its axis of symmetry, thus forming a volume of solid of revolution. Calculate the volume enclosed between this surface and a plane perpendicular to the *y*-axis. This plane is a distance of 7 units from the origin.

10 Find the volume of the solid of revolution formed when the area included between the *x*-axis and one wavelength of the curve $y = b\sin\frac{x}{a}$ is rotated through 360° about the *x*-axis.

11 Consider the part curve $y^2 = x^2 \sin x$ which lies between $x = (n - 1)\pi$ and $x = (n + 1)\pi$ where *n* is an integer. Find the volume generated when this area is rotated through 2π radians about the *x*-axis.

12 **a** Using the substitution $x = \sin\theta$, evaluate $\int \sqrt{1 - x^2}\,\mathrm{d}x$.

b Hence or otherwise, find the volume generated when the area bounded by the curve $y^2 = 1 - x^4$, the *y*-axis and the line $y = a$, $0 < a < 1$, is rotated through 2π radians about the *y*-axis.

Review exercise

1 The region *A* is bounded by the curve $y = \sin\left(2x + \frac{\pi}{3}\right)$ and by the lines $x = 0$ and $x = \frac{\pi}{6}$. Find the exact value of the volume formed when the area *A* is rotated fully about the *x*-axis.

2 Solve the differential equation $xy\frac{\mathrm{d}y}{\mathrm{d}x} = 1 + y^2$, given that $y = 0$ when $x = 2$.

[IB Nov 00 P1 Q17]

3 A particle moves in a straight line with velocity, in metres per second, at time *t* seconds, given by $v(t) = 6t^2 - 6t$, $t \geq 0$.

Calculate the total distance travelled by the particle in the first two seconds of motion. [IB Nov 02 P1 Q11]

4 Consider the region bounded by the curve $y = \mathrm{e}^{-2x}$, the *x*-axis and the lines $x = \pm a$. Find in terms of *a*, the volume of the solid generated when this region is rotated through 2π radians about the *x*-axis.

5 Solve the differential equation $\frac{\mathrm{d}y}{\mathrm{d}x} = 5xy$ and sketch one of the solution curves which does not pass through $y = 0$.

6 The acceleration of a body is given in terms of the displacement *s* metres as $a = \frac{3s}{s^2 + 1}$. Determine a formula for the velocity as a function of the displacement given that when $s = 1$ m, $v = 2$ ms^{-1}. Hence find the exact velocity when the body has travelled 5 m.

7 The temperature *T*°C of an object in a room, after *t* minutes, satisfies the differential equation $\frac{\mathrm{d}T}{\mathrm{d}t} = k(T - 22)$ where *k* is a constant.

a Solve this equation to show that $T = A\mathrm{e}^{kt} + 22$ where *A* is a constant.
b When $t = 0, T = 100$ and when $t = 15, T = 70$.
  i Use this information to find the value of *A* and of *k*.
  ii Hence find the value of *t* when $T = 40$. [IB May 04 P1 Q4]

8 The velocity of a particle is given by the formula $v = \frac{1}{t^2\sqrt{t - 1}}$ for $t > 1$. Using the substitution $t = \sec^2\theta$, find the displacement travelled between $t = 2$ seconds and $t = T$ seconds.

9 Consider the curve $y = -\frac{r}{h}x + r$. The triangular region of this curve which occupies the first quadrant is rotated fully about the *x*-axis. Show that the volume of the cone formed is $\frac{1}{3}\pi r^2 h$.

10 A sample of radioactive material decays at a rate which is proportional to the amount of material present in the sample. Find the half-life of the material if 50 grams decay to 48 grams in 10 years. [IB Nov 01 P1 Q19]

11 The acceleration in ms^{-2} of a particle moving in a straight line at time *t*, is given by the formula $a = \sin\frac{2\pi}{3}t$. The particle starts from rest from a point where its displacement is 0.5 m from a fixed point O on the line.

a Find the velocity and displacement of the particle from O at any time *t*.
b Find the time that elapses before the particle comes to rest again.

12 **a** Let $y = \sin(kx) - kx\cos(kx)$, where *k* is a constant.

Show that $\frac{\mathrm{d}y}{\mathrm{d}x} = k^2 x \sin(kx)$.

A particle is moving along a straight line so that *t* seconds after passing through a fixed point O on the line, its velocity $v(t)$ ms^{-1} is given by $v(t) = t\sin\left(\frac{\pi}{3}t\right)$.

b Find the values of *t* for which $v(t) = 0$, given that $0 \leq t \leq 6$.
c **i** Write down a mathematical expression for the **total** distance travelled by the particle in the first six seconds after passing through O.
  ii Find this distance. [IB Nov 01 P2 Q2]

13 When air is released from an inflated balloon it is found that the rate of decrease of the volume of the balloon is proportional to the volume of the balloon. This can be represented by the differential equation $\frac{\mathrm{d}v}{\mathrm{d}t} = -kv$, where *v* is the volume, *t* is the time and *k* is the constant of proportionality.

a If the initial volume of the balloon is v_0, find an expression, in terms of *k*, for the volume of the balloon at time *t*.
b Find an expression, in terms of *k*, for the time when the volume is $\frac{v_0}{2}$.

[IB May 99 P1 Q19]

14 Show by means of the substitution $x = \tan\theta$ that

$\int_0^1 \frac{1}{(x^2 + 1)^2}\mathrm{d}x = \int_0^{\frac{\pi}{4}} \cos^2\theta\,\mathrm{d}\theta$. Hence find the exact value of the volume formed when the curve $y = \frac{1}{x^2 + 1}$ bounded by the lines $x = 0$ and $x = 1$ is rotated fully about the *x*-axis.

15 Consider the curve $y^2 = 9a(4a - x)$.

a Sketch the part of the curve that lies in the first quadrant.
b Find the exact value of the volume V_x when this part of the curve is rotated through 360° about the *x*-axis.
c Show that $\frac{V_y}{V_x} = \frac{a}{b}$ where V_y is the volume generated when the curve is rotated fully about the *y*-axis and *a* and *b* are integers.

temperature variations. This introduces a major uncertainty in calculations of lift and drag. Aerodynamic forces are also affected by the flow and the pressure distribution of the rocket exhaust gases, as explained in Chapter 20.

A vehicle's flight regime in the neighborhood of Mach 1 is called the transonic flight region. Here strong unsteady aerodynamic forces often develop (due to shock-induced buffeting), which are noticeable in the steep rise and subsequent decrease of the coefficients as shown in Fig. 4–4. In some cases a vehicle's maximum load capabilities during transonic flight have been exceeded leading to structural failures.

For properly designed space launch vehicles and ballistic missiles the integrated drag losses, when expressed in terms of Δu, are typically 5 to 10% of the final ideal vehicle velocity. These relatively low values result from air densities (and thus dynamic pressures), being low at high altitudes where velocities are high, and being high at altitudes where vehicle velocities are low.

Gravitational attraction is exerted upon any flying space vehicle by all planets, stars, and moons. Gravity forces pull the vehicle in the direction of the center of mass of the attracting body. Within the immediate vicinity of the Earth, the attraction of other planets and celestial bodies (like our sun and moon) can be negligibly small compared to the Earth's gravitational force. This force or gravitational pull makes up the object's *weight*.

When Earth gravity variations with the geographical features and the oblate shape are neglected, the acceleration of gravity g varies inversely as the square of the distance from the Earth's center. If R_0 is the mean radius at the (spherical) Earth's surface at which g_0 is the acceleration of gravity, by Newton's law of gravitation, g changes with altitude (h) as

$$\begin{aligned} g &= g_0(R_0/R)^2 \\ &= g_0[R_0/(R_0 + h)]^2 \end{aligned} \tag{4–12}$$

At the equator the spherical Earth's radius is 6378.388 km and the standard value of g_0 is 9.80665 m/sec^2. At distances as far away as the moon, the Earth's gravity acceleration is only about $3.3 \times 10^{-4} g_0$. For the most accurate analyses, the value of g will vary locally with the Earth's bulge at the equator, with the height of nearby mountains, and with the local difference of the Earth's density at specific regions.

4.3. BASIC RELATIONS OF MOTION

For any vehicle that flies within the Earth's proximity, the gravitational attractions from all other heavenly bodies are neglected. Assume next that the vehicle is moving in rectilinear equilibrium flight and that all control forces, lateral forces, and moments that tend to turn the vehicle are zero. The resulting trajectory is two-dimensional and is contained in a fixed plane. Assume further that the vehicle has wings inclined to the flight path at an angle of attack α providing lift in a direction normal to the flight path. The direction of flight need not coincide with the direction of thrust as shown schematically in Figure 4–5.

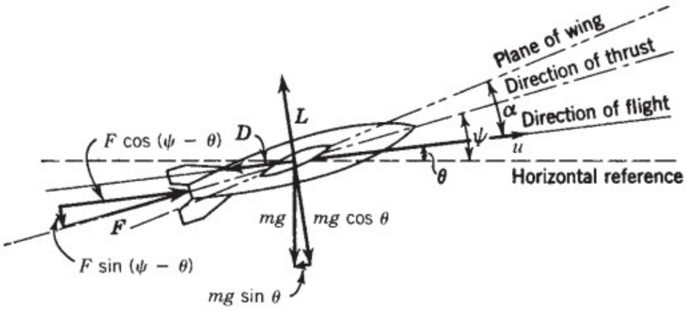

FIGURE 4–5. Two-dimensional free-body force diagram for flying vehicle with wings and fins.

Let θ be the angle of the flight path with the horizontal and ψ the angle of the direction of thrust with the horizontal. Along the flight path direction, the product of the mass and the acceleration has to equal the vector sum of the propulsive, aerodynamic, and gravitational forces:

$$m(du/dt) = F\cos(\psi - \theta) - D - mg\sin\theta \qquad (4\text{–}13)$$

The acceleration perpendicular to the flight path is $u(d\theta/dt)$; for a given value of u and at the instantaneous Earth radius R (from the Earth's center) of the flight path, it becomes u^2/R. The equation of motion in a direction normal to the flight velocity is

$$mu(d\theta/dt) = F\sin(\psi - \theta) + L - mg\cos\theta \qquad (4\text{–}14)$$

By substituting from Eqs. 4–10 and 4–11, these two basic equations can be solved for the accelerations as follows:

$$\frac{du}{dt} = \frac{F}{m}\cos(\psi - \theta) - \frac{C_D}{2m}\rho u^2 A - g\,\sin\theta \qquad (4\text{–}15)$$

$$u\frac{d\theta}{dt} = \frac{F}{m}\sin(\psi - \theta) + \frac{C_L}{2m}\rho u^2 A - g\,\cos\theta \qquad (4\text{–}16)$$

No general solution can be given to these equations, since t_p, u, C_D, C_L, ρ, θ, and/or ψ may vary independently with time, mission profile, and/or altitude. Also, C_D and C_L are functions of velocity or Mach number. In more sophisticated analyses, other factors may also be considered, such as any propellant used for nonpropulsive purposes (e.g., attitude control or flight stability). See Refs. 4–1, 4–8, 4–11, and 4–12 for background material on flight performance in some of these flight regimes. Because rocket propulsion systems are usually tailored to fit specific flight missions, different flight performance parameters are maximized (or optimized) for different rocket flight missions or flight regimes such as Δu, range, orbit height and shape, time-to-target, or altitude.

For actual trajectory analyses, navigation computation, space flight path determination, or missile-firing tables, the above two-dimensional simplified theory is not sufficiently accurate; perturbation effects, such as those listed in Section 4.4, must then be considered in addition to drag and gravity, and computer modelling is necessary to handle such complex relations. Suitable divisions of the trajectory into small elements and step-by-step or numerical integrations to define a trajectory are usually indicated. More generally, three-body theories include the gravitational attraction among three masses (for example, the Earth, the moon, and the space vehicle) and this is considered necessary in many space flight problems (see Refs. 4–2 to 4–5). The form and the solution to the given equations become further complicated when propellant flow and thrust are not constant and when the flight path is three dimensional.

For each mission or flight one can obtain actual histories of velocities and distances traveled and thus complete trajectories when integrating Eqs. 4–15 and 4–16. More general cases require six equations: three for translation along each of three perpendicular axes and three for rotation about these axes. The choice of coordinate systems of reference points can simplify the mathematical solutions (see Refs. 4–3 and 4–5) but there are always a number of trade-offs in selecting the best trajectory for the flight of a rocket vehicle. For example, for a fixed thrust the trade-off is between burn time, drag, payload, maximum velocity, and maximum altitude (or range). Reference 4–2 describes the trade-offs between payload, maximum altitude, and flight stability for sounding rockets.

Equations 4–15 and 4–16 may be further simplified for various special applications, as shown below; results of such calculations for velocity, altitude, or range using the above two basic equations are often adequate for rough design estimates. A form of these equations is also useful for determining the actual thrust or actual specific impulse during vehicle flight from accurately observed trajectory data, such as from optical or radar tracking data. Vehicle acceleration (*du*/*dt*) is essentially proportional to net thrust and, by making assumptions or measurements of propellant flow (which usually varies in a predetermined manner) and from analyses of aerodynamic forces, it is possible to determine a rocket propulsion system's actual thrust under flight conditions.

Equations 4–15 and 4–16 simplify for wingless rocket projectiles, space launch vehicles, or missiles with constant thrust and propellant flow. In Fig. 4–6 the flight direction θ is the same as the thrust direction and any lift forces for a symmetrical, wingless, stably flying vehicle are neglected at zero angle of attack. For a two-dimensional trajectory in a single plane (no wind forces) and a stationary Earth, the acceleration in the direction of flight is given below, where t_p is the operating or burn time of the propellant and ζ is the propellant mass fraction:

$$\frac{du}{dt} = \frac{c\zeta/t_p}{1 - \zeta t/t_p} - g\sin\theta - \frac{C_D \frac{1}{2}\rho u^2 A/m_0}{1 - \zeta t/t_p} \tag{4–17}$$

The force vector diagram in Fig. 4–6 also shows the net force (the addition of thrust, drag, and gravity vectors) to be at an angle to the flight path, which will therefore

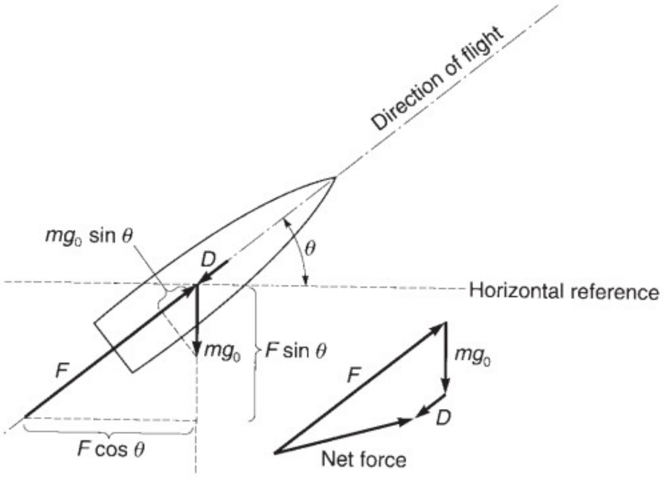

FIGURE 4–6. Simplified free-body force diagram for a vehicle without wings or fins. The force vector diagram shows the net force on the vehicle. All forces act through the vehicle's center of gravity.

be curved. These types of diagram form the basis for iterative trajectory numerical solutions.

All further relationships in this section correspond to two-dimensional flight paths, ones that lie in a single plane. If maneuvers out of that plane take place (e.g., due to solar attraction, thrust misalignment, or wind), then another set of equations will be needed—it requires both force and energy to push a vehicle out of its flight plane; Reference 4–1 describes equations for the motion of rocket projectiles in the atmosphere in three dimensions. Trajectories must be calculated accurately in order to reach any intended flight objective and today these are done exclusively with the aid of computers. Several *computer programs* for analyzing flight trajectories exist (which are maintained by aerospace companies and/or government agencies). Some are two-dimensional, relatively simple, and used for making preliminary estimates or comparisons of alternative flight paths, alternative vehicle designs, or alternative propulsion schemes. Several use a stationary flat Earth, while others use a rotating curved Earth. Three-dimensional programs used for more accurate flight path analyses may include some or all significant perturbations, orbit plane changes, or flying at angles of attack. Reference 4–4 explains their nature and complexity.

When the flight trajectory is vertical (as for a sounding rocket), then Eq. 4–17 becomes

$$\frac{du}{dt} = \frac{c\zeta/t_p}{1 - \zeta t/t_p} - g - \frac{C_D\frac{1}{2}\rho u^2 A/m_0}{1 - \zeta t/t_p} \tag{4–18}$$

The velocity at the end of burning can be found by integrating between the limits of $t = 0$ and $t = t_p$ where $u = u_0$ and then $u = u_p$. The first two terms can readily be integrated. The last term is of significance only if the vehicle spends a considerable portion of time within the lower atmosphere. It may be integrated graphically or numerically, and its value can be designated by the term BC_DA/m_0, where

$$B \equiv \int_0^{t_p} \frac{\frac{1}{2}\rho u^2}{1 - \zeta t/t_p} dt$$

The cutoff velocity or velocity at the end of propellant burning u_p then becomes

$$u_p = -\bar{c}\ln(1 - \zeta) - \bar{g}t_p - \frac{BC_DA}{m_0} + u_0 \tag{4–19}$$

where u_0 is an initial velocity such as may be given by a booster, $\bar{g}$ is an average gravitational attraction evaluated with respect to time and altitude from Eq. 4–12, and $\bar{c}$ is a time average of the effective exhaust velocity, which also depends on altitude. For nonvertical flight paths, the gravity loss becomes a function of the angle between the flight direction and the local horizontal; more specifically, the gravity loss is then given by the integral $\int (g \sin\theta)dt$.

When aerodynamic forces within the atmosphere may be neglected (or for vacuum operation) and when no booster or means for attaining an initial velocity ($u_0 = 0$) are present, the velocity at the end of the burning reached with a vertically ascending trajectory becomes simply

$$\begin{aligned} u_p &= -\bar{c}\ln(1 - \zeta) - \bar{g}t_p \\ &= -\bar{c}\ln \mathbf{MR} - \bar{g}t_p = \bar{c}\ln(1/\mathbf{MR}) - \bar{g}t_p \end{aligned} \tag{4–20}$$

The first term on the right side is usually the largest and is identical to Eq. 4–6. It is directly proportional to the effective rocket exhaust velocity and very sensitive to changes in the mass ratio. The second term is related to the Earth's gravity and is always negative during ascent, but its magnitude can be small when the burn time t_p is short or when flight is taking place at high orbits or in space where $\bar{g}$ is comparatively small.

For the simplified case given in Eq. 4–20 the net initial acceleration a_0 for vertical takeoff at sea level is

$$a_0 = (F_0 g_0/w_0) - g_0 \tag{4–21}$$

$$a_0/g_0 = (F_0/w_0) - 1 \tag{4–22}$$

where a_0/g_0 is the *initial takeoff acceleration* in multiples of the sea-level gravitational acceleration g_0, and F_0/w_0 is the thrust-to-weight ratio at takeoff. For large surface-launched vehicles, this initial-thrust-to-initial-weight ratio typically has values between 1.2 and 2.2; for small missiles (air-to-air, air-to-surface, and surface-to-air types) this ratio is usually larger, sometimes even as high as 50 or 100. *The final* or *terminal acceleration* a_f of a vehicle in vertical Earth ascent usually occurs just before the rocket engine is shut off and/or before the useable propellant is completely consumed. If drag is neglected, then the final acceleration a_f acting on the final mass m_f becomes

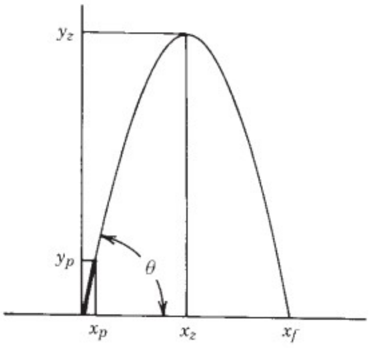
$$a_f = (F_f/m_f) - g \tag{4–23}$$

This equation applies when the powered flight path traverses a substantial range of altitude with g decreasing according to Eq. 4–12. For rocket propulsion systems with constant propellant flow, the final acceleration is usually also the maximum acceleration because the vehicle mass being accelerated is a minimum just before propellant termination, and for ascending rockets thrust usually increases with altitude. When this terminal acceleration is found to be too large (e.g., causes overstressing of the structure, thus necessitating an increase in structure mass), then the thrust must be reduced by redesign to a lower value for the last portion of the burning period. In manned flights, maximum accelerations are limited to the maximum g-loading that can be withstood by the crew.

Example 4–1. A simple single-stage rocket for a rescue flare has the following characteristics. Its flight path nomenclature is shown in the accompanying sketch.

Launch weight (w_0)	4.0 lbf
Useful propellant weight (w_p)	0.4 lbf
Effective specific impulse	120 sec
Launch angle θ (relative to horizontal)	80°
Burn time t_p (with constant thrust)	1.0 sec

The heavy line in the ascending trajectory designates the powered portion of the flight.



Drag may be neglected since flight velocities are low. Assume that the acceleration of gravity is unchanged from its sea-level value g_0, which then makes the propellant mass numerically equal to the propellant weight in the EE system, or 0.4 lbm. Also assume that start and stop transients are short and can be neglected.

Solve for the initial and final acceleration during powered flight, the maximum trajectory height and the time to reach maximum height, the range or horizontal distance to impact, and the angle at propulsion cutoff.

SOLUTION. We will divide the flight path into three portions: the powered flight for 1 sec, the unpowered ascent after cutoff, and the free-fall descent. The thrust is obtained from Eq. 2–5:

$$F = I_s w_p/t_p = 120 \times 0.4/1.0 = 48 \text{ lbf}$$

The initial accelerations along the x-horizontal and y-vertical directions are, from Eq. 4–22,

$$(a_0)_y = g_0[(F \sin\theta/w) - 1] = 32.17[(48/4.0)\sin 80^\circ - 1] = 348 \text{ ft/sec}^2$$

$$(a_0)_x = g_0(F \cos\theta/w) = 32.17(48/4.0)\cos 80^\circ = 67.03 \text{ ft/sec}^2$$

At thrust termination the final flight acceleration becomes

$$a_0 = \sqrt{(a_0)_x^2 + (a_0)_y^2} = 354.4 \text{ ft/sec}^2$$

The vertical and horizontal components of the velocity u_p at the end of powered flight can be obtained from Eq. 4–20. Note that the vehicle mass has been diminished by the propellant that has been consumed:

$$\begin{aligned}(u_p)_y &= c \ln(m_0/m_f) \sin\theta - g_0 t_p = 32.17 \times 120 \times \ln(4/3.6) \times 0.984 - 32.17 \times 1.0\\ &= 368 \text{ m/sec}\\ (u_p)_x &= c \ln(m_0/m_f) \cos\theta = 32.17 \times 120 \times \ln(4/3.6) \times 0.1736 = 70.6 \text{ m/sec}\end{aligned}$$

The effective exhaust velocity $c = I_s g_0$ (Eq. 2–6). The trajectory angle with the horizontal at rocket cutoff in dragless flight is

$$\tan^{-1}(368/70.6) = 79.1°$$

The final acceleration is found, using Eq. 4–22 with the final mass, as $a_f = 400 \text{ m/sec}^2$.

For the powered flight, the coordinates at propulsion burnout y_p and x_p can be calculated from the time integration of their respective velocities, using Eq. 2–6. The results are

$$\begin{aligned}y_p &= ct_p[1 - \ln(m_0/m_f)/(m_0/m_f - 1)]\sin\theta - 1/2 g_0 t_p^2\\ &= 32.17 \times 120[1 - \ln(4/3.6)/(4/3.6 - 1)] \times 0.984 - \tfrac{1}{2} \times 32.17 \times (1.0)^2 = 181 \text{ ft}\\ x_p &= ct_p[1 - \ln(m_0/m_f)/(m_0/m_f - 1)]\cos\theta\\ &= 32.17 \times 120[1 - \ln(4/3.6)/(4/3.6 - 1)] \times 0.173 = 34.7 \text{ ft}\end{aligned}$$

The unpowered part of the trajectory reaches zero vertical velocity at its zenith. The height gained in unpowered free flight may be obtained by equating the vertical kinetic energy at power cutoff to its equivalent potential energy, $g_0(y_z - y_p) = \frac{1}{2}(u_p)_y^2$

so that

$$(y_z - y_p) = \tfrac{1}{2}(u_p)_y^2/g_o = \tfrac{1}{2}(368)^2/32.17 = 2105 \text{ ft}$$

The maximum height or zenith location thus becomes $y_z = 2105 + 181 = 2259$ ft. What remains now is to solve the free-flight portion of vertical descent. The time for descent from the zenith is $t_z = \sqrt{2y_z/g_0} = 11.85$ sec and the final vertical or impact vertical velocity $(u_f)y - g_0 t_z = 381$ ft/sec.

The total horizontal range to the zenith is the sum of the powered and free-flight contributions. During free flight, the horizontal velocity remains unchanged at 70.6 ft/sec because there are no accelerations (i.e., no drag, wind, or gravity component). We now need to find the free-flight time from burnout to the zenith, which is $t = (u_p)y/g_0 = 11.4$ sec. The total free-flight time becomes $t_{ff} = 11.4 + 11.85 = 23.25$ sec.

Now, the horizontal or total range becomes $\Delta x = 34.7 + 70.6 \times 23.25 = 1676$ ft.

The impact angle would be around 79°. If drag had been included, solving this problem would have required information on the drag coefficient (C_D) and a numerical solution using Eq. 4–18. All resulting velocities and distances would turn out somewhat lower in value. A set of flight trajectories for sounding rockets is given in Ref. 4–3.

4.4. SPACE FLIGHT

Newton's law of gravitation defines the gravitational attraction force F_g between two bodies in space as:

$$F_g = Gm_1m_2/R^2 = \mu m_2/R^2 \tag{4–24}$$

Here G is the universal gravity constant ($G = 6.674 \times 10^{-11}\mathrm{m}^3/\mathrm{kg} - \mathrm{sec}^2$), m_1 and m_2 are the masses of the two attracting bodies (such as the Earth and the moon, or the Earth and a spacecraft, or the sun and a planet), and R is the distance between their centers of mass. The Earth's gravitational constant μ is the product of Newton's universal constant G and the mass of the Earth, m_1 (5.974×10^{24}kg). It is $\mu = 3.987 \times 10^{14}\mathrm{m}^3/\mathrm{sec}^2$.

Rockets offer a means for escaping the Earth's pull for lunar and interplanetary travel, for escaping our solar system, and for launching stationary or moving platforms in space. The flight velocity required to escape from the Earth can be found by equating the kinetic energy of the moving body to the work necessary to overcome gravity, neglecting the rotation of the Earth and the attraction of other celestial bodies, namely,

$$\tfrac{1}{2}mu^2 = m\int g\,dR$$

By substituting for g from Eq. 4–12 and neglecting air friction, the following relation for the Earth's escape velocity v_e is obtained:

$$v_e = R_0\sqrt{\frac{2g_0}{R_0 + h}} = \sqrt{\frac{2\mu}{R}} \tag{4–25}$$

Here, R_0 is the effective Earth mean radius (6374.2 km), h is the circular orbit's altitude above sea level, and g_0 is the acceleration of gravity at the Earth's surface (9.806 m/sec). The satellite flight radius R as measured from the earth's center is $R = R_0 + h$. The velocity of escape from the Earth's surface is 11,179 m/sec or 36,676 ft/sec and does not vary appreciably within the Earth's atmosphere, as shown by Fig. 4–7. Escape velocities for surface launches are given in Table 4–1 from the sun, the planets, and the moon. Launching from the Earth's surface at the escape velocity is not practical because as such vehicle ascends through the Earth's atmosphere, it is subject to severe aerodynamic heating and dynamic pressures. A practical launch vehicle has to traverse the lower atmosphere at relatively low velocities and then accelerate to high velocities beyond the dense atmosphere. For example, during a portion of the Space Shuttle's ascent, its main engines were actually throttled to a lower thrust. Alternatively, an Earth escape vehicle may be launched above the denser atmosphere from an orbiting space station or from an orbiting launch vehicle's upper stage.

Any rocket or spaceship may become an Earth *satellite*, revolving around the Earth in a fashion similar to that of the moon. Low Earth orbits, typically below 500 km altitude, are designated as LEO. Most orbit altitudes are above the Earth's lower atmosphere because this minimizes the energy expended to overcome the drag that

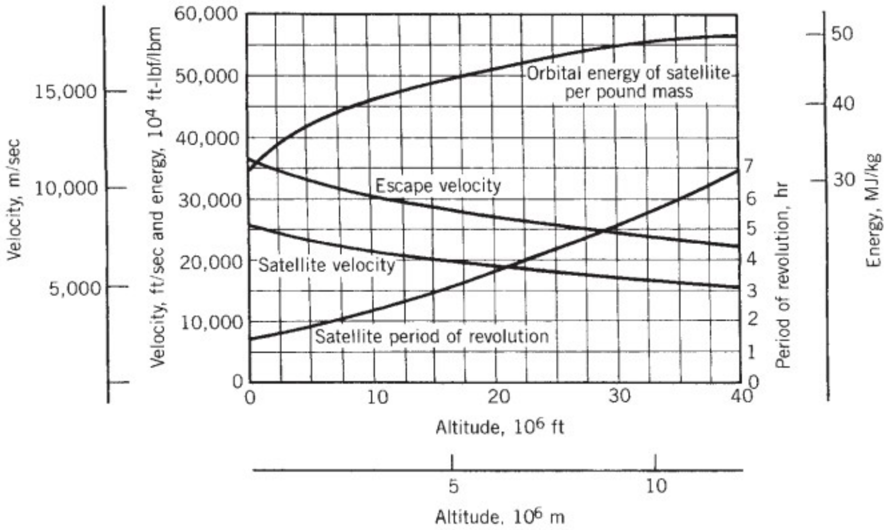


FIGURE 4–7. Orbital energy, orbital velocity, period of revolution, and Earth escape velocity for a space vehicle as a function of altitude for circular satellite orbits. Values are based on a spherical Earth and neglect the Earth's oblate shape, its rotation, and atmospheric drag.

continuously brings the vehicle's orbit closer to the Earth. However, radiation effects in the Van Allen belt on human beings and on sensitive equipment at times often necessitate the selection of Earth orbits at low altitudes.

For a satellite's circular trajectory, the velocity must be sufficient so that its centrifugal force precisely balances the Earth's gravitational attraction:

$$mu_s^2/R = mg$$

For a circular orbit, the satellite velocity u_s is found by using Eq. 4–12,

$$u_s = R_0\sqrt{g_0/(R_0 + h)} = \sqrt{\mu/R} \tag{4–26}$$

which is smaller than the escape velocity by a factor of $\sqrt{2}$. The period τ in seconds for one revolution in a circular orbit relative to a stationary Earth is

$$\tau = 2\pi(R_0 + h)/u_s = 2\pi(R_0 + h)^{3/2}/(R_0\sqrt{g_0}) \tag{4–27}$$

Neglecting drag, the energy E necessary to bring a unit of mass into a circular satellite orbit consists of its kinetic and potential energy, namely,

$$\begin{aligned} E &= \tfrac{1}{2}u_s^2 + \int_{R_0}^{R} g\,dR \\ &= \tfrac{1}{2}R_0^2\tfrac{g_0}{R_0+h} + \int_{R_0}^{R} g_0\tfrac{R_0^2}{R^2}dR = \tfrac{1}{2}R_0 g_0\tfrac{R_0+2h}{R_0+h} \end{aligned} \tag{4–28}$$

TABLE 4–1. Characteristic Data for Several Heavenly Bodies

Name	Mean Radius of Orbit (million km)	Period of Revolution	Mean Diameter (km)	Relative Mass (*Earth* = 1.0)[a]	Specific Gravity	Acceleration of Gravity at Surface (m/sec^2)	Escape Velocity at Surface (m/sec)

[a] Earth mass is 5.976×10^{24} kg.

Source: In part from Refs 4–3 and 4–4.

Escape velocity, satellite velocity, satellite period, and satellite orbital energy are all shown as functions of altitude in Fig. 4–7.

A satellite moving around the Earth at an altitude of 300 miles or 482.8 km has a velocity u_s of about 7375 m/sec or 24,200 ft/sec, circles a stationary Earth in $\tau =$ 1.63 hr.; ideally it requires an energy of 3.35×10^7 J to place 1 kg of spaceship mass into its orbit. An equatorial satellite in a circular orbit at an altitude of 6.611 Earth radii (about 26,200 miles, 42,200 km, or 22,700 nautical miles) has a period of revolution of exactly 24 hr. It will, therefore, appear stationary to an observer on Earth. This is known as a *synchronous* satellite in *geo synchronous Earth orbit*, usually abbreviated as GEO. This orbit is used extensively for communications satellite and Earth observation applications. In the part of Section 4.7 on launch vehicles, we describe how the payload of any given space vehicle diminishes as the orbit's circular altitude is increased and as the inclination (angle between orbit plane and Earth equatorial plane) is changed. See Refs. 4–3, 4–4, 4–5, 4–6 and 4–9.

Elliptical Orbits

The circular orbit described above is a special case of the more general elliptical orbit shown in Fig. 4–8; here, the Earth (or any other heavenly body around which another body is moving) is located at one of the focal points of this ellipse. The relevant equations of motion come from Kepler's laws and elliptical orbits may be described as follows, when expressed in polar coordinates:

$$u = \left[\mu\left(\frac{2}{R} - \frac{1}{a}\right)\right]^{1/2} \tag{4–29}$$

where u is the velocity of the body in the elliptical orbit, R is the instantaneous radius from the center of the Earth (a vector quantity, which changes direction as well as magnitude), a is the major axis of the ellipse, and μ is the Earth's gravitational constant, 3.986×10^{14} m^3/sec^2. These symbols are defined in Fig. 4–8. From Eq. 4–29 it can be seen that the velocity has its maximum value u_p when the moving body comes closest to its focal point at its orbit's *perigee* and the minimum value u_a at its *apogee*. By substituting for R in Eq. 4–29, and by defining the ellipse's shape factor e as the *eccentricity of the ellipse*, $e = \sqrt{a^2 - b^2}/a$, the apogee and perigee velocities can be expressed as

$$u_a = \sqrt{\frac{\mu(1-e)}{a(1+e)}} \tag{4–30}$$

$$u_p = \sqrt{\frac{\mu(1+e)}{a(1-e)}} \tag{4–31}$$

Another property of an elliptical orbit is that the product of velocity and instantaneous radius remains constant for any location x or y on the ellipse, namely, $u_x R_x = u_y R_y = uR$. The exact path that a satellite takes depends on the velocity (magnitude and vector orientation) with which it is started or was injected into orbit.

For *interplanetary transfers*, an ideal mission can be achieved with minimum energy with a simple transfer ellipse, as suggested originally by Hohmann (see Ref. 4–7). Assuming that planetary orbits about the sun are circular and coplanar, Hohmann demonstrated that the path of minimum energy is an ellipse tangent to both planetary orbits as shown in Fig. 4–9. This operation requires a velocity increment (of relatively high thrust) at the initiation (planet A at time t_1) and another at termination (planet B at time t_2): both increments equal the velocity differences between the respective circular planetary velocities and the perigee and apogee velocities which define the transfer ellipse. Thrust levels at the beginning and end maneuvers of the Hohmann ellipse must be high enough to amount to a short operating time and an acceleration of at least 0.01 g_0, but preferably more. Note that because electrical propulsion accelerations are much lower, amounting

to about $10^{-5}g_0$, and operating times longer, weeks or months, the best transfer trajectories in electrical propulsion turn out to be much different from Hohmann ellipses; these are described in Chapter 17.

Departure dates or the *relative positions of the launch planet and the target planet* in planetary transfer missions become critical, because the spacecraft must meet with the target planet when it arrives at the target orbit. Transfer times $(t_2 - t_1)$ for Hohmann-ellipse flights starting on Earth are about 116 hours to go to the moon and about 259 days to Mars. If faster flight paths (shorter transfer times) are desired (see dashed lines in Fig. 4–9), they will require more energy than those with a Hohmann transfer ellipse. This means a larger vehicle with more propellant and a larger propulsion system, or a higher total impulse. There always is a *time window* for launching a spacecraft that will make for a successful rendezvous. For Mars missions an Earth-launched spacecraft may have a launch time window of more than two months. Hohmann transfer ellipses or faster transfer paths apply not only to planetary flight but also to Earth satellites when they go from one circular orbit to another (but within the same plane). Also, if one spacecraft goes to rendezvous with another spacecraft in a different orbit, the two have to be in the proper predetermined positions prior to any thrust application to simultaneously reach their rendezvous location.

When the launch orbit (or launch planet) is not in the same plane as the target orbit, then additional energy will be needed for applying thrust in directions normal to the launch orbit plane. More information can be found in Refs. 4–3, 4–4, 4–6, and 4–10.

Example 4–2. A satellite is launched from a circular equatorial parking orbit at an altitude of 160 km into a coplanar circular synchronous orbit by using a Hohmann transfer ellipse. Assume a homogeneous spherical Earth with a radius of 6371 km. Determine the velocity increments for entering the transfer ellipse and for achieving the synchronous orbit at 42,200 km altitude. See Fig. 4–9 for the terminology of the orbits.

SOLUTION. The two orbits are $R_A = 6.531 \times 10^6$ m; $R_B = 48.571 \times 10^6$ m. The major axis a_{te} of the transfer ellipse is

$$a_{te} = \tfrac{1}{2}(R_A + R_B) = 27.551 \times 10^6 \mathrm{m}$$

The orbit velocities of the two satellites are

$$u_A = \sqrt{\mu/R_A} = [3.986005 \times 10^{14}/6.571 \times 10^6]^{1/2} = 7788 \text{ m/sec}$$

$$u_B = \sqrt{\mu/R_B} = 2864.7 \text{ m/sec}$$

The velocities needed to enter and exit the transfer ellipse are

$$(u_{te})_A = \sqrt{\mu}[(2/R_A) - (1/a)]^{1/2} = 10{,}337 \text{ m/sec}$$

$$(u_{te})_B = \sqrt{\mu}[(2/R_B) - (1/a)]^{1/2} = 1394 \text{ m/sec}$$

The changes in velocity going from parking orbit to ellipse Δu_A and from ellipse to final orbit Δu_B are

$$\Delta u_A = |(u_{te})_A - u_A| = 2549 \text{ m/sec}$$

$$\Delta u_B = |u_B - (u_{te})_B = 1471 \text{ m/sec}$$

The total velocity change for the transfer maneuvers is

$$\Delta u_{\text{total}} = \Delta u_A + \Delta u_B = 4020 \text{ m/sec}$$

Figure 4–10 shows the elliptical transfer trajectory of a ballistic missile or a satellite launch or an ascent vehicle. During the initial powered flight the trajectory angle is adjusted by signals from the guidance system and torques from the reaction control system to an angle that will allow the vehicle to reach the apogee of its elliptical path at exactly the desired altitude. An *orbit injection velocity* increase of the space vehicle is now applied by a chemical propulsion system at this apogee, which causes the vehicle to change from an elliptical transfer flight path to a circular-orbit flight path. The horizontal arrow symbolizes this velocity increase. For an ideal satellite the simplified theory assumes that an orbit injection maneuver is essentially an instantaneous application of the total impulse when the ballistic elliptic trajectory reaches its

FIGURE 4–10. Long-range ballistic missiles follow an elliptical free flight trajectory, which is nearly drag free, with the Earth's center as one of the focal points. The surface launch is usually vertically up (not shown here) but the flight path is quickly tilted during the early powered flight to enter into an elliptic trajectory. The ballistic range is the arc distance on the Earth's surface. The same elliptical flight path can be used by launch vehicles for satellites; another powered flight period occurs (called orbit injection) just as the vehicle reaches its elliptical apogee (as indicated by the arrow), causing the vehicle to enter an orbit.

apogee or zenith. In reality, the rocket propulsion system for orbit injection operates over a finite time, during which gravity losses and changes in altitude occur.

Deep Space

Lunar and *interplanetary* missions may include circumnavigation, landing, and return flights. The energy necessary to escape from the Earth may be calculated as $\frac{1}{2}mv_e^2$ from Eq. 4–25 as 6.26×10^7 J/kg, which is more than that required to launch an Earth satellite. The gravitational attraction of various heavenly bodies and their respective escape velocities depends on their mass and diameter; approximate values are listed in Table 4–1. An idealized diagram of an interplanetary landing mission is shown in Fig. 4–11.

Escape from the solar system requires approximately 5.03×10^8 J/kg which is eight times as much energy as is required for escape from the Earth. Technology exists today to send small, unmanned probes away from the sun into outer space, but before any mission to the nearest star can be achieved some very long-duration, novel, rocket propulsion system must be introduced. The ideal trajectory for a spacecraft to escape from the sun is either a parabola (minimum energy) or a hyperbola. See Refs. 4–6 and 4–10.

The *Voyager 2 Spacecraft*, developed by NASA's Jet Propulsion Laboratory, was the first man-made object to escape from the solar system and enter interplanetary space. It was launched on August 20, 1977 for exploring the outer planets (flybys of Jupiter, Saturn, Neptune, and Uranus) and then leaving the solar system. It was not expected that Voyager 2 would continue to be operational for over 37 years. A three-axis stabilization system with gyroscopic and celestial reference instruments

4.1 Rotations

In classical mechanics, rotations of three-vectors can be represented by a rotation matrix $\mathbf{R}$ acting upon vectors such as $\mathbf{x} = (x, y, z)$ as

$$x_i \to x'_i = \mathbf{R}_{ij} x_j . \tag{4.1}$$

In quantum mechanics, rotation transformations are represented by unitary operators $U(\boldsymbol{\theta})$ acting upon state vectors $|\psi\rangle$ such that

$$|\psi\rangle \to |\psi'\rangle = U(\boldsymbol{\theta})|\psi\rangle, \tag{4.2}$$

where the direction of $\boldsymbol{\theta}$ is along the axis about which the rotation occurs, and its magnitude is the rotation angle. For infinitesimal rotations, the operator $U(\boldsymbol{\theta})$ can be written as $U(\boldsymbol{\theta}) \simeq 1 + \mathrm{i}\boldsymbol{\theta} \cdot \mathbf{J}$, where the Hermitian operators $\mathbf{J}$ are the rotation generators. For spinless states, J_i can be represented as differential operators ($J_k = \frac{1}{2}\epsilon_{ijk} J_{ij}$, with $J_{ij} = -\mathrm{i}(x_i \partial_j - x_j \partial_i)$), it is easy to check that the commutation relations

$$[J_i, J_j] = \mathrm{i}\epsilon_{ijk} J_k \tag{4.3}$$

are satisfied for $i, j = 1, 2, 3 \leftrightarrow x, y, z$. Finite rotations can be built up from an infinite product of infinitesimal ones, so that the operator $U(\boldsymbol{\theta}) = \exp(\mathrm{i}\boldsymbol{\theta} \cdot \mathbf{J})$. The operators $U(\boldsymbol{\theta})$ form a representation of the Lie group $SU(2)$, for which the J_i are the group generators, and where Eq. (4.3) defines the Lie algebra associated with the group $SU(2)$. Since the parameters θ_i each run over a compact domain 0 to 2π, we say that $SU(2)$ is a compact Lie group.

A Casimir operator is an operator that commutes with all of the group generators. The eigenvalues of a Casimir operator are unchanged under group transformations, so they serve as a useful tool to classify group representations. The representations of $SU(2)$ can be labelled according to the eigenvalues of the quadratic Casimir operator

4

The supersymmetry algebra

4.1 Rotations

In classical mechanics, rotations of three-vectors can be represented by a rotation matrix $\mathbf{R}$ acting upon vectors such as $\mathbf{x} = (x, y, z)$ as

$$x_i \to x'_i = \mathbf{R}_{ij} x_j. \tag{4.1}$$

In quantum mechanics, rotation transformations are represented by unitary operators $U(\boldsymbol{\theta})$ acting upon state vectors $|\psi\rangle$ such that

$$|\psi\rangle \to |\psi'\rangle = U(\boldsymbol{\theta})|\psi\rangle, \tag{4.2}$$

where the direction of $\boldsymbol{\theta}$ is along the axis about which the rotation occurs, and its magnitude is the rotation angle. For infinitesimal rotations, the operator $U(\boldsymbol{\theta})$ can be written as $U(\boldsymbol{\theta}) \simeq 1 + \mathrm{i}\boldsymbol{\theta} \cdot \mathbf{J}$, where the Hermitian operators $\mathbf{J}$ are the rotation generators. For spinless states, J_i can be represented as differential operators ($J_k = \frac{1}{2}\epsilon_{ijk} J_{ij}$, with $J_{ij} = -\mathrm{i}(x_i \partial_j - x_j \partial_i)$), it is easy to check that the commutation relations

$$[J_i, J_j] = \mathrm{i}\epsilon_{ijk} J_k \tag{4.3}$$

are satisfied for $i, j = 1, 2, 3 \leftrightarrow x, y, z$. Finite rotations can be built up from an infinite product of infinitesimal ones, so that the operator $U(\boldsymbol{\theta}) = \exp(\mathrm{i}\boldsymbol{\theta} \cdot \mathbf{J})$. The operators $U(\boldsymbol{\theta})$ form a representation of the Lie group $SU(2)$, for which the J_i are the group generators, and where Eq. (4.3) defines the Lie algebra associated with the group $SU(2)$. Since the parameters θ_i each run over a compact domain 0 to 2π, we say that $SU(2)$ is a compact Lie group.

A Casimir operator is an operator that commutes with all of the group generators. The eigenvalues of a Casimir operator are unchanged under group transformations, so they serve as a useful tool to classify group representations. The representations of $SU(2)$ can be labelled according to the eigenvalues of the quadratic Casimir operator

$J^2 = \mathbf{J} \cdot \mathbf{J}$, for which $J^2|jm\rangle = j(j+1)|jm\rangle$, with $j = 0, 1/2, 1, 3/2, 2, \ldots$ For the $j = 1/2$ representation, the operators J_i can be represented by the Pauli spin matrices $J_i = \sigma_i/2$, and the state vectors can be represented by 2-component spinors. Higher j representations can be constructed by taking direct products of lower j representations. For higher j representations of $SU(2)$, the J_i's can be represented by $(2j+1) \times (2j+1)$ matrices, and the corresponding state vectors by $2j+1$ component column matrices.

4.2 The Lorentz group

We want to build a quantum theory that is invariant under Lorentz transformations. We restrict our discussion to proper, orthochronous Lorentz transformations, i.e. boosts and rotations, and neglect parity and time reversal. In addition to rotations which mix the spatial coordinates amongst themselves, we now have boost transformations which mix the time co-ordinate x^0 with the spatial co-ordinates; e.g. a boost along the x^1 direction can be written as $x'^0 = x^0 \cosh\phi + x^1 \sinh\phi$, $x'^1 = x^0 \sinh\phi + x^1 \cosh\phi$, $x'^2 = x^2$ and $x'^3 = x^3$. The usual velocity parameter β that characterizes the boost is given in terms of the rapidity ϕ by $\beta = \tanh\phi$. The infinitesimal transformation matrix U that transforms quantum mechanical states can then be augmented to,

$$U(\boldsymbol{\theta}, \boldsymbol{\phi}) \simeq 1 + \mathrm{i}\boldsymbol{\theta} \cdot \mathbf{J} + \mathrm{i}\boldsymbol{\phi} \cdot \mathbf{K}, \tag{4.4}$$

where K_i are the boost generators and $\boldsymbol{\phi}$ points along the direction of the boost.[1] A Lorentz transformation is thus characterized by the six parameters (θ_i, ϕ_j). Since the parameters ϕ_j are not restricted to a compact interval, the Lorentz group, unlike the rotation group, is not compact.

The Lorentz group generators satisfy

$$[J_i, J_j] = \mathrm{i}\epsilon_{ijk} J_k, \quad [K_i, J_j] = \mathrm{i}\epsilon_{ijk} K_k, \quad [K_i, K_j] = -\mathrm{i}\epsilon_{ijk} J_k. \tag{4.5}$$

The first of these relations shows that rotation generators form a closed sub-algebra, so that the rotation group forms a subgroup of the Lorentz group. The commutator of two boost generators is a rotation generator (this is the origin of Thomas precession) so that the boosts, by themselves, do not form a sub-algebra.

The Lorentz algebra that we have introduced above can be written in a manifestly covariant form by writing the generators as the six components of an antisymmetric second rank tensor generator $M_{\mu\nu}$, with $M_{ij} = \epsilon_{ijk} J_k$ and $M_{0i} = -M_{i0} = -K_i$. The commutators for the Lorentz group generators can then be recast into covariant form

---

[1] For infinitesimal boosts, notice that $|\boldsymbol{\phi}| = |\boldsymbol{\beta}|$.

$$[M_{\mu\nu}, M_{\rho\sigma}] = -\mathrm{i}(g_{\mu\rho}M_{\nu\sigma} - g_{\mu\sigma}M_{\nu\rho} - g_{\nu\rho}M_{\mu\sigma} + g_{\nu\sigma}M_{\mu\rho}). \tag{4.6}$$

To find the finite-dimensional unitary representations of the Lorentz group, the generators can be alternatively written by defining $S_i = \frac{1}{2}(J_i + \mathrm{i}K_i)$ and $T_i = \frac{1}{2}(J_i - \mathrm{i}K_i)$. In this case, it is easy to check that the commutators of the generators become

$$[S_i, S_j] = \mathrm{i}\epsilon_{ijk}S_k, \quad [T_i, T_j] = \mathrm{i}\epsilon_{ijk}T_k, \quad [S_i, T_j] = 0, \tag{4.7}$$

i.e. the algebra decomposes into the product of two independent $SU(2)$ groups, for which we know the representations. For the Lorentz group, there are thus *two* Casimir operators, S^2 and T^2, with eigenvalues $s(s+1)$ and $t(t+1)$, again with $s, t = 0, 1/2, 1, \ldots$ (Note that J^2 is no longer a Casimir operator since it no longer commutes with all the group generators, e.g. $[J^2, K_1] \neq 0$.) The irreducible representations can be categorized according to values of (s, t). A Lorentz scalar transforms as the $(0, 0)$ representation while a four-vector transforms as $(1/2, 1/2)$ representation. There are *two* distinct fundamental representations $(1/2, 0)$ and $(0, 1/2)$, each of which corresponds to two-spinors. The $(1/2, 0)$ object, as we will soon see, transforms as a left-handed Weyl two-spinor whose components are usually denoted by $\psi_{\mathrm{L}A}$, with $A = 1, 2$. The $(0, 1/2)$ object transforms as a right-handed two-spinor with components $\psi_{\mathrm{R}}^{\dot{A}}$, where the dot on the index calls attention to the fact that the spinor transforms under the second of the two $SU(2)$ groups.

Exercise *Verify that the boost transformation for a state transforming as the* $(1/2, 0)$ *and* $(0, 1/2)$ *representations of the Lorentz group are respectively given by* $\psi'_{\mathrm{L,R}} = (\cosh\frac{\phi}{2} \mp \boldsymbol{\sigma}\cdot\hat{\mathbf{p}}\sinh\frac{\phi}{2})\psi_{\mathrm{L,R}}$, *where* $\hat{\mathbf{p}}$ *is a unit vector along the direction of* $\mathbf{p}$. *Recalling that* $\tanh\phi = \beta$, *show that the spinors for states with momentum* $\mathbf{p}$ *can be obtained from the corresponding rest frame states as,*

$$\psi_{\mathrm{L,R}}(\mathbf{p}) = \frac{E + m \mp \boldsymbol{\sigma}\cdot\mathbf{p}}{\sqrt{2m(E+m)}}\psi_{\mathrm{L,R}}(0).$$

Noting that $\psi_{\mathrm{L}}(0) = \psi_{\mathrm{R}}(0)$ *because there is no preferred direction in the rest frame to define the particle's handedness, show that*

$$(E \pm \boldsymbol{\sigma}\cdot\mathbf{p})\psi_{\mathrm{L,R}}(\mathbf{p}) = m\psi_{R,L}(\mathbf{p}).$$

This is just the Dirac equation in two-component notation. Notice that for $m = 0$, *we have* $(\boldsymbol{\sigma}\cdot\hat{\mathbf{p}})\psi_{\mathrm{L,R}}(\mathbf{p}) = \mp\psi_{\mathrm{L,R}}(\mathbf{p})$, *which justifies the use of our labels left and right for the states transforming as the* $(1/2, 0)$ *and* $(0, 1/2)$ *representations of the Lorentz group.*

A four-component Dirac spinor can be built out of the direct sum of two-component spinors $(1/2, 0) \oplus (0, 1/2)$ so that

$$\psi_a^D = \begin{pmatrix} \psi_{\mathrm{L}A} \\ \chi_{\mathrm{R}}^{\dot{A}} \end{pmatrix}. \tag{4.8}$$

The two spinors ψ_{L} and χ_{R} are independent. It is simple to check that the two-component spinor $-\mathrm{i}\sigma_2\psi_{\mathrm{L}}^*$ transforms as a $(0, 1/2)$ representation of the Lorentz group, i.e. it transforms as χ_{R}. We can thus construct a different four-component spinor whose right-handed piece is completely determined by its left-handed pieces via $\chi_{\mathrm{R}} = -\mathrm{i}\sigma_2\psi_{\mathrm{L}}^*$. This four-spinor would transform as the $(1/2, 0) \oplus (0, 1/2)$ representation of the Lorentz group, but would have just half as many independent components as ψ^D above. It can be expressed as

$$\psi_a = \begin{pmatrix} \psi_{\mathrm{L}A} \\ (-\mathrm{i}\sigma_2\psi_{\mathrm{L}}^*)^{\dot{A}} \end{pmatrix}. \tag{4.9}$$

This object is the Majorana spinor that we have already encountered in Chapter 3, and the relation $\chi_{\mathrm{R}} = -\mathrm{i}\sigma_2\psi_{\mathrm{L}}^*$ is simply (3.3).[2] Since the Dirac spinor contains twice as many independent components as a Majorana spinor, it can be thought of as a combination of two Majorana spinors, in much the same way that we can think of a complex number as a combination of two real numbers.

Many textbooks and review articles use the more fundamental two-component spinor notation. Here, we formulate everything in terms of four-component spinors, which are perhaps more familiar to particle physicists interested in performing phenomenological calculations.

4.3 The Poincaré group

In addition to rotations and boosts, the other spacetime transformations include translations in space and time. Translations in space and time are generated by the energy–momentum operator P_μ, which can be represented by the differential operator $P_\mu = \mathrm{i}\partial_\mu$. The Poincaré group is formed by combining rotations, boosts, and translations. We then have *ten* independent generators: the six $M_{\mu\nu}$ plus the four P_μ. It is then straightforward to work out the commutation relations for the generators, using their representation as differential operators. One finds:

---

[2] In Chapter 3 and elsewhere, $\psi_{\mathrm{L,R}}$ is also used to denote the four-component spinor $P_{\mathrm{L,R}}\psi$ which has only two non-vanishing components in the representation where the matrix γ_5 is diagonal. These non-vanishing components are just the components of the two-spinor $\psi_{\mathrm{L,R}}$ discussed in this chapter. Although this is an abuse of notation, it should be clear from the context whether we are using $\psi_{\mathrm{L,R}}$ to denote four- or two-component spinors.

$$[P_\mu, P_\nu] = 0, \tag{4.10a}$$

$$[M_{\mu\nu}, P_\lambda] = \mathrm{i}(g_{\nu\lambda} P_\mu - g_{\mu\lambda} P_\nu), \tag{4.10b}$$

$$[M_{\mu\nu}, M_{\rho\sigma}] = -\mathrm{i}(g_{\mu\rho} M_{\nu\sigma} - g_{\mu\sigma} M_{\nu\rho} - g_{\nu\rho} M_{\mu\sigma} + g_{\nu\sigma} M_{\mu\rho}). \tag{4.10c}$$

To classify the representations of the Poincaré group, we again look for Casimir operators. One of these is the operator P^2, which certainly commutes with all the group generators. Its eigenvalue operating on particle state vectors is just the squared mass $P^2|\psi\rangle = m^2|\psi\rangle$. The other Casimir operator is obtained from the Pauli–Lubanski four-vector $W_\mu = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma} P^\nu M^{\rho\sigma}$, with $W^\mu P_\mu = 0$. The square of the Pauli–Lubanski vector, W^2, can be shown to commute with all the generators of the Poincaré group. Notice also that in the rest frame (of a massive state) W^i is proportional to the rotation generator J^i. The various representations of the Poincaré group were first worked out by Wigner. The physically realized unitary representations which are of interest to us are:

- $P^2 \equiv m^2 > 0$, with $W^2 = -m^2 s(s+1)$, where s denotes the spin quantum number $s = 0, \frac{1}{2}, 1, \ldots$ Thus, these states correspond to particles of definite mass and discrete spin values.
- $P^2 = 0$, $W^2 = 0$ so that $W_\mu = \lambda P_\mu$. Here λ is the state helicity value, and $\lambda = \pm s$, for $s = 0, \frac{1}{2}, 1, \ldots$ These correspond e.g. to single particle states of massless particles such as photons with $\lambda = \pm 1$ or the graviton with $\lambda = \pm 2$.
- Finally, $P^\mu \equiv 0$, corresponding to the vacuum state which is invariant under Poincaré transformations.

In the 1960s, a number of papers were written about the possibility of embedding the spacetime symmetries (i.e. the Poincaré group) into some larger *master* group such as $SU(6)$ that would serve as a more general framework for the symmetry of the laws of physics. These efforts culminated in several no-go theorems, the most general of which was the Coleman–Mandula theorem.[3] It states the following.

Theorem Let G be a connected symmetry group of the S matrix (its generators commute with the S matrix), and assume the following.

- G contains a subgroup which is locally isomorphic to the Poincaré group (Poincaré invariance).
- All particle types correspond to positive energy representations of the Poincaré group. For any finite mass m, there are only a finite number of types of particles with mass less than m.

---

[3] S. Coleman and J. Mandula, *Phys. Rev.* **159**, 1251 (1967).

- Elastic scattering amplitudes are analytic functions of the Mandelstam variables s and t in some neighborhood of the physical region, except at normal thresholds, and the S matrix is non-trivial in the sense that essentially any two one-particle momentum states scatter, except perhaps for isolated values of s.
- Finally, a technical assumption: the generators of G, considered as integral operators in momentum space, have distributions as their kernels.

Coleman and Mandula asserted that if these conditions hold, *G is locally isomorphic to the direct product of a compact symmetry group and the Poincaré group.*

Stated more simply, under a number of physically reasonable assumptions, it is not possible to form a non-trivial merger of the Poincaré symmetry with other symmetries of the S matrix into a bigger group. It is not possible to have a larger spacetime symmetry and, further, internal symmetries such as local gauge symmetries or additional global symmetries (e.g. isospin) can only be realized as a direct product of these symmetry groups with the Poincaré group. It is intriguing that all the Poincaré group symmetries of the S matrix are in fact realized in nature. It is important to recognize that Coleman and Mandula did not envisage the possibility of anticommuting spinorial charges in their analysis. It is precisely the inclusion of these that allows us to enlarge the spacetime symmetry group to include supersymmetry, as we have already seen in Chapter 3.

4.4 The supersymmetry algebra

Our investigation of the Wess–Zumino model in Chapter 3 shows that it is possible to construct a relativistic quantum field theory that is invariant under supersymmetry transformations, for which the generators are anticommuting spinorial charges Q_a. We saw that the algebra of the Q_a's (this involved anticommutators, which is how the Coleman–Mandula theorem is circumvented) closes to yield P_μ, so that the supersymmetry is, in effect, a spacetime symmetry. In this sense, supersymmetry can be looked upon as a generalization of the special theory of relativity.

We had already worked out the algebra of the spinorial generators Q_a amongst themselves and with the translation generators in Chapter 3. Since this involves anticommutators of the super-charges, it is called a graded Lie algebra. The commutator of the Lorentz generators with the super-charges Q_a is simply given by the fact that these are spin $\frac{1}{2}$ objects. We can thus write the supersymmetric extension of the Poincaré algebra, known as the super-Poincaré algebra, as

$$[P_\mu, P_\nu] = 0, \tag{4.11a}$$

$$[M_{\mu\nu}, P_\lambda] = \mathrm{i}(g_{\nu\lambda} P_\mu - g_{\mu\lambda} P_\nu), \tag{4.11b}$$

$$[M_{\mu\nu}, M_{\rho\sigma}] = -\mathrm{i}(g_{\mu\rho} M_{\nu\sigma} - g_{\mu\sigma} M_{\nu\rho} - g_{\nu\rho} M_{\mu\sigma} + g_{\nu\sigma} M_{\mu\rho}), \tag{4.11c}$$

$$[P_\mu, Q_a] = 0, \tag{4.11d}$$

$$[M_{\mu\nu}, Q_a] = -(\tfrac{1}{2}\sigma_{\mu\nu})_{ab}Q_b, \tag{4.11e}$$

$$\{Q_a, \bar{Q}_b\} = 2(\gamma^\mu)_{ab}P_\mu. \tag{4.11f}$$

Since Q is a Majorana spinor charge, we can use the last of these relations to work out the anticommutators between two Q's or $\bar{Q}$'s.

Exercise: *Verify that*

$$\{Q_a, Q_b\} = -2(\gamma^\mu C)_{ab}P_\mu,$$
$$\{\bar{Q}_a, \bar{Q}_b\} = 2(C^{-1}\gamma^\mu)_{ab}P_\mu.$$

An extension of the Coleman–Mandula type analysis that allows for spinorial charges was worked out by Haag, Lopuszanski, and Sohnius who showed that the super-Poincaré algebra above is indeed the most general extension of the Poincaré algebra, provided we have just a single spinorial charge Q.[4] These authors also showed that theories with more than one spinorial generator are possible. These are referred to as extended supersymmetry theories. Such theories do not allow chiral representations which, as we know, are crucial for phenomenology. Only theories with a single spinorial generator Q_a, known as $N = 1$ supersymmetry theories, allow chiral representations. For this reason, we restrict our attention only to $N = 1$ supersymmetry.[5] To sum up, the Haag–Lopuszanski–Sohnius theorem tells us that the most general symmetry of the S matrix is the direct product of some internal symmetry with super-Poincaré invariance.

The irreducible representations of the super-algebra can be worked out as usual by finding the relevant Casimir operators. For the SUSY algebra above, the operator P^2 again commutes with all generators, so that all particles occurring in a supermultiplet will have the same mass. However, the square of the Pauli–Lubanski pseudovector W^2 is no longer a Casimir invariant, so that supermultiplets can now contain particles of differing spins. We will not discuss the construction of a new Casimir operator for this case, but instead focus on the particle supermultiplets that furnish representations of the super-Poincaré algebra.

For the massive case $P^2 \equiv m^2 > 0$, the representations are labeled by (m, j) with $j = 0, 1/2, 1, \ldots$ For fixed m, the complete supermultiplet contains a state each corresponding to spin $s = j \pm 1/2$, and two states with spin $s = j$ (except for the case $j = 0$ where the state with $s = j - 1/2$ is absent), all of which have the same mass. Notice that the number of helicity states for the two objects with spin j $[2(2j + 1)]$ is exactly balanced by the corresponding number of helicity states for the two states with spins $j \pm \frac{1}{2}$ $[2(j+1/2)+1+2(j-1/2)+1]$. This is just the statement that the number of bosonic and fermionic helicity states are the same. If $j=0$, we have the multiplet of the Wess–Zumino model – two spin zero states and two spin half states – as we discussed in Chapter 3. If $j=1/2$, there are four bosonic degrees of freedom (three spin 1 and one spin zero) balanced by four fermionic degrees of freedom corresponding to two Majorana spin half fermions as we will see when we study spontaneously broken gauge theories.

---

[4] R. Haag, J. Lopuszanski and M. Sohnius, *Nucl. Phys.* **B88**, 257 (1975).

[5] The underlying fundamental theory could be an extended supersymmetric theory, but all but one (or none!) of the supersymmetries must somehow be broken at much higher scales, leaving an $N = 1$ supersymmetric theory as the extension of the Standard Model that could have phenomenological relevance.

For the massless case, one can show that if j is the state with largest helicity in a supermultiplet, it is always accompanied by another state with helicity $j-1/2$. Furthermore, a Lorentz invariant field theory always contains these states together with their CPT conjugates which have opposite helicities, $-j$ and $-j+1/2$ and which are also massless. These states constitute a complete massless supermultiplet. If $j=1/2$, this multiplet consists of two fermionic states with helicities $\pm 1/2$, and a pair of spin zero bosonic states. This multiplet occurs in the massless Wess–Zumino model. Such a multiplet would also describe a massless neutrino and antineutrino together with its supersymmetric partners which would be two spin zero states (which can be regarded as quanta of one massless *complex* scalar field). For $j=1$, the bosonic states would correspond to a massless gauge boson (helicities ± 1); the fermionic partner states, which have helicity $\pm 1/2$, then correspond to a Majorana fermion referred to as a *gaugino*. This "gauge multiplet" is a crucial ingredient of supersymmetric gauge theories, which form the basis of all supersymmetry phenomenology. Finally, if $j=2$, we see that the two bosonic states have helicities ± 2. These are thought to correspond to a graviton, the massless spin two quantum that mediates gravity. The fermionic partners of these $j=2$ states have helicities $\pm 3/2$ and describe a spin $\frac{3}{2}$ massless Majorana fermion referred to as a *gravitino*. This "gravity multiplet" is essential for theories in which the parameter α of SUSY transformations depends on x^{μ}. These locally supersymmetric theories necessarily involve Einsteinian gravity, and are referred to as *supergravity* theories.

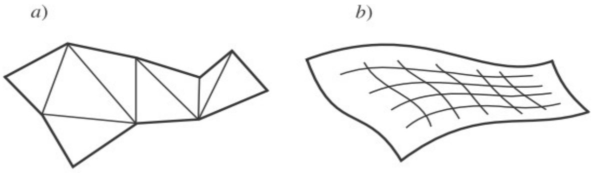

Figure 1.1. Approximate realization (a) of a curved surface (b).

trying to test spacetime geometry by physical measurements. His/her conclusions will also be valid locally for true gravitational fields, on the basis of the PE. Assume that the observer sits at the centre of the disc, and has two identical clocks: one of them is placed at the centre, the other at some point on the periphery. The observer will see that the clock on the periphery is running slower (time dilatation from SR). Consequently, clocks at various positions in the gravitational field run faster or slower, depending on the local strength of the field. There is no definition of time that is pertinent to the whole spacetime in general. The observer will also conclude that the length of a piece of line orthogonal to the radius of the disc will be shortened (length contraction from SR). Therefore, the ratio of the circumference of the circle to its radius will be smaller than 2π, so that the Euclidean geometry of space does not hold in GR.

Geometry of curved surfaces. We have seen that in spacetime, within a limited region, we can always choose a suitable reference frame, called the local inertial frame. Taking spacetime apart into locally inertial components, we can apply the laws of SR in each such component and derive various dynamical conclusions. Reconstruction of the related global dynamical picture, based on the PE (and some additional, simple geometric assumptions), gives rise to GR.

This procedure for dissecting spacetime into locally inertial components, out of which we can reconstruct, using the PE, the global structure of spacetime containing the gravitational field, can be compared geometrically with an attempt to build a curved surface, approximately, from a lot of small, plane elements ‘continuously’ bound to each other (figure 1.1). A locally flat surface is a geometric analogue of locally inertial spacetime.

GR makes essential use of curved spaces (or, more accurately curved spacetimes). Since the curved, four-dimensional spacetime cannot be visualized, let us try to understand the basic features of curved spaces by considering a two-dimensional surface X_2. We shall focus our attention on those geometric properties of X_2, which could be determined by an intelligent, two-dimensional being entirely confined to live and measure in the surface, a being that does not know anything about the embedding Euclidean space E_3. Such properties determine the *intrinsic geometry* on X_2.

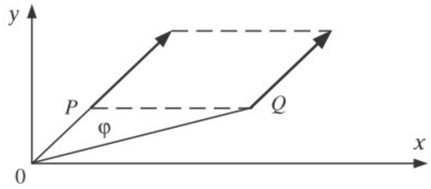

Figure 1.2. Vector components change under the parallel transport.

On a general surface we cannot set up Cartesian coordinates; the best we can do is to introduce two arbitrary families of coordinate lines and label them by $u^\alpha = (u^1, u^2)$. These curvilinear (or Gaussian) coordinates do not always have a direct geometric interpretation.

Let us now imagine a surface X_2 embedded in E_3, and consider a point P in X_2 with Cartesian coordinates (x, y, z) in E_3; since P is in X_2, these coordinates can be expressed as functions of u^α. The squared distance between two neighbouring points in X_2, $P(x, y, z)$ and $Q(x+\mathrm{d}x, y+\mathrm{d}y, z+\mathrm{d}z)$, is given by $\mathrm{d}s^2 = \mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2$. Going over to u^α we obtain

$$\mathrm{d}s^2 = g_{\alpha\beta}\,\mathrm{d}u^\alpha\,\mathrm{d}u^\beta \tag{1.6}$$

where the set of functions $g_{\alpha\beta}(u^1, u^2)$ defines the *metric* on X_2. The metric is an essential intrinsic property of X_2, independent of its embedding in E_3. A two-dimensional continuum X_2, equipped with a squared differential distance according to (1.6), becomes the *metric space*, $G_2 = (X_2, \boldsymbol{g})$ (it is now clear that the symbol X_2 is used to denote an abstract two-dimensional continuum, disregarding all metric properties of the real surface).

Studying the motion of particles in X_2 our observer could have arrived at the idea of the tangent vector, $\boldsymbol{a} = (a^1, a^2)$. Consider, further, two tangent vectors $\boldsymbol{a}$ and $\boldsymbol{b}$, defined at neighbouring points P and Q. If we wish to compare these two vectors we have to know how one of them can be transported to the position of the other. This transport is called *parallel transport*. The continuum X_2 together with the parallel transport law, denoted by Γ, is called a *linearly connected* (or *affine*) space, $L_2 = (X_2, \Gamma)$.

The components of a vector in curvilinear coordinates are expected to change under parallel transport. This can be easily seen by considering the parallel transport of a vector in a plane, using polar coordinates (r, θ). As shown in figure 1.2, if the unit vector $\boldsymbol{a}$ at point P has components $(a^r = 1, a^\theta = 0)$, after parallel transport from P to Q its components become $(a^r = \cos\varphi, a^\theta = \sin\varphi)$.

A two-dimensional observer should determine the rule of parallel transport of vectors in accordance with his/her own experience. This rule is generally independent of the concept of a metric. If X_2 is equipped with a rule of

parallel transport and the independent concept of a metric, we obtain the *linearly connected metric* space $(X_2, \Gamma, \boldsymbol{g}) = (L_2, \boldsymbol{g}) = (G_2, \Gamma)$.

It is very probable that our two-dimensional observer will demand that the lengths of vectors should remain unchanged under parallel transport. After adopting this very natural property, which relates Γ and $\boldsymbol{g}$, the linearly connected metric space becomes the *Riemann–Cartan* space U_2. The usual surfaces have some additional geometric structure, and belong to the class of *Riemann* spaces V_2.

This discussion was slightly more general than strictly necessary for studying surfaces embedded in E_3, in order to emphasize that the intrinsic geometry on X_2 is defined in terms of

- the metric $\boldsymbol{g}$ and
- the rule of parallel transport Γ.

These basic concepts of the intrinsic geometry of surfaces can be extended directly to spaces with higher dimensions, although in this case we lose the intuitive geometric picture.

Any Riemann space is locally Euclidean, i.e. its metric is positive definite ($\mathrm{d}s^2 > 0$). A slight generalization of this case, that consists in admitting metrics that are pseudo-Euclidean, leads to a pseudo-Riemannian geometry or Riemannian geometry with an indefinite metric.

Relativity, covariance and Mach's ideas

Relativity and covariance. We have seen previously that inertial frames play a particularly important role in SR. Einstein considered this to be an expression of the incompleteness of SR. He wanted to generalize the relativity of inertial motions to the relativity of all motions, including accelerated ones. This idea can be formulated as the general principle of relativity:

> *General PR: The form of physical laws is the same in all reference frames.*

Equations expressing physical laws are often formulated using specific coordinates. Thus, for instance, spatial positions in an inertial laboratory L can be determined using Cartesian coordinates (x, y, z) or the coordinates obtained from these by a rotation around the z-axis for a fixed angle φ. If we allow the angle φ to change with time as $\varphi = \omega t$, new coordinates can be naturally attached to a new physical reference frame, rotating relative to L with the angular velocity ω around the z-axis. We see that coordinate transformations can be interpreted as describing transitions from one to another laboratory (the so-called active interpretation). Thus, it becomes clear that the general PR can be realized with the help of the principle of general covariance:

> *General covariance: The form of physical laws does not depend on the choice of coordinates.*

General covariance is a technical way to express the general PR.

When mathematicians study the geometric properties of space, they use certain geometric objects with properties that do not depend on the choice of coordinates. The covariance means that physical laws can be expressed in terms of these geometric objects. In classical physics such objects are tensors, so that covariant equations must be tensorial.

General covariance seems to be a powerful principle which determines acceptable forms of physical equations. Is it really so? The next example shows a certain triviality of this principle. Consider Newton's second law in an inertial frame S, $m\boldsymbol{a} = \boldsymbol{F}$, which is invariant under the group of Galilean transformations G. Going over to a non-inertial frame $\widetilde{S}$ that has linear acceleration $\boldsymbol{a}_0$ and angular velocity $\boldsymbol{\omega}$ relative to S, Newton's equation transforms into

$$m\boldsymbol{a} = \boldsymbol{F} - m\boldsymbol{a}_0 - 2m\boldsymbol{\omega} \times \boldsymbol{v} - m\dot{\boldsymbol{\omega}} \times \boldsymbol{r} - m\boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{r}). \tag{1.7}$$

The transition from S to $\widetilde{S}$ can be described as a Galilean transformation (a spatial translation combined with a rotation) with time-dependent parameters. The set of these transformations forms a group, denoted as $\widetilde{G}$, which is larger than the Galilean group G. In this way we obtained the $\widetilde{G}$-covariant form of Newton's equation. Other physical equations can also be covariantized in a similar manner, which means that covariance implies that there are no stringent conditions on the form of the physical equations.

It is important to note that equation (1.7) is completely determined by its original form in S and the process of covariantization. The original equation has Galilean symmetry, and the covariantization 'knows' of this property, since it is based on $\widetilde{G}$ transformations. Using modern language, we can describe this procedure as an incomplete *localization* of Galilean symmetry, based on time-dependent parameters. Since the procedure does not depend on the form of the original equation but only on its global symmetry, it is clear that covariantization does not restrict the form of physically acceptable equations.

In spite of this conclusion, we know that Einstein's covariant equations have experimental consequences that are essentially different from those of Newton's theory of gravity, so that general covariance still seems to be an important principle for physics. This dilemma can be resolved in the following way. If we restrict ourselves to weak gravitational fields for simplicity, we obtain an approximate, non-covariant form of Einstein's theory, known as the Pauli–Fierz field theory in M_4. Comparing this field theory with Newton's action-at-a-distance theory we easily find significant differences; in particular, these theories have different global symmetries (Poincaré and Galilean, respectively). It is therefore quite natural that their physical contents are essentially different. This difference has nothing to do with the covariance of Einstein's equations.

After clarifying this point, we are now ready to conclude that general covariance by itself does not have any physical content. However, we should note that Einstein related covariance to the PE, so that general covariance (transition to accelerated frames) represents an important technical procedure for *introducing the gravitational field* into any physical theory. Thus, Einstein's theory of gravity is obtained by unifying the principle of general covariance with the PE:

General covariance + PE ⇒ theory of gravity.

Here, general covariance stands essentially for the general PR, while the PE tells us not only how to introduce gravity, but also the kind of physics we have in the absence of gravity.

General covariance is only a statement about the effects of gravity, it does not imply the validity of SR in locally inertial frames. Although the local validity of SR is usually assumed, theoretically it is not necessary; for instance, we could assume Galilean relativity in locally inertial frames. This is particularly clear if we think of gravity as a locally invariant theory.

Covariance and symmetry. Although the concepts of general covariance and symmetry have certain formal similarities, they are, in fact, essentially different. In order to illustrate this difference, consider the interval in $G_4 = (X_4, \boldsymbol{g})$,

$$\mathrm{d}s^2 = g_{\mu\nu}(x)\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu \tag{1.8a}$$

which is expressed in some coordinate system K. This equation is covariant with respect to general coordinate transformations $x \to x' = x'(x)$, since it has the same form in the new coordinate system K' as it had in K:

$$\mathrm{d}s^2 = g'_{\mu\nu}(x')\,\mathrm{d}x^{\mu'}\,\mathrm{d}x^{\nu'}. \tag{1.8b}$$

Here, the coordinate transformation induces a related functional change in the metric, $g_{\mu\nu} \to g'_{\mu\nu}$, where the prime denotes a new function. Now, if we restrict ourselves to those transformations that do not change the form of the metric, $g'_{\mu\nu}(x) = g_{\mu\nu}(x)$, we obtain symmetry transformations (or isometries) of the space G_4.

To see the meaning of this definition in Minkowski space, let us consider equation (1.8a) in an inertial frame S, where $g_{\mu\nu} = \eta_{\mu\nu}$ is the metric of M_4. If we look for coordinate transformations that do not change the form of the metric, we obtain Poincaré transformations. They express the symmetry of physical laws under transition from one inertial frame to another in M_4.

Mach's principle. In his attempts to build GR, Einstein was led by the idea of abolishing the privileged role of inertial frames from physics. Even if it were possible to develop a satisfactory theory of gravity within SR, he would not have stopped there—he had to go beyond SR. On this route he was greatly influenced by the ideas of the philosopher E Mach (1836–1916), who gave the first constructive critique of Newton's understanding of inertia and absolute space, and proposed a new approach to these questions.

The conclusion drawn by Newton on the basis of his experiment with a rotating vessel (that the acceleration of the water with respect to the vessel does not produce inertial forces, they are produced only by the acceleration of the water with respect to absolute space) cannot be considered as well founded. Newton's experiment only shows that the rotation of the water relative to a *small* vessel produces no noticeable inertial forces. It is not clear how the experiment would have turned out if the vessel had been more massive—these were the suspicions raised by Mach. He believed that water rotating relative to a very massive vessel would remain flat, since it would be at rest with respect to the very close and massive vessel, while the water that does not rotate would be curved, since its motion with respect to the vessel would be accelerated. In other words, inertial forces are caused by the acceleration of the water relative to the average mass distribution in the universe, not with respect to absolute space.

We shall now illustrate the difference between Newton and Mach by another example. Consider an elastic sphere that is rotating relative to some inertial frame, getting larger at the equator. How does the sphere 'know' that it is rotating and hence must deform? Newton might have said that it was accelerated relative to absolute space, which thereby causes the inertial forces that deformed it. Mach would have said that the sphere was accelerated relative to distant masses in the universe, which was the cause of deformation.

It is interesting to observe that both Newton and Mach explained the appearance of inertial forces by the *acceleration* of a body, not by its velocity. Why is that so? Mach's considerations were general in nature, he was not able to give any quantitative description of these ideas. The inertial influence of cosmic matter was clearly defined in Einstein's GR (inertia is a manifestation of the geometry of spacetime, geometry is affected by the presence of matter) which, to some extent, realizes Mach's abstract ideas in a concrete physical theory.

Mach's principle can be roughly expressed in the form of the following (not completely independent) statements:

- Space as such plays no role in physics; it is merely an abstraction from the totality of spatial relations between material objects.
- The inertial properties of every particle are determined by its interaction with all the other masses in the universe.
- Any motion is relative and can be determined only with respect to all the other masses in the universe.
- Inertial forces are caused by an acceleration of a body relative to the average mass distribution in the universe.

It is often believed that Mach's principle is so general that it cannot be checked experimentally so that, essentially, it has no physical content. Yet, there are examples showing clearly that this is not so. In spite of this, there is still no direct experimental verification (Rindler 1977).

Bearing in mind the strong influence of Mach's principle on Einstein, it is interesting to clarify to what extent this principle has been justified by GR. We can say that GR has realized only some of Mach's ideas; indeed, solutions of Einstein's field equations are determined not only by matter distribution, but also by boundary conditions. Hence, the same mass distribution may give rise to different gravitational fields. Mach wanted to abolish space in its own right and replace it with the relative configuration of matter; Einstein retained spacetime but made it non-absolute. Although Mach's principle helped stimulate the development of GR, there is no reason today to consider it as a basic principle of physics.

Perspectives of further developments

Einstein's theory of gravity predicted a number of physical effects which can be completely verified experimentally. Nevertheless, we should stress that certain properties of this theory deserve critical analysis.

GR is characterized by the existence of *singularities*, which are generic features of solutions describing both localized physical systems (black holes) and cosmology (big bang). A spacetime singularity can be intuitively characterized by an infinite growth of some physical quantities in some regions of spacetime and the analogous pathological behaviour of the related geometric objects. Both cosmology and black holes represent very interesting phenomena in gravitational physics—their features cast light on the intrinsic limitations of GR and serve as a signpost towards a new, consistent approach to gravitation.

The standard cosmological model predicts that at some finite time in the past, the universe was in a singular state (big bang). For many years it was generally believed that this prediction was due merely to the simplifying assumptions of the model. However, the singularity theorems of GR have shown that singularities are generic features of cosmological solutions. We expect that the singular behaviour can be avoided either by modifying classical GR and/or by taking quantum effects into account.

General singularity theorems also apply to black holes—gravitational objects that inevitably arise at the endpoint of the thermonuclear evolution of some stars. After a finite proper time all the matter of the star meets at one point, where the density of matter and the curvature of spacetime become infinite.

A cosmological singularity means that there existed a moment of time in the past, such that nothing before that moment, even time itself, did not have any sense, did not exist. The singularity of the black hole is related to the future, and means that for an observer falling into the black hole, there will come a moment at which not only the observer's life will end, but also time itself will go out of existence. In these extreme conditions, where the density of matter becomes very large and the predictions of GR contradict the fundamental concepts of classical

Abstract

Recent progress on string theory in curved spacetimes is reviewed. The string dynamics in cosmological and black hole spacetimes is investigated. The different methods available to solve the string equations of motion and constraints in curved spacetimes are described. That is, the string perturbation approach, the null string approach, the τ-expansion, and the construction of global solutions (for instance by inverse scattering methods).

The classical behaviour of strings in FRW and inflationary spacetimes is now understood in a large extent from the various types of explicit string solutions. Three different types of behaviour appear: **unstable, dual** to unstable and **stable**. For the unstable strings, the energy and size grow for large scale factors $R \to \infty$, proportional to R. For the dual to unstable strings, the energy and size blow up for $R \to 0$ as $1/R$. For stable strings, the energy and proper size are bounded. (In Minkowski spacetime, all string solutions are of the stable type).

Recent progress on self-consistent solutions to the Einstein equations for string dominated universes is reviewed. The energy-momentum tensor for a gas of strings is then considered as source of the spacetime geometry and from the above string behaviours the string equation of state is **derived**. The self-consistent string solution exhibits the realistic matter dominated behaviour $R \simeq T^{2/3}$ for large times and the radiation dominated behaviour $R \simeq T^{1/2}$ for early times (T being the cosmic time).

We report on the **exact integrability** of the string equations plus the constraints in de Sitter spacetime that allows to systematically find **exact** string solutions by soliton methods and the multistring solutions. **Multistring solutions** are a new feature in curved spacetimes. That is, a single world-sheet simultaneously describes many different and independent strings. This phenomenon has no analogue in flat spacetime and follows to the coupling of the strings with the geometry.

Finally, the string dynamics next and inside a Schwarzschild black hole is analyzed and their physical properties discussed.

Chapter 3

String dynamics in flat space

The Minkowski spacetime is the only background metric of cosmological interest in which the string equation of motion (2.14) can be integrated exactly. It is, therefore, not surprising that most work on string dynamics has been done in the Minkowski background, and that string dynamics in flat space is reasonably well understood. Only the Robertson–Walker background is of comparable importance and there little can be done without resort to approximations or numerical techniques (see section 5.1).

In this chapter the Minkowski version of the string equation of motion will be examined in some detail. The various laws relating to conservation of momentum, angular momentum and invariant length will be formulated explicitly and the inter-relationship between the kinks, cusps and self-intersections of a string loop will be analysed with the aid of a particular representation known as the Kibble–Turok sphere. In addition, a number of methods for generating exact periodic solutions will be presented.

3.1 The aligned standard gauge

In what follows, it is assumed that the Minkowski metric tensor $\eta_{\mu\nu}$ has its Cartesian form $\mathrm{diag}(1, -1, -1, -1)$ and that the parametrization $x^\mu = X^\mu(\tau, \sigma)$ of the world sheet has been chosen so that τ and σ are standard-gauge coordinates (see section 2.3). As mentioned in the previous chapter, there is no unique choice for the gauge coordinates in the standard gauge. One simple way to eliminate the residual gauge freedom is to identify τ with the Minkowski time coordinate $x^0 = t$. I will call this choice the *aligned standard gauge*.

Whichever form of the standard gauge is prescribed, the equation of motion (2.31) in a Minkowski background reads:

$$X^\mu{}_{,\tau\tau} = X^\mu{}_{,\sigma\sigma} \tag{3.1}$$

subject to the gauge conditions

$$X_\tau^2 + X_\sigma^2 = 0 \qquad \text{and} \qquad X_\tau \cdot X_\sigma = 0. \tag{3.2}$$

The general solution to (3.1) is

$$X^\mu(\tau,\sigma) = A^\mu(\tau+\sigma) + B^\mu(\tau-\sigma) \tag{3.3}$$

where A^μ and B^μ are arbitrary functions of their arguments, save for the gauge constraints

$$A'^2 = B'^2 = 0 \tag{3.4}$$

where a prime here denotes the derivative with respect to the relevant argument. The trajectory $X^\mu(\tau,\sigma)$ is thus a linear superposition of left- and right-moving modes which propagate along the string at the speed of light.

If the gauge coordinates (τ,σ) are not initially aligned with the time coordinate t, this can easily be achieved by defining a new pair of standard-gauge coordinates $(\overline{\tau},\overline{\sigma})$ which satisfy the equations

$$A^0(\tau+\sigma) = \tfrac{1}{2}(\overline{\tau}+\overline{\sigma}) \qquad \text{and} \qquad B^0(\tau-\sigma) = \tfrac{1}{2}(\overline{\tau}-\overline{\sigma}). \tag{3.5}$$

Then, after dropping the bars, the general solution (3.3) becomes

$$X^\mu(\tau,\sigma) = [\tau,\ \tfrac{1}{2}\mathbf{a}(\tau+\sigma) + \tfrac{1}{2}\mathbf{b}(\tau-\sigma)] \tag{3.6}$$

where **a** and **b** are 3-vector functions with the property that

$$\mathbf{a}'^2 = \mathbf{b}'^2 = 1. \tag{3.7}$$

The functions $\mathbf{a}'$ and $\mathbf{b}'$, therefore, lie on the surface of a unit sphere, first introduced by Tom Kibble and Neil Turok in 1982 [KT82] and as a result often referred to as the *Kibble–Turok sphere*[1]. The implications of the Kibble–Turok sphere for the dynamics of a string loop will be considered in more detail in sections 3.6–3.9.

If the string is closed and contains only one connected component (so that the world sheet **T** has strict cylindrical topology), then in the aligned standard gauge lines of constant τ form closed loops on **T**. The function $X^\mu(\tau,\sigma)$ is, therefore, periodic in σ with some constant gauge period L, so that

$$X^\mu(\tau,0) = X^\mu(\tau,L) \tag{3.8}$$

for all values of τ. In terms of the mode functions **a** and **b**, the periodicity condition (3.8) reads:

$$\mathbf{a}(\tau) + \mathbf{b}(\tau) = \mathbf{a}(\tau+L) + \mathbf{b}(\tau-L). \tag{3.9}$$

---

[1] It should be mentioned that many authors have chosen to use a gauge convention in which **a** is a function of $\sigma-\tau$ and **b** a function of $\sigma+\tau$. The principal drawback of this convention is that cusps occur when $\mathbf{a}'$ and $\mathbf{b}'$ are anti-parallel rather than parallel, which, in turn, complicates discussion of the Kibble–Turok representation. In what follows, I will adhere to the convention of (3.6) throughout, transforming previously published solutions into this form where necessary.

Since the tangent vector X^{μ}_{σ} is also a periodic function of σ, it follows that

$$\mathbf{a}'(\tau) - \mathbf{b}'(\tau) = \mathbf{a}'(\tau + L) - \mathbf{b}'(\tau - L) \tag{3.10}$$

as well. The most general solution of these two equations is

$$\mathbf{a}(\tau) = \widehat{\mathbf{a}}(\tau) + \mathbf{V}\tau \qquad \text{and} \qquad \mathbf{b}(\tau) = \widehat{\mathbf{b}}(\tau) + \mathbf{V}\tau \tag{3.11}$$

where $\mathbf{V}$ is a constant vector, and $\widehat{\mathbf{a}}$ and $\widehat{\mathbf{b}}$ are periodic functions with period L satisfying the relations

$$(\widehat{\mathbf{a}}' + \mathbf{V})^2 = (\widehat{\mathbf{b}}' + \mathbf{V})^2 = 1. \tag{3.12}$$

As will be seen shortly, the vector $\mathbf{V}$ can be interpreted as the bulk velocity of the string loop, while the gauge period L is related to the energy of the loop.

In terms of the periodic mode functions $\widehat{\mathbf{a}}$ and $\widehat{\mathbf{b}}$, the string trajectory takes the form

$$X^{\mu}(\tau, \sigma) = [\tau, \tfrac{1}{2}\widehat{\mathbf{a}}(\tau + \sigma) + \tfrac{1}{2}\widehat{\mathbf{b}}(\tau - \sigma) + \mathbf{V}\tau]. \tag{3.13}$$

Although the functions $\widehat{\mathbf{a}}$ and $\widehat{\mathbf{b}}$ each have period L, the entire trajectory, in fact, has period $L/2$, as was first pointed out by Kibble and Turok [KT82]. To see this, note that

$$\begin{aligned} X^{\mu}&(\tau + L/2, \sigma + L/2) \\ &= [\tau + L/2, \tfrac{1}{2}\widehat{\mathbf{a}}(\tau + \sigma + L) + \tfrac{1}{2}\widehat{\mathbf{b}}(\tau - \sigma) + \mathbf{V}(\tau + L/2)] \\ &= [\tau + L/2, \tfrac{1}{2}\widehat{\mathbf{a}}(\tau + \sigma) + \tfrac{1}{2}\widehat{\mathbf{b}}(\tau - \sigma) + \mathbf{V}(\tau + L/2)] \end{aligned} \tag{3.14}$$

which is simply the original configuration (3.13) translated by an amount $L\mathbf{V}/2$.

3.2 The GGRT gauge

An alternative method of fixing a choice of standard gauge, first formulated by Goddard, Goldstone, Rebbi and Thorn in 1973 [GGRT73], is to choose a constant timelike or null vector u^{μ} and define

$$\tau = \frac{u \cdot X}{2u \cdot P} \tag{3.15}$$

where P^{μ} is the constant total 4-momentum of the string. If u^{μ} is timelike, the effect is to set τ equal to $\frac{1}{2E'}t'$, where t' is the time coordinate and E' the energy of the string in a frame with 4-velocity parallel to u^{μ}. Goddard *et al* [GGRT73] themselves preferred a gauge choice in which u^{μ} is null, as this leads to some simplifications when quantizing the relativistic string, which was their primary concern. The resulting gauge is what was originally meant by the term ‘light-cone gauge’ or (less commonly) ‘light-front gauge’. I will refer to it simply as the *GGRT gauge*.

Since the total 4-momentum P^μ of an infinite string is undefined, it is often preferable to replace the factor $2u \cdot P$ in (3.15) with some fixed constant. Following Christopher Thompson [Tho88], who revived the GGRT gauge in 1988, I will replace $2u \cdot P$ with 1 and make the choice

$$u^\mu = [1, 0, 0, -1] \tag{3.16}$$

so that

$$\tau = t + z \tag{3.17}$$

where z is the third spatial component of X^μ.

As in the aligned standard gauge, the general solution (3.3) to the equation of motion consists of a linear superposition of left- and right-moving modes, which in the present case will be written as

$$X^\mu(\tau, \sigma) = [t_{\mathrm{L}}(\tau+\sigma)+t_{\mathrm{R}}(\tau-\sigma), \mathbf{p}(\tau+\sigma)+\mathbf{q}(\tau-\sigma), z_{\mathrm{L}}(\tau+\sigma)+z_{\mathrm{R}}(\tau-\sigma)] \tag{3.18}$$

where $\mathbf{p}$ and $\mathbf{q}$ are 2-vector functions. The GGRT gauge choice $\tau = t + z$ implies that

$$t'_{\mathrm{L}} + z'_{\mathrm{L}} = \tfrac{1}{2} \qquad \text{and} \qquad t'_{\mathrm{R}} + z'_{\mathrm{R}} = \tfrac{1}{2} \tag{3.19}$$

and so, after some algebraic manipulation, the gauge constraints (3.2) read:

$$t'_{\mathrm{L}} - z'_{\mathrm{L}} = 2\mathbf{p}'^2 \qquad \text{and} \qquad t'_{\mathrm{R}} - z'_{\mathrm{R}} = 2\mathbf{q}'^2. \tag{3.20}$$

Solving the last two sets of equations simultaneously gives

$$t'_{\mathrm{L}} = \tfrac{1}{4} + \mathbf{p}'^2 \qquad t'_{\mathrm{R}} = \tfrac{1}{4} + \mathbf{q}'^2$$

and

$$z'_{\mathrm{L}} = \tfrac{1}{4} - \mathbf{p}'^2 \qquad z'_{\mathrm{R}} = \tfrac{1}{4} - \mathbf{q}'^2. \tag{3.21}$$

These restrictions, which take the place of the constraints $\mathbf{a}'^2 = \mathbf{b}'^2 = 1$ in the aligned standard gauge, have the specific advantage of being linear in the t–z mode functions. Thus, for example, a solution containing only a finite number of harmonics in $\sigma_\pm = \tau \pm \sigma$ can be generated by simply choosing the functions $\mathbf{p}$ and $\mathbf{q}$ to be finite harmonic series and integrating (3.21). The corresponding procedure in the aligned standard gauge is far more complicated (see section 3.5).

However, if the string forms a closed loop then the equations (3.21) need to be supplemented by the condition

$$\int_0^L (t'_{\mathrm{L}} - t'_{\mathrm{R}})\,\mathrm{d}\sigma = \int_0^L (z'_{\mathrm{L}} - z'_{\mathrm{R}})\,\mathrm{d}\sigma = 0 \tag{3.22}$$

or, equivalently,

$$\int_0^L \mathbf{p}'^2\,\mathrm{d}\sigma_+ = \int_0^L \mathbf{q}'^2\,\mathrm{d}\sigma_- \tag{3.23}$$

which, to a large extent, vitiates the advantage of the GGRT gauge in generating finite-harmonic solutions.

Another disadvantage of the GGRT gauge is that the coordinates τ and σ are singular at a cusp if the cusp velocity is parallel to u^μ (as $u \cdot X_\tau = 1$ everywhere but $u \cdot X_\tau = 0$ at a cusp in any non-singular gauge). Furthermore, solutions in the GGRT gauge trace out curves on the surface of the paraboloid $t - x^2 - y^2 = \frac{1}{4}$ rather than on the unit sphere. The resulting geometric description is typically harder to visualize and so has less heuristic value than the Kibble–Turok sphere.

Finally, it should be noted that for any particular choice of u^μ the GGRT gauge is incompatible with all standard-gauge solutions (3.3) in which either $u \cdot A$ or $u \cdot B$ is identically zero, as in such cases there is no reparametrization $\{\overline{\sigma}_+(\sigma_+), \overline{\sigma}_-(\sigma_-)\}$ that can transform $u \cdot X$ into a function of $\overline{\tau}$ alone. Since A'^μ and B'^μ are both null vectors the (unwelcome) possibility that either $u \cdot A = 0$ or $u \cdot B = 0$ is consistent with the gauge conditions if u^μ is null but not if u^μ is timelike. An example of this problem will be encountered in section 5.6.

Despite these caveats, the use of the GGRT gauge has helped to generate a number of simple solutions that would otherwise have remained undiscovered (see [Tho88]).

3.3 Conservation laws in flat space

Because the Minkowski spacetime has maximal symmetry, the components of the world-sheet momentum currents P^A_μ defined in section 2.4 are all separately conserved. The contravariant components of the momentum currents are

$$P^{\mu A} = \mu \gamma^{1/2} \gamma^{AB} X^\mu{}_{,B} \tag{3.24}$$

where, in the aligned standard gauge,

$$X^\mu_\tau = [1, \tfrac{1}{2}\mathbf{a}' + \tfrac{1}{2}\mathbf{b}'] \qquad X^\mu_\sigma = [0, \tfrac{1}{2}\mathbf{a}' - \tfrac{1}{2}\mathbf{b}'] \tag{3.25}$$

$$\gamma^{1/2} = X^2_\tau = \tfrac{1}{2}(1 - \mathbf{a}' \cdot \mathbf{b}') \tag{3.26}$$

and

$$\gamma^{AB} = \gamma^{-1/2}\, \mathrm{diag}(1, -1). \tag{3.27}$$

The local Lorentz factor of the string is $\lambda = \gamma^{-1/4}$, which diverges (and so indicates the formation of a cusp) whenever $\mathbf{a}' \cdot \mathbf{b}' = 1$.

An observer at rest with respect to the spacetime coordinates would measure the local 4-momentum at any point on the string to be

$$p^\mu = \lambda \mu X^\mu_\tau = \gamma^{-1/4} \mu [1, \tfrac{1}{2}\mathbf{a}' + \tfrac{1}{2}\mathbf{b}'] \tag{3.28}$$

and the element of proper distance along the string as

$$\mathrm{d}\ell = (-X^2_\sigma)^{1/2}\, \mathrm{d}\sigma = \gamma^{1/4}\, \mathrm{d}\sigma. \tag{3.29}$$

Hence, the total energy ΔE and momentum $\Delta\mathbf{p}$ of a segment of the string covering the parameter range σ to $\sigma + \Delta\sigma$ as measured by such an observer are

$$\Delta E = \int p^0 d\ell = \mu\Delta\sigma \qquad \text{and} \qquad \Delta\mathbf{p} = \int \mathbf{p}\,\mathrm{d}\ell = \tfrac{1}{2}\mu(\Delta\mathbf{a} - \Delta\mathbf{b}). \quad (3.30)$$

Note, in particular, that the local energy content of the string is proportional to σ in the aligned standard gauge.

The total 4-momentum P^μ of a string loop with parametric period L is most conveniently calculated by integrating $P^{\mu A}$ around a curve of constant τ, as in equation (2.48), so that

$$P^\mu = \mu \int_0^L X^\mu_\tau \,\mathrm{d}\sigma = \mu \int_0^L [1, \tfrac{1}{2}\widehat{\mathbf{a}}'(\tau+\sigma) + \tfrac{1}{2}\widehat{\mathbf{b}}'(\tau-\sigma) + \mathbf{V}]\,\mathrm{d}\sigma. \quad (3.31)$$

Since the mode functions $\widehat{\mathbf{a}}$ and $\widehat{\mathbf{b}}$ are periodic with period L, they make no contribution to P^μ, and so

$$P^\mu = \mu L[1, \mathbf{V}]. \quad (3.32)$$

Hence, μL is the total energy of the string as expected, and $\mathbf{V}$ can be interpreted as its bulk velocity.

A similar conclusion can be drawn from the dynamics of the centre-of-mass 4-vector $\bar{X}^\mu$ of the loop, which is defined by

$$\bar{X}^\mu(\tau) = L^{-1} \int_0^L X^\mu \,\mathrm{d}\sigma = L^{-1} \int_0^L [\tau, \tfrac{1}{2}\widehat{\mathbf{a}}(\tau+\sigma) + \tfrac{1}{2}\widehat{\mathbf{b}}(\tau-\sigma) + \mathbf{V}\tau]\,\mathrm{d}\sigma. \quad (3.33)$$

In view of the periodicity of $\widehat{\mathbf{a}}$ and $\widehat{\mathbf{b}}$, this equation can be expressed more compactly as

$$\bar{X}^\mu(\tau) = [\tau, \bar{\mathbf{X}}_0 + \mathbf{V}\tau] \quad (3.34)$$

where

$$\bar{\mathbf{X}}_0 = L^{-1} \int_0^L [\tfrac{1}{2}\widehat{\mathbf{a}}(\sigma) + \tfrac{1}{2}\widehat{\mathbf{b}}(-\sigma)]\,\mathrm{d}\sigma \quad (3.35)$$

is the spatial centre-of-mass at time $\tau = 0$. Thus the centre-of-mass of the loop follows an inertial trajectory with 3-velocity $\mathbf{V}$.

An additional result, due to Tom Kibble [Kib85], is that the root mean square velocity of a string loop in its centre-of-momentum frame, averaged over a period of oscillation, is $\frac{1}{\sqrt{2}}$. This follows from the fact that, if $\mathbf{r}(\tau, \sigma)$ is the spatial position vector of the string, then

$$\mathbf{r}_{,\tau\tau} = \mathbf{r}_{,\sigma\sigma} \qquad \text{and} \qquad \mathbf{r}_\sigma^2 = 1 - \mathbf{r}_\tau^2 \quad (3.36)$$

and so the period mean of $\mathbf{r}_\tau^2$ in a general Lorentz frame is

$$\langle \mathbf{r}_\tau^2 \rangle \equiv \frac{1}{L^2} \int_0^L \int_0^L \mathbf{r}_\tau^2 \,\mathrm{d}\sigma\,\mathrm{d}\tau = \frac{1}{L} \int_0^L \mathbf{V}\cdot\mathbf{r}_\tau \,\mathrm{d}\sigma - \frac{1}{L^2} \int_0^L \int_0^L \mathbf{r}\cdot\mathbf{r}_{,\tau\tau} \,\mathrm{d}\sigma\,\mathrm{d}\tau$$

$$= \mathbf{V}^2 - \frac{1}{L^2}\int_0^L\int_0^L \mathbf{r}\cdot\mathbf{r}_{,\sigma\sigma}\,\mathrm{d}\sigma\,\mathrm{d}\tau = \mathbf{V}^2 + \frac{1}{L^2}\int_0^L\int_0^L \mathbf{r}_\sigma^2\,\mathrm{d}\sigma\,\mathrm{d}\tau$$

$$= \mathbf{V}^2 + \langle 1 - \mathbf{r}_\tau^2\rangle. \tag{3.37}$$

Hence, $\langle\mathbf{r}_\tau^2\rangle = \frac{1}{2}(1+\mathbf{V}^2)$ and so, in particular, $\langle\mathbf{r}_\tau^2\rangle = \frac{1}{2}$ in the centre-of-momentum frame. Since $\langle\mathbf{r}_\tau\rangle = \mathbf{V}$, the mean square deviation of $\mathbf{r}_\tau$ from the bulk velocity $\mathbf{V}$ in a more general frame is

$$\langle(\mathbf{r}_\tau - \mathbf{V})^2\rangle = \tfrac{1}{2}(1-\mathbf{V}^2). \tag{3.38}$$

However, it should be pointed out that the integrals over σ in (3.37) are mass-weighted averages rather than ordinary spatial averages, as it is $\gamma^{1/4}\,\mathrm{d}\sigma$ rather than $\mathrm{d}\sigma$ that is the proper distance element. This is evident also from the calculation of the total 4-momentum P^μ, which indicates that the bulk velocity $\langle\mathbf{r}_\tau\rangle = \mathbf{V}$ is mass-weighted. As a result, the value of $\langle\mathbf{r}_\tau^2\rangle$ is weighted towards segments of the loop with high Lorentz factor and so, in a sense, overstates the actual mean square velocity.

Another useful conserved quantity is the total angular momentum of a string loop [Tur84]. This can be calculated in two ways. If $\mathbf{n}$ is any unit 3-vector then the rotational Killing vector about $\mathbf{n}$ is

$$k_\mu = [0, \mathbf{n}\times\mathbf{r}] \tag{3.39}$$

where $\mathbf{r}$ is again the spatial position vector. The total angular momentum of the string about $\mathbf{n}$ is, therefore,

$$J(\mathbf{n}) = \mu\int_0^L k\cdot X_\tau\,\mathrm{d}\sigma = \tfrac{1}{4}\mu\mathbf{n}\cdot\int_0^L(\mathbf{a}+\mathbf{b})\times(\mathbf{a}'+\mathbf{b}')\,\mathrm{d}\sigma. \tag{3.40}$$

Now, in terms of the periodic mode functions $\widehat{\mathbf{a}}$ and $\widehat{\mathbf{b}}$,

$$\begin{aligned}(\mathbf{a}+\mathbf{b})\times(\mathbf{a}'+\mathbf{b}') &= \widehat{\mathbf{a}}\times\widehat{\mathbf{a}}' + \widehat{\mathbf{b}}\times\widehat{\mathbf{b}}' + \widehat{\mathbf{a}}\times\widehat{\mathbf{b}}' + \widehat{\mathbf{b}}\times\widehat{\mathbf{a}}'\\ &\quad + 2\tau\mathbf{V}\times(\widehat{\mathbf{a}}'+\widehat{\mathbf{b}}') + 2(\widehat{\mathbf{a}}+\widehat{\mathbf{b}})\times\mathbf{V}\end{aligned} \tag{3.41}$$

where, since

$$\frac{\mathrm{d}}{\mathrm{d}\sigma}[\widehat{\mathbf{b}}(\tau-\sigma)\times\widehat{\mathbf{a}}(\tau+\sigma)] = \widehat{\mathbf{b}}(\tau-\sigma)\times\widehat{\mathbf{a}}'(\tau+\sigma) + \widehat{\mathbf{a}}(\tau+\sigma)\times\widehat{\mathbf{b}}'(\tau-\sigma) \tag{3.42}$$

the third, fourth and fifth terms on the right of (3.41) all vanish on integration. Hence,

$$J(\mathbf{n}) = \tfrac{1}{4}\mu\mathbf{n}\cdot\int_0^L(\widehat{\mathbf{a}}\times\widehat{\mathbf{a}}' + \widehat{\mathbf{b}}\times\widehat{\mathbf{b}}')\,\mathrm{d}\sigma + \mathbf{n}\cdot(\mathbf{M}\times\mathbf{V}) \tag{3.43}$$

where

$$\mathbf{M} = \tfrac{1}{2}\mu\int_0^L(\widehat{\mathbf{a}}+\widehat{\mathbf{b}})\,\mathrm{d}\sigma \equiv \tfrac{1}{2}\mu L\bar{\mathbf{X}}_0 \tag{3.44}$$

is the mass moment of the loop. The angular momentum vector measured by an observer at rest with respect to the coordinate system is, therefore,

$$\mathbf{J} = \tfrac{1}{4}\mu \int_0^L (\widehat{\mathbf{a}} \times \widehat{\mathbf{a}}' + \widehat{\mathbf{b}} \times \widehat{\mathbf{b}}')\, \mathrm{d}\sigma + \mathbf{M} \times \mathbf{V}. \tag{3.45}$$

Note, in particular, that the left- and right-moving modes contribute separately to $\mathbf{J}$.

In the rest frame of the loop, $\widehat{\mathbf{a}}'$ and $\widehat{\mathbf{b}}'$ are both unit vectors, and so $\widehat{\mathbf{a}}$ and $\widehat{\mathbf{b}}$ trace out closed curves each of length L in $\mathbb{R}^3$. Suppose that $\widehat{\mathbf{a}}$ traces a planar curve which does not intersect itself. Then

$$\mathbf{A}_a = \tfrac{1}{2} \int_0^L \widehat{\mathbf{a}} \times \widehat{\mathbf{a}}'\, \mathrm{d}\sigma \tag{3.46}$$

is a vector normal to the plane with magnitude equal to the area enclosed by the curve. In the more general case where the curve does intersect itself, $\mathbf{A}_a$ can be found by breaking the curve up into non-intersecting closed segments and adding the corresponding vector areas. Furthermore, if the curve is not planar, it is always possible to project $\widehat{\mathbf{a}}$ onto a plane normal to the direction of $\mathbf{A}_a$ and so generate a closed planar curve with length strictly less than L; the magnitude of $\mathbf{A}_a$ is then the area enclosed by this curve.

Since the area enclosed by a curve of fixed length is maximal when the curve is a circle, $|\mathbf{A}_a|$ is bounded above by $L^2/(4\pi)$. A similar argument applies to the contribution of the $\widehat{\mathbf{b}}$ mode to the angular momentum vector $\mathbf{J}$, and so

$$|\mathbf{J}| \leq \frac{1}{4\pi} \mu L^2 \tag{3.47}$$

for any loop configuration [SQSP90]. Equality holds in (3.47) if and only if the mode functions $\widehat{\mathbf{a}}$ and $\widehat{\mathbf{b}}$ trace out co-planar circles with the same orientation. This corresponds to a trajectory in the form of a rotating doubled straight line whose ends are moving at the speed of light (see section 4.2.2).

An alternative way to characterize the angular momentum of a loop is to first construct the angular momentum currents

$$M_A^{\mu\nu} = \mu(X^\mu X^\nu{}_{,A} - X^\nu X^\mu{}_{,A}). \tag{3.48}$$

By virtue of the flat-space equation of motion $\gamma^{AB} X^\mu{}_{,AB} = 0$, these satisfy the conservation equation

$$\gamma^{AB} M_A^{\mu\nu}{}_{,B} = \mu(X^\mu \gamma^{AB} X^\nu{}_{,AB} - X^\nu \gamma^{AB} X^\mu{}_{,AB}) = 0. \tag{3.49}$$

Hence, the conserved total angular momentum tensor of the loop is

$$M^{\mu\nu} = \int_0^L M_\tau^{\mu\nu}\, \mathrm{d}\sigma = \begin{pmatrix} 0 & -M_x & -M_y & -M_y \\ M_x & 0 & J_z & -J_y \\ M_y & -J_z & 0 & J_x \\ M_z & J_y & -J_x & 0 \end{pmatrix} \tag{3.50}$$

and so can be used to reconstruct the components of both **M** and **J** in any Lorentz frame.

A further macroscopic property of interest is the invariant length of a closed loop. The parametric period L in an aligned standard gauge typically has different values in different reference frames. The minimum possible value of the parametric period occurs in the rest frame of the loop, and is

$$L_{\min} = (1 - \mathbf{V}^2)^{1/2} L \tag{3.51}$$

where L and $\mathbf{V}$ are the parametric period and bulk velocity of the loop in an arbitrary frame. Since the quantity $\mu L_{\min}$ is the magnitude of the 4-momentum P^{μ} (equation (3.32)), it is natural to interpret $L_{\min}$ as, in some sense, the rest length of the string. It was first identified by Tanmay Vachaspati and Alexander Vilenkin [VV85] in 1985, and called by them the *invariant length* of the loop.

As previously mentioned (section 2.5), the invariant length $\ell_{\mathrm{I}}(\mathfrak{p})$ of a string loop in an arbitrary background spacetime is defined to be twice the square root of the area of the subset $D(\mathfrak{p})$ whose interior is causally disconnected from the point $\mathfrak{p}$. This definition is motivated by the fact that $\ell_{\mathrm{I}}(\mathfrak{p})$ is a natural world-sheet scalar and reduces to the invariant length $L_{\min}$ at all points on the world sheet when the background is Minkowski. To see this, it is most convenient to calculate ℓ_{I} in the light-cone coordinates $\sigma_{\pm} = \tau \pm \sigma$ corresponding to an arbitrary aligned standard gauge (τ, σ). Then

$$\begin{aligned} \ell_{\mathrm{I}}(\sigma_+, \sigma_-) &= 2\left(\int_{\sigma_- - L}^{\sigma_-} \int_{\sigma_+}^{\sigma_+ + L} X_+ \cdot X_- \, \mathrm{d}\sigma_+ \, \mathrm{d}\sigma_- \right)^{1/2} \\ &= \left[\int_{\sigma_- - L}^{\sigma_-} \int_{\sigma_+}^{\sigma_+ + L} (1 - \mathbf{a}' \cdot \mathbf{b}') \, \mathrm{d}\sigma_+ \, d\sigma_- \right]^{1/2} \end{aligned} \tag{3.52}$$

where, in terms of the periodic mode functions $\widehat{\mathbf{a}}(\sigma_+)$ and $\widehat{\mathbf{b}}(\sigma_-)$,

$$1 - \mathbf{a}' \cdot \mathbf{b}' = 1 - \widehat{\mathbf{a}}' \cdot \widehat{\mathbf{b}}' - (\widehat{\mathbf{a}}' + \widehat{\mathbf{b}}') \cdot \mathbf{V} - \mathbf{V}^2. \tag{3.53}$$

Hence,

$$\ell_{\mathrm{I}}(\sigma_+, \sigma_-) = \left[\int_{\sigma_- - L}^{\sigma_-} \int_{\sigma_+}^{\sigma_+ + L} (1 - \mathbf{V}^2) \, \mathrm{d}\sigma_+ \, \mathrm{d}\sigma_- \right]^{1/2} = (1 - \mathbf{V}^2)^{1/2} L \tag{3.54}$$

as claimed.

As well as comprising a strict lower bound for the parametric period L, the invariant length $L_{\min}$ has the useful property that it forms an upper bound for the proper length of the string loop as measured in any Lorentz frame. The length ℓ of the loop on a cross-sectional surface of constant τ in the aligned standard gauge is

$$\ell(\tau) = \int_0^L (-X_\sigma^2)^{1/2} \, \mathrm{d}\sigma \le \left[L \int_0^L (-X_\sigma^2) \, \mathrm{d}\sigma \right]^{1/2} \tag{3.55}$$

where the second term on the right follows from Schwarz's inequality. Now,

$$-X_\sigma^2 = \tfrac{1}{4}(\widehat{\mathbf{a}}'^2 + \widehat{\mathbf{b}}'^2 - 2\widehat{\mathbf{a}}' \cdot \widehat{\mathbf{b}}') \leq \tfrac{1}{4}(\widehat{\mathbf{a}}'^2 + \widehat{\mathbf{b}}'^2 + 2|\widehat{\mathbf{a}}'||\widehat{\mathbf{b}}'|) \tag{3.56}$$

and so, again by virtue of Schwarz's inequality,

$$\int_0^L (-X_\sigma^2)\,\mathrm{d}\sigma \leq \tfrac{1}{4}\int_0^L \widehat{\mathbf{a}}'^2\,\mathrm{d}\sigma + \tfrac{1}{4}\int_0^L \widehat{\mathbf{b}}'^2\,\mathrm{d}\sigma + \tfrac{1}{2}\left(\int_0^L \widehat{\mathbf{a}}'^2\,\mathrm{d}\sigma\right)^{1/2}\left(\int_0^L \widehat{\mathbf{b}}'^2\,\mathrm{d}\sigma\right)^{1/2}. \tag{3.57}$$

Finally, in view of the gauge conditions (3.12) on the periodic mode functions $\widehat{\mathbf{a}}$ and $\widehat{\mathbf{b}}$,

$$\widehat{\mathbf{a}}'^2 = 1 - 2\widehat{\mathbf{a}}' \cdot \mathbf{V} - \mathbf{V}^2 \qquad \text{and} \qquad \widehat{\mathbf{b}}'^2 = 1 - 2\widehat{\mathbf{b}}' \cdot \mathbf{V} - \mathbf{V}^2 \tag{3.58}$$

and, therefore,

$$\ell(\tau) \leq (1 - \mathbf{V}^2)^{1/2} L = L_{\min}. \tag{3.59}$$

Note that this upper bound is achievable whenever $\widehat{\mathbf{a}}'$ and $\widehat{\mathbf{b}}'$ are anti-parallel and X_σ^2 is constant at all points on the surface of constant τ. This will occur if and only if the periodic mode functions have the form

$$\widehat{\mathbf{a}}(\tau + \sigma) = (1 - \mathbf{V}^2)^{1/2}\,\widehat{\mathbf{u}}(\sigma + \tau - \tau_0) \tag{3.60}$$

and

$$\widehat{\mathbf{b}}(\tau - \sigma) = (1 - \mathbf{V}^2)^{1/2}\,\widehat{\mathbf{u}}(\sigma + \tau_0 - \tau) \tag{3.61}$$

where τ_0 is a constant, and $\widehat{\mathbf{u}}$ is a periodic function with period L and satisfies the constraints

$$\widehat{\mathbf{u}}'^2 = 1 \qquad \text{and} \qquad \widehat{\mathbf{u}}' \cdot \mathbf{V} = 0. \tag{3.62}$$

In particular, the measured length will be equal to the invariant length $L_{\min}$ in the rest frame of the string loop whenever the loop is momentarily stationary.

3.4 Initial-value formulation for a string loop

A considerable amount of effort has been invested by a number of authors in generating simple yet interesting solutions which satisfy the periodicity condition (3.8), largely for the purpose of estimating the flux of gravitational radiation from realistic string loops (see section 6.5). A common method is to decompose the trajectory into Fourier components and then impose the constraints $\mathbf{a}'^2 = \mathbf{b}'^2 = 1$, a procedure which can be simplified considerably by using a spinorial representation (see section 3.5). However, a method which has more direct physical appeal is to reconstruct a trajectory from its initial data on a surface of constant Minkowski time t.

Suppose then that on an initial surface $t = 0$ a string loop has position vector $\mathbf{r}_0(\theta)$ and velocity $\mathbf{v}_0(\theta)$, where θ is a parametric variable with range 0 to θ^*, and $\mathbf{r}_0$ and $\mathbf{v}_0$ are periodic functions of θ so that

$$\mathbf{r}_0(0) = \mathbf{r}_0(\theta^*) \qquad \text{and} \qquad \mathbf{v}_0(0) = \mathbf{v}_0(\theta^*). \tag{3.63}$$

If the trajectory of the loop is described using the aligned standard gauge, θ must be a function of the spacelike gauge coordinate σ on the initial surface, and so at $\tau = 0$ the world-sheet tangent vectors have the form

$$X^\mu_\tau = [1, \mathbf{v}_0] \tag{3.64}$$

and

$$X^\mu_\sigma = \left[0, \mathbf{r}'_0 \frac{\mathrm{d}\theta}{\mathrm{d}\sigma}\right]. \tag{3.65}$$

The gauge constraint $X_\tau \cdot X_\sigma = 0$ then requires that $\mathbf{v}_0 \cdot \mathbf{r}'_0 = 0$, so the initial velocity of the loop must be chosen to be everywhere orthogonal to $\mathbf{r}'_0$. This restriction is simply a reflection of the fact that a string is locally invariant with respect to boosts parallel to the world sheet, and so any longitudinal component in the string's velocity is undetectable. In view of the second gauge constraint

$$0 = X^2_\tau + X^2_\sigma = 1 - \mathbf{r}'^2_0 \left(\frac{\mathrm{d}\theta}{\mathrm{d}\sigma}\right)^2 - \mathbf{v}^2_0 \tag{3.66}$$

the parameter θ and the gauge coordinate σ are related by the equation

$$\frac{\mathrm{d}\theta}{\mathrm{d}\sigma} = |\mathbf{r}'_0|^{-1}\sqrt{1 - \mathbf{v}^2_0}. \tag{3.67}$$

Since according to equation (3.6), the tangent vectors on the initial surface $\tau = 0$ are just

$$X^\mu_\tau(0, \sigma) = [1, \tfrac{1}{2}\mathbf{a}'(\sigma) + \tfrac{1}{2}\mathbf{b}'(-\sigma)] \tag{3.68}$$

and

$$X^\mu_\sigma(0, \sigma) = [0, \tfrac{1}{2}\mathbf{a}'(\sigma) - \tfrac{1}{2}\mathbf{b}'(-\sigma)] \tag{3.69}$$

it follows immediately that, if $\theta(0) = 0$,

$$\mathbf{a}(\tau + \sigma) = \mathbf{r}_0(\theta(\sigma + \tau)) + \int_0^{\theta(\sigma+\tau)} \mathbf{v}_0 \frac{\mathrm{d}\sigma}{\mathrm{d}\theta}\, \mathrm{d}\theta \tag{3.70}$$

and

$$\mathbf{b}(\tau - \sigma) = \mathbf{r}_0(\theta(\sigma - \tau)) - \int_0^{\theta(\sigma-\tau)} \mathbf{v}_0 \frac{\mathrm{d}\sigma}{\mathrm{d}\theta}\, \mathrm{d}\theta. \tag{3.71}$$

In particular, if the loop is initially motionless then the full trajectory is

$$X^\mu(\tau, \sigma) = [\tau, \tfrac{1}{2}\mathbf{r}_0(\theta(\sigma + \tau)) + \tfrac{1}{2}\mathbf{r}_0(\theta(\sigma - \tau))] \tag{3.72}$$

where the function $\theta(\sigma)$ is determined implicitly by the equation

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\theta} = |\mathbf{r}_0'|. \tag{3.73}$$

In the more general case of non-static initial data, the parametric period L of the loop is given by

$$L = \int_0^{\theta^*} (1 - \mathbf{v}_0^2)^{-1/2} |\mathbf{r}_0'| \, \mathrm{d}\theta \tag{3.74}$$

while the bulk velocity of the loop is

$$\mathbf{V} = L^{-1} \int_0^{\theta^*} (1 - \mathbf{v}_0^2)^{-1/2} |\mathbf{r}_0'| \mathbf{v}_0 \, \mathrm{d}\theta. \tag{3.75}$$

Examples of solutions generated using this method will be given in section 4.6.

3.5 Periodic solutions in the spinor representation

Even though the general solution (3.6) to the string equation of motion in a Minkowski background is extremely simple, the problem of constructing periodic solutions which satisfy the gauge condition $\mathbf{a}'^2 = \mathbf{b}'^2 = 1$ is not entirely trivial. As mentioned earlier, one possible method is to begin with periodic initial data, although the integrals (3.70) and (3.71) which then result are usually very complicated. An alternative is to expand the mode functions $\mathbf{a}'$ and $\mathbf{b}'$ as a finite series of harmonics in $\sigma_+ = \tau + \sigma$ and $\sigma_- = \tau - \sigma$, respectively.

For example, if $\mathbf{a}'$ contains only zero- and first-order harmonics then it has the general form

$$\mathbf{a}' = \mathbf{V} + \mathbf{C}\cos(2\pi\sigma_+/L) + \mathbf{S}\sin(2\pi\sigma_+/L) \tag{3.76}$$

where $\mathbf{C}$ and $\mathbf{S}$ are constant vectors. The gauge condition $\mathbf{a}'^2 = 1$ then implies that

$$\mathbf{C}\cdot\mathbf{V} = \mathbf{S}\cdot\mathbf{V} = \mathbf{C}\cdot\mathbf{S} = 0 \qquad \mathbf{C}^2 = \mathbf{S}^2 \qquad \text{and} \qquad \mathbf{V}^2 + \mathbf{C}^2 = 1 \tag{3.77}$$

so that the general solution for $\mathbf{a}'$ reads:

$$\mathbf{a}' = (\mathbf{n}_1 \times \mathbf{n}_2)\cos\phi + \mathbf{n}_1 \sin\phi\cos(2\pi\sigma_+/L) + \mathbf{n}_2 \sin\phi\sin(2\pi\sigma_+/L) \tag{3.78}$$

where $\mathbf{n}_1$ and $\mathbf{n}_2$ are any two orthogonal unit vectors and ϕ is an arbitrary constant. A similar first-order solution exists for $\mathbf{b}'$.

Finding periodic solutions in this way rapidly becomes unworkable as the number of harmonics increases. If $\mathbf{a}'$ contains all harmonics up to order N, so that

$$\mathbf{a}' = \mathbf{V} + \sum_{n=1}^{N} \mathbf{C}_n \cos(2\pi n\sigma_+/L) + \sum_{n=1}^{N} \mathbf{S}_n \sin(2\pi n\sigma_+/L) \tag{3.79}$$

21.04.2020

Cartesian coordinates. the best we can do is to introduce two arbitrary of coordinate lines and label them by $u^\alpha = (u^1, u^2)$. these curvilinear (or Gaussian) coordinates do not always a direct geometric interpretation.

String dynamics in flat space

the Minkowski spacetime is the only background metric of cosmological interest in which the string equation of motion (2.14) can be integrated exactly.

Inductance, Inductors, and Energy

An inductor is a circuit element that produces a voltage proportional to the time rate of change of the current passing through it,

$$V = -L\,dI/dt\,,$$

where L is the inductance, measured in *henrys*, 1 H = 1 V s/A.

The inductance of a solenoid with n turns per unit length, volume $\mathcal{V}$, and core permeability μ is approximately

$$L_{\text{solenoid}} \cong n^2 \mathcal{V} \mu\,.$$

The energy stored in an inductor is $E_{\text{EM}} = LI^2/2$. This is a special case of the general expression for energy stored in magnetic fields,

$$E_{\text{EM}} = \frac{1}{2\mu} \int dV\, |\boldsymbol{B}|^2\,.$$

second circuit, proportional to the rate of change of the current in the first,

$$\mathcal{E}_2 = -M_{21} \frac{dI_1}{dt}. \tag{3.72}$$

Similarly, a time-dependent current in circuit two leads to an EMF in circuit one: $\mathcal{E}_1 = -M_{12} dI_2/dt$. It is possible to show using conservation of energy (Problem 3.23) that this relationship is symmetric: $M_{12} = M_{21} \equiv M$, where M is known as the **mutual inductance** of circuits one and two. The sign of M depends on the relative orientation of the two circuits. In general $M^2 \le L_1 L_2$, and the ideal limit $M^2 = L_1 L_2$ is reached only when all the magnetic flux loops both circuits – as it would for two coincident ideal solenoids of the same area and length. A conceptual model of such a system is shown in Figure 3.24. The symbol for a mutual inductor is , two inductors with lines denoting an iron core that channels the magnetic flux between them.

Mutual inductance enables the construction of one of the most common and useful electrical devices: the **transformer**. Consider the AC circuit shown in Figure 3.25. The left-hand circuit (the **primary**) is coupled by mutual inductance to the right-hand circuit (the **secondary**). In the ideal limit where $M^2 = L_P L_S$, all magnetic flux lines go through both inductors, so $\mathcal{E}_P = -N_P d\Phi/dt$, $\mathcal{E}_S = -N_S d\Phi/dt$, and,

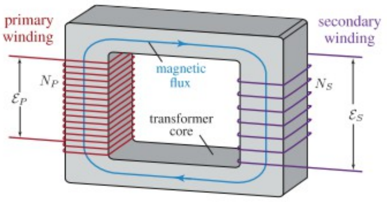

Figure 3.24 A simple transformer. Two coils are wound around a core with high magnetic permeability (typically iron), which acts as a *magnetic circuit*, channelling the magnetic flux through both coils. In the ideal limit where all magnetic flux goes through both coils, the ratio of secondary to primary voltages $\mathcal{E}_S/\mathcal{E}_P$ is given by the ratio of the number of turns, in this case roughly 1:2.

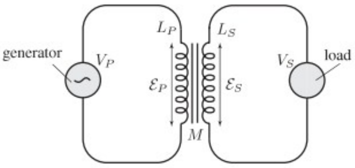

Figure 3.25 Two circuits, the *primary* (left) and the *secondary* (right), are coupled by mutual inductance. The resulting device, a *transformer*, transforms the AC voltage on the left V_P to $\sqrt{L_S/L_P}\,V_P$ on the right.

$$\frac{\mathcal{E}_S}{\mathcal{E}_P} = \frac{V_S}{V_P} = \sqrt{\frac{L_S}{L_P}} = \frac{N_S}{N_P} \tag{3.73}$$

(see Problem 3.25). Power is transmitted from the generator on the left to the load on the right.

Transformers play an essential role in the manipulation of AC power in electric power distribution networks. In the absence of imperfections such as resistance in the coils and incomplete containment of the magnetic flux, the efficiency of a transformer would be 100%. Those used in electric power distribution reach 98% or higher. We describe the role of transformers in electrical grids further in §38.

3.6 Maxwell's Equations

Up to this point, we have introduced four equations that describe the way that electric and magnetic fields interact with matter and with one another. Gauss's law (3.12) and Ampere's law (3.49) prescribe the way that electric and magnetic fields are produced by charges and currents. Two other equations – eq. (3.47), associated with the absence of magnetic charge, and Faraday's law (3.66) – constrain $\boldsymbol{E}$ and $\boldsymbol{B}$. Although we stated these laws under special conditions – for example, Gauss's law was derived only for static charges – all but one of these equations continue to hold under all known conditions.

The one equation that needs further modification is Ampere's law, which we have described only in the conditions of steady currents and constant charge distribution. As discussed earlier, Ampere's law as stated in eq. (3.49) is not consistent with charge conservation. To see this, take the divergence of eq. (3.49). Since $\nabla \cdot (\nabla \times \boldsymbol{B}) = 0$ (B.21), eq. (3.49) implies $\nabla \cdot \boldsymbol{j} = 0$, which only holds if $\partial \rho / \partial t = 0$ (see eq. (3.33)). When current and charge densities change with time, this is not true. Around 1860, the English physicist James Clerk Maxwell recognized this problem, and solved it by subtracting a term proportional to $\partial \boldsymbol{E} / \partial t$ from the left-hand side of Ampere's law. Maxwell's alteration of Ampere's law reads,

$$\nabla \times \boldsymbol{B} - \mu_0 \epsilon_0 \frac{\partial \boldsymbol{E}}{\partial t} = \mu_0 \boldsymbol{j}. \tag{3.74}$$

The demonstration that this equation is consistent with current conservation is left to Problem 3.26. Note that this modification of Ampere's law, which states that a time-varying electric field gives rise to a magnetic field, is closely parallel to Faraday's law of induction stating that a time-varying magnetic field gives rise to an electric field. Indeed, in the absence of electric charges and currents, the laws of electromagnetism are invariant under a symmetry exchanging $\boldsymbol{B}$ and $\sqrt{\mu_0 \epsilon_0}\boldsymbol{E}$.

Maxwell's modification of Ampere's law completed the unification of electricity and magnetism that began with Faraday's discovery of induction. Together with the Lorentz force law (3.45), which describes the way that electric and magnetic fields act on charges and currents, **Maxwell's equations** give a complete description of electromagnetic phenomena. These equations paved the way for Einstein's special theory of relativity, which further illuminated the unified structure of electromagnetism. Maxwell's achievement initiated great advances in understanding and application of electromagnetic theory, including the realization that light is an electromagnetic wave and that other forms of electromagnetic radiation could be produced from oscillating charges and currents.

Maxwell's Equations

Gauss's law	$\nabla \cdot \boldsymbol{E} = \frac{\rho}{\epsilon_0}$
No magnetic charge	$\nabla \cdot \boldsymbol{B} = 0$
Faraday's law	$\nabla \times \boldsymbol{E} + \frac{\partial \boldsymbol{B}}{\partial t} = 0$
Ampere–Maxwell law	$\nabla \times \boldsymbol{B} - \mu_0 \epsilon_0 \frac{\partial \boldsymbol{E}}{\partial t} = \mu_0 \boldsymbol{j}$

Discussion/Investigation Questions

3.1 Think of some devices that generally are not run on electrical power. Discuss the reasons why other power sources are favored for these devices.

3.2 Can you identify the largest component of your personal electric power consumption?

3.3 Most countries provide AC electricity at $V_{\text{RMS}} \approx 220$–240 V to residential customers. In the US and parts of South America $V_{\text{RMS}} \approx 110$–120 V is provided. How do resistive losses in household wires compare between the two? Given the result, why do you think even higher voltages are not used?

3.4 Discuss the statement that Lenz's law follows from conservation of energy. Consider, for example, the scenario of Figure 3.22(b) if the sign of eq. (3.64) were reversed.

3.5 Currents produce magnetic fields, and magnetic fields exert forces on currents. When a current flows through a wire, does the magnetic field it produces act to make the wire expand or contract? What about the force on the wires in a solenoid? Does it act to make the solenoid expand or contract? These are significant effects for wires carrying very large currents.

Problems

3.1 The electric field outside a charged conducting sphere is the same as if the charge were centered at its origin. Use this fact to calculate the capacitance of a sphere of radius R, taking the second conductor to be located at infinity. What is the most charge you can store on an otherwise isolated spherical conductor of radius R without a breakdown of the surrounding air as discussed in Example 3.2? What is the maximum energy you can store on a conducting sphere of radius 1 mm?

3.2 [**T**] Prove Gauss's law from Coulomb's law for static charge distributions by showing that the electric field of a single charge satisfies the integral form of Gauss's law and then invoking linearity.

3.3 How much energy can you store on a parallel plate capacitor with $d = 1\,\mu\text{m}$, $A = 10\,\text{cm}^2$, and $\epsilon = 100\epsilon_0$, assuming that the breakdown field of the dielectric is the same as for air?

3.4 [**T**] Starting from Gauss's law and ignoring edge effects (i.e. assume that the plates are very large and the electric field is uniform and perpendicular to the plates), derive the formula for the capacitance of a parallel plate capacitor, $C = \epsilon_0 A/d$. Refer to Figure 3.8. You can assume that the electric field vanishes outside the plates defining the capacitor. Show that the energy stored in the capacitor, $\frac{1}{2}CV^2$, can be written as the integral of $\epsilon_0|\boldsymbol{E}|^2/2$ over the region within the capacitor (as asserted in eq. (3.20)).

3.5 Suppose that a capacitor with capacitance C is charged to some voltage V and then allowed to discharge through a resistance R. Write an equation governing the rate at which energy in the capacitor decreases with time due to resistive heating. Show that the solution of this equation is $E(t) = E(0)e^{-2t/RC}$. You can ignore the internal resistance of the capacitor. Show that the heat produced in the resistor equals the energy originally stored in the capacitor.

3.6 The dielectrics in capacitors allow some *leakage current* to pass from one plate to the other. The leakage can be parameterized in terms of a *leakage resistance* R_L. This limits the amount of time a capacitor can be used to store electromagnetic energy. The circuit diagram describing an isolated capacitor, slowly leaking charge, is therefore similar to the one analyzed in Problem 3.5. The Maxwell BCAP0310 ultracapacitor (see §37.4.2) is listed as having a capacitance of 310 F with a voltage up to 2.85 V, and a maximum leakage current of 0.45 mA when fully charged. Take this to be the current at $t = 0$. What is the leakage resistance of the BCAP0310? Estimate the time scale over which the charge on the capacitor falls to $1/e$ of its initial value.

3.7 A cloud-to-ground lightning bolt can be modeled as a parallel plate capacitor discharge, with Earth's surface and the bottom of the cloud forming the two plates (see Example 3.2). A particular bolt of lightning passes to the ground from a cloud bottom at a height of 300 m. The bolt transfers a total charge of 5 C and a total energy of 500 MJ to the ground, with an average current of 50 kA. How long did the lightning bolt last? What was the electric field strength in the *cloud–earth capacitor* just before it discharged? How does this electric field compare with the breakdown field of air (3 MV/m)? (It is now known that various effects cause lightning to begin at fields that are considerably smaller than the breakdown field.)

3.8 [**T**] Consider an electric dipole composed of two charges $\pm Q$ at positions $\pm\boldsymbol{\xi}/2$. Write the exact electric field from the two charges and show that the leading term in an expansion in $1/r$ matches the $\boldsymbol{E}$-field quoted in Box 3.2. [Hint: consider the binomial expansion, eq. (B.66).]

3.9 If each of the batteries used in the flashlight in Example 3.3 has an internal resistance of 0.5 Ω (in series with the circuit), what fraction of power is lost to Joule heating within the batteries?

3.10 [**T**] Consider two resistors placed in **series**, one after the other, in an electric circuit connected to a battery with voltage V. Show that the effective resistance of the pair is $R_1 + R_2$ by using the fact that the current through both resistors is the same while voltages add. Now connect the resistors in **parallel**, so that the voltage across both resistors is V. Compute the total current and show that the effective resistance satisfies $1/R = 1/R_1 + 1/R_2$.

3.11 An appliance that uses 1000 W of power is connected by 12 gauge (diameter 2.053 mm) copper wire to a 120 V (RMS) AC outlet. Estimate the power lost per meter, dP_{lost}/dL, (in W/m) as resistive heating in the wire. (Remember that the wire to the appliance has two separate current-carrying wires in a single sheath.)

3.12 Electrical power is often used to boil water for cooking. Here are the results of an experiment: a liter of water initially at 30 °C was boiled on an electric stove top burner. The burner is rated at 6.67 A (maximum instantaneous current) and 240 V_{RMS}. It took 7 minutes 40 seconds to reach the boiling point. The experiment was repeated using an "electric kettle." The kettle is rated at 15 A (maximum instantaneous current again) and uses ordinary (US) line voltage of 120 V_{RMS}. This time it took 4 minutes and 40 seconds to reach boiling. What are the power outputs and resistances of the burner and the kettle? Compare the efficiency for boiling water of the stove top burner and the kettle. To what do you attribute the difference?

3.13 [**T**] Use the magnetic force law (3.42) and the definition of work $W = -\int_a^b d\boldsymbol{x}\cdot\boldsymbol{F}$ to show that magnetic forces do no work. [Hint: Consider the vector identity (B.6).]

3.14 [**T**] Show that a charged particle moving in the xy-plane in the presence of a magnetic field $\boldsymbol{B} = B\hat{\boldsymbol{z}}$ will move in a circle. Compute the radius of the circle and frequency of rotation in terms of the speed v of the particle. Show that adding a constant velocity $u\hat{\boldsymbol{z}}$ in the z-direction still gives a solution with no further acceleration.

3.15 [**T**] Review how magnetic fields are calculated from Ampere's law by computing (a) the magnetic field due to a straight wire and (b) the magnetic field in the interior of a very long solenoid. The contours $\mathcal{C}_1$, $\mathcal{C}_2$ shown in red in Figure 3.18 will help. You may use the fact that the magnetic field vanishes just outside the outer boundary of the solenoid in (b).

3.16 [**T**] Show that the force per unit area on the windings of an air-core solenoid from the magnetic field of the solenoid itself is of order $F/A \sim \boldsymbol{B}^2/\mu_0$. Check that the dimensions of this expression are correct and estimate F/A in pascals if $|\boldsymbol{B}| = 1\,\text{T}$.

3.17 [**T**] Derive eq. (3.52) from eq. (3.43) and eq. (3.50). Make sure you get the both the direction and magnitude.

3.18 An electric motor operates at 1000 rpm with an average torque of $\tau = 0.1\,\text{Nm}$. What is its power output? If it is running on 1.2 A of current, estimate the back-EMF from the rotor.

3.19 Consider the motor described in Box 3.4. If the resistance in the wire wrapping the rotor is $1\,\Omega$, compute the energy lost under the conditions described. What fraction of energy is lost to Joule heating in this situation? If the current is doubled but the rotation rate is kept fixed, how do the output power, Joule heating losses, and fraction of lost energy change?

3.20 [**T**] In §3.4.2 we derived the EMF on a wire loop rotating in a magnetic field using the Lorentz force law to compute the forces on the mobile charges. Although Faraday's law of induction (3.64) does not apply in a rotating reference frame, show that the same relation (3.62) follows from Faraday's law.

3.21 [**T**] Explain why the integral $\int_S d\boldsymbol{S} \cdot \boldsymbol{B}$ that appears in eq. (3.65) is independent of the choice of surface S. [Hint: make use of eq. (3.46).]

3.22 [**T**] Consider a long, hollow solenoid of volume $\mathcal{V}$. Show that, ignoring end effects, its inductance is $L = n^2\mathcal{V}\mu_0$, and that the magnetic energy it stores $E_{\text{EM}} = LI^2/2$ can be written in the form of eq. (3.71).

3.23 [**T**] Prove that the mutual inductance is a symmetric relation, $M_{12} = M_{21}$, by computing the energy stored when current I_1 is established in loop 1 and then current I_2 is established in loop 2. Then set up the same currents in the opposite order.

3.24 Design a transmission system to carry power from wind farms in North Dakota to the state of Illinois (about 1200 km). The system should handle Illinois's summertime electricity demand of 42 GW. Land for transmission towers is at a premium, so the system uses very high voltage ($V_{\text{RMS}} = 765\,\text{kV}$). Assume that the electricity is transmitted as ordinary alternating current, although in practice *three-phase power* (see §38.3.1) would be used. Assume that each tower can carry 36 aluminum cables (nine lines, each consisting of four conductors separated by non-conducting spacers). The conductors are $750\,\text{mm}^2$ in cross section. How many separate strings of transmission towers are needed if the transmission losses are to be kept below 5%? Assume a purely resistive load.

3.25 [**T**] Consider the transformer in Figure 3.25. Suppose the load is a resistor R and that the transformer is ideal, with $M^2 = L_S L_P$ and all magnetic flux lines passing through both inductors. Show that the voltage drop across the resistor is $V_S = \sqrt{L_S/L_P}\,V_P = N_S V_P/N_P$ and that the time-averaged power consumed in the resistor is $P = (L_S/L_P)(V_P^2/2R) = N_S^2 V_P^2/2N_P^2 R$.

3.26 [**T**] Take the divergence of both sides of eq. (3.74), use Coulomb's law on the left and current conservation on right to show that the equation is consistent.

CHAPTER

14

The Forces of Nature

Elementary particles and the forces that act between them are the fundamental ingredients in our most complete theoretical description of microscopic physics. Forces transform energy from one form to another when they act on matter. The study of energy thus inevitably leads to the question: What are the fundamental forces of nature, and what are the elementary particles on which these forces act? Gravity and electromagnetism are the most familiar two of the four forces that store and transform energy in our world. The other two, manifested by the *strong interactions* that hold nuclei together and the more subtle *weak interactions*, are usually the subject of more advanced physics courses.

All four forces contribute to the production and concentration of the forms of energy that we use on Earth. Gravity pulls together hydrogen atoms deep in the Sun. Strong nuclear interactions between these hydrogen atoms, facilitated by crucial weak interactions, result in the release of energy that is radiated from the Sun as electromagnetic waves, some of which hit Earth. Nuclear fission power plants rely on the interplay of strong nuclear forces, electromagnetism, and the weak interactions. Nuclear fuel is found in regions of high concentration in Earth's crust that result from a combination of gravitational pressure and chemical electromagnetic interactions. Geothermal energy, as well, arises from the combined action of the four forces. Indeed, with the exception of tidal energy, which is essentially the result of gravity and electromagnetic forces, all energy sources used by humanity rely on a happy conjunction among all four forces of nature.

The most familiar energy processes that we encounter on a day-to-day basis can be described in terms of electromagnetic and gravitational forces and interactions. The same is true of all the energy systems treated in this book so far. Much of the energy we use, however, originates in the *strong interactions*, which are not encountered in everyday experience (unless, like Homer Simpson, you work at a nuclear reactor). The drama of the strong interactions involves some relatively familiar players such as the nuclei of atoms, but it also includes a menagerie of exotic particles such as *quarks* and *gluons* that, while they are just as real as electrons and atoms, are never seen outside of the atomic nucleus. In order to explain the origins of solar, nuclear, and geothermal energy, we must first describe some of the basic properties of the strong force. Along the way, we have the opportunity to put gravity and the electromagnetic force into a somewhat broader context.

Reader's Guide

This chapter forms an "interlude" in which we survey the fundamental particles and forces that determine the structure of matter and its interactions with energy. Because they are less well known than gravity and electromagnetism, special attention is paid to the strong force that holds the nucleus together and to the weak force responsible for many nuclear decays. After discussing the four forces, we describe the properties of all the known elementary particles. We then present a simplified version of particle physics that is adequate for most of our purposes, in which only five particles, the proton, neutron, electron, photon, and antineutrino appear. The chapter closes with an introduction to β-decay and related processes that are important for understanding nuclear energy and related radiation.

Prerequisites: §2 (Mechanics), §3 (Electromagnetism), and §7 (Quantum mechanics), although much of this chapter is accessible with little technical background.

The strong and weak forces are important ingredients in the description of nuclei and nuclear energy in §17–§19, and ionizing radiation in §20. β-decay is key to understanding many nuclear decays. Gravity figures centrally in the large-scale structure of the universe (§21).

The fourth force, which is also only relevant in the microworld, is known as the *weak interaction*. Weak

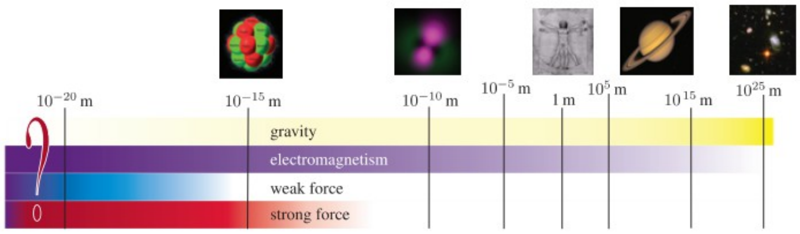

Figure 14.1 An illustration of the relative importance of the four forces over distances ranging from subnuclear (10^{-20} m) to cosmological (10^{25} m).

interactions play only a minor part in the actual generation of energy, but they act as a *facilitator* for many of the most important nuclear energy processes. Weak interactions play a role in fundamental physics a bit like fungi do in the environment. They are often overlooked; they do not contribute to building up great structures (such as nuclei and atoms); and, above all, they are the mediators of decay! Nevertheless we need to understand some of the features of the weak force because so many processes that figure significantly in energy physics would not occur without it.

Fortunately, the list of forces that affect our world stops at four: strong, electromagnetic, weak, and gravitational. There may be other forces locked away at very short distances, or that involve as-yet-undiscovered particles. Even if additional forces exist, however, we already know that they do not influence the dynamics of our familiar world in any significant way at the human scale (see Figure 14.1). We can be sure of this because we can account for essentially *all* the phenomena so far observed in nature in terms of the four known forces.[1] This may sound like an exaggeration: after all there are many common phenomena not yet fully understood by science, from the turbulent flow of liquids to the origins of life. These are generally, however, phenomena characterized by complexity, and there is no evidence that they arise from additional, as yet unknown, fundamental interactions.

The Standard Model of Particle Physics

The *Standard Model of particle physics* is a *quantum field theory* that, in concert with the classical theory of gravity, describes almost all observed phenomena to a high degree of accuracy in terms of four forces and 17 elementary particles.

If one focuses in on short distances and small systems, processes simplify, and everything that we can observe seems to be explained by a relatively simple set of fundamental equations. Our understanding is summarized in a meticulously tested and so far perfectly successful set of laws of physics, known as the **Standard Model of particle physics**. The word "*model*" connotes less certainty than "*theory*" or "*law*" – the terms typically used to designate well-established principles of physics. The Standard Model, however, which is formulated in terms of a theoretical framework known as *relativistic quantum field theory*, has described observed physical phenomena to a higher degree of precision than any other physical theory ever developed. Quantum field theory and the Standard Model are on a similar footing to Newton's and Coulomb's laws; they provide a set of simple and basic equations from which the behavior of matter can be deduced by mathematical analysis. The specific structure of the Standard Model dictates that matter is made of essentially pointlike particles with spin $1/2$ (quantum spin was discussed in §7). These particles interact with each other by emitting and absorbing photons and other massless and massive quanta that are cousins to the photon. The elementary spin-1/2 particles form families whose membership is limited by symmetry constraints and whose members have common properties. The details are beyond the scope of this book, but some aspects of the Standard Model are summarized in Tables 14.1 and 14.2 and in Figure 14.4.

Despite its successes, the Standard Model is neither a perfect nor a complete theory of nature. One glaring inadequacy is that it has about 20 parameters – numbers like the mass of the electron and the strength of the electric charge – whose origins we do not know. It also has a peculiar redundancy: each type of particle – the electron for example – comes in three versions that differ in mass, but little else. This redundancy, as well as the *raison d'etre* for the particular assortment of particles and fields that appear in nature, and other relationships in the Standard Model, are beyond our present understanding. There are some detailed aspects of the Standard Model, related to *neutrinos* and the *Higgs particle*, which are not fully settled experimentally. And, as mentioned above, it is possible that new forces or other novel phenomena are relevant at very high energies and short distance scales that have not yet been probed experimentally. Finally, and arguably at a more fundamental level, in our current understanding gravity is appended to the Standard Model only as a classical (rather than quantum) field, even though gravity also must exhibit quantum features at very short distance and length scales. Unifying gravity and quantum mechanics has challenged physicists for decades. An approach often called *string theory* provides a framework in which gravity and other forces can be described within a quantum-mechanical theory. Whether and how the Standard Model and the global structure of the universe in which we live is described within the framework of string theory is, however, still an open problem (§21).

---

[1] A few fundamental observed phenomena lie beyond the limits of our understanding. For example, *dark energy* and *dark matter*, which are discussed further in §21 (Energy in the universe), dominate the total energy budget of the universe. Important though they are at the cosmic scale, they play no role at all in the energy transformations of everyday life.

All the limitations of the Standard Model that we have just listed are irrelevant, in any case, for the purposes of this book. All known energy sources can be understood with only a subset of the structure in the Standard Model, and it is hard to imagine any way in which physics beyond the Standard Model could have practical consequences for human energy use in the forseeable future. Thus, for all intents and purposes, the fundamental physics underlying any conceivable energy system that may be relevant in this century should be described within the Standard Model.

The aim of this chapter is to take a brief tour of the Standard Model, emphasizing those bits that are most important for the physics of energy and skirting as much as possible the complexities that usually relegate the subject to graduate-level physics courses. Although the concepts discussed here are relatively remote from everyday experience, they are nevertheless relevant to practical energy systems. In fact, the basic ideas presented here are essential for understanding the origins of nuclear and solar energy and the nature of radioactivity. In §14.1 we describe the four fundamental forces in more depth. Starting at the largest distance scales, where gravity is most important, we work our way down to sub-atomic distances, encountering electromagnetic, strong, and weak interactions in succession. Next (§14.2) we meet the players in the drama of subatomic physics, the elementary particles. Before exploring the whole zoo of particles, we introduce a stripped-down version of the Standard Model that includes almost everything needed to understand energy production and flow in the observable universe at the present time. This *Standard Model "lite"* comprises the proton, neutron, electron, photon, and one potentially less familiar addition, the *(anti-)neutrino*. We briefly survey the other particles in the Standard Model and then conclude the chapter (§14.3) with a close look at β-decay, a weak interaction of particular importance in energy physics.

Non-technical introductions to particle physics can be found in many books, for example [66]. Reference [67] provides a more technical introduction, at an advanced undergraduate level.

14.1 Forces, Energies, and Distance Scales

To survey the hierarchy of strengths, distances, and energy scales that characterize the four forces, we start at astronomical distances and work our way into the interior of the atomic nucleus.

Gravitational and electromagnetic potential energies fall off like $1/r$ away from their sources. This is a special case of a more general form

$$V(r) \sim g^2 \frac{e^{-r/b}}{r}\,, \tag{14.1}$$

where b is known as the **range** of the force and g is a measure of its *strength*. Equation (14.1) defines what is known as a **Yukawa interaction**, named after the Japanese physicist Hideki Yukawa who proposed it as a model for the strong nuclear force in the 1930s. The $1/r$ potential of gravity and electromagnetism emerges when the parameter b goes to ∞. Hence, these are called *infinite range* forces. In the framework of *quantum field theory*, interactions between massive particles are the result of the exchange of particles called **force carriers** (Figure 14.2). For example, the *photon* is the force carrier for electromagnetism. In general, the exchange of a force carrier of mass m gives rise to a force of the form (14.1), where the parameter b is proportional to $1/m$. Thus, the long-range nature of the electromagnetic force arises from the fact that the photon is massless. We now go through each of the forces in turn and discuss various aspects of each.

14.1.1 Gravitational Interactions

Only gravitational forces are important at astronomical distances. Gravity alone persists at the scale of stars and galaxies not because gravity is strong – in fact gravity

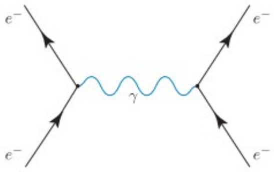

Figure 14.2 In *quantum field theory*, interactions between massive particles are mediated by the exchange of massless or massive *force carriers*. The figure depicts a *Feynman diagram* describing two electrons interacting through exchange of a *photon*, the force carrier for electromagnetic interactions.

is by far the weakest of the four forces (see Table 14.1). The reason that gravity dominates over electromagnetism on astronomical scales is that *gravity is universally attractive* and its strength is proportional to the mass (or, more generally, the total energy) of an object. In contrast, electromagnetic forces depend on the signs of the electric charges; electromagnetic attraction and repulsion between charged particles are so strong that unless we work very hard to prevent it, matter always relaxes to a state in which it is electrically neutral. So matter at macroscopic scales is essentially electromagnetically uncharged, and the force of gravity can dominate at very large scales. Thus, Newton's law of universal gravitation governs the motions of planets and stars. For very dense and very massive objects, Newton's theory of gravity must be corrected or even replaced by Einstein's General Theory of Relativity, which is described in §21.[2]

As soon as one leaves the astronomical domain, gravity subsides in importance and electromagnetic forces become equally or more important. Of course, gravity holds us here on Earth's surface – again because a very large mass is involved, namely the mass of Earth. To support the claim that gravity is unimportant on human distance scales, consider the strength of the gravitational force between, for example, two one-gram masses, separated by one meter. According to Newton, the gravitational force between them is

$$|\boldsymbol{F}_{\text{gravity}}| = G_N\,\frac{m_1 m_2}{r^2} = 6.67\times 10^{-11}\,\frac{\text{m}^3}{\text{kg}\,\text{s}^2} \times \frac{(10^{-3}\,\text{kg})^2}{1\,\text{m}^2} = 6.67\times 10^{-17}\,\text{N}\,, \quad (14.2)$$

which is far too weak to observe.

14.1.2 Electromagnetic Interactions

To gauge the strength of electromagnetic forces compared to gravity, we compute the electrostatic (Coulomb's law) force between the same two one-gram lumps of matter described above if the electric charges were not neutralized. That is, we compute the electrostatic force between the positively charged protons in the two lumps. Since about half of the mass of one gram of material comes from protons (the other half comes from neutrons; the electrons are only about 1/2000th of the mass), one gram contains about $N_A/2 \approx 3\times 10^{23}$ protons, each with charge 1.6×10^{-19} C, for a total charge of $\approx 4.8\times 10^4$ C. This generates a force of

$$|\boldsymbol{F}_{\text{EM}}| = \frac{1}{4\pi\epsilon_0}\,\frac{Q_1 Q_2}{r^2} \approx 9.0\times 10^9\,\frac{\text{Nm}^2}{\text{C}^2} \times \frac{(4.8\times 10^4\,\text{C})^2}{1\,\text{m}^2} \approx 2.1\times 10^{19}\,\text{N}. \quad (14.3)$$

Between comparable quantities of stuff, therefore, the electromagnetic force exceeds the gravitational force by $\sim$36 orders of magnitude. Of course, the repulsive Coulomb forces among the protons are so strong that there is no way we could isolate and study a gram of material with charge 4.8×10^4 C. Electromagnetic forces subside to manageable scales because – to very high accuracy – matter is neutral.

Many of the large-scale processes on Earth's surface result from the dynamic balance between electromagnetic and gravitational forces. For example, the electromagnetic repulsion between electrons in different atoms keeps matter from collapsing under huge gravitational pressures in Earth's core, and – at a more human scale – keeps you from falling through your chair. Gravitational and electromagnetic forces maintain the dynamic balance that governs the circulation of the atmosphere and oceans; the Sun's energy is absorbed and transmitted through electromagnetic forces while the overall vertical order is maintained by the pressure sustained by gravity.

There is no specific natural energy scale for the effects of *classical* gravity or electromagnetism. The larger the mass or charge, or the closer the objects, the greater the energy that can be stored in gravitational or electromagnetic potential energy. When quantum mechanics gets into the game, however, energies and charges are quantized,

---

[2] That is not to say, however, that electromagnetism can be ignored in astronomy! For example, we see distant objects only because of the light they give off. Electromagnetism is important for dynamical reasons as well. A cloud of gas cannot collapse to form a star unless it can find a way to give off some potential and kinetic energy, and radiating away energy through electromagnetic waves is the principal way that this happens.

Gravity and Electromagnetism

Gravitational and electromagnetic forces have infinite range and determine the behavior of matter over a huge range of distance scales. With minor exceptions such as natural radioactivity and geothermal energy produced by radioactive decay, natural processes on Earth's surface involve electromagnetic and gravitational interactions alone.

Maxwell's equations and quantum mechanics, along with classical gravity, are sufficient to describe basic dynamical processes from Earth-like distances down to a small fraction of the diameter of an atom.

and the quantum of energy associated with a particular force acting between elementary particles sets the fundamental scale for energies that can be absorbed, liberated, or stored by those forces acting on the quantum level. In §7 we saw that the energy of the electron in a hydrogen atom,

$$E_{\text{Bohr}} = -\frac{1}{2}\left(\frac{1}{4\pi\epsilon_0}\right)^2 \frac{me^4}{\hbar^2} = -13.6\,\text{eV}, \qquad (14.4)$$

sets a scale for the energies of atomic physics. (Remember that the minus sign in eq. (14.4) indicates that the electron in hydrogen is bound – it takes 13.6 eV of energy to remove it far away from the proton.) When a bond is formed or broken, energies of this order of magnitude are absorbed or emitted. The scale of energy available from chemical processes never strays far from the fundamental scale given in eq. (14.4), set by the mass and charge of the electron. When we manipulate materials, whether they are hydrocarbons or more exotic materials, the amount of energy we can get from them per unit mass from chemical processes is roughly the same as that available from burning coal (see Problem 14.1). To find energy sources that have much higher *energy density*, that is, more joules per kilogram, we must consider a stronger force.

14.1.3 Strong Interactions

From the human scale of meters down to the smallest distances that we can see with an optical microscopic, physics is governed by electromagnetism and gravity. Journeying inward to still shorter distances, at somewhat less than 10^{-14} m, things change rather suddenly and dramatically. The nuclei at the centers of atoms are composed of protons and neutrons (collectively referred to as **nucleons**), held together by forces known as **strong nuclear interactions**, which are a hundred times stronger than electromagnetism, and of a different nature.

The strong interactions between nucleons are complex, residual manifestations of simpler and more fundamental forces between elementary particles called **quarks**, of which the nucleons themselves are composed. The interactions among quarks, which are specified by the Standard Model, are known as **chromodynamic** forces in analogy to the *electrodynamic forces*, which they resemble in important ways.[3] Chromodynamic forces between quarks are mediated by **gluons**, massless particles that play a similar role to that of photons in electromagnetism. The forces between nucleons are to quark forces as molecular forces are to the underlying electromagnetic force between a proton and an electron. Just as the primary electric forces cancel out in neutral atoms or molecules, so the primary forces between quarks *cancel out* when the quarks group themselves together into *chromodynamically neutral* protons and neutrons. Like the residual forces between atoms and molecules (see, e.g., §9.3.1), the forces between nucleons left over after this cancellation are complicated and cannot be described accurately by a single simple mathematical formula. The name *strong interactions* was applied to these forces long before quarks and the Standard Model were discovered. Here we reserve the term "strong nuclear interactions" for these residual forces between nucleons and nuclei and distinguish them from the (in some ways even stronger, but conceptually simpler) chromodynamic forces between quarks. The strong nuclear interactions hold nuclei together and are responsible for the dynamics of fission, fusion, and radioactivity, so we explore them further here.

One way in which chromodynamics differs from electrodynamics is that the fundamental forces between quarks are so strong that quarks can never be separated from one another. Only bound states of quarks in which the primary chromodynamic forces are neutralized can exist in nature. These chromodynamically neutral **hadrons**, as they are known, include the proton and neutron and a host of other short-lived particles that can be produced in laboratory experiments. Because the chromodynamic force is so strong, it is very difficult to compute the form of the strong interaction between nucleons analytically from the theoretically simpler interactions between quarks. The best we can do at the present time is to study the nuclear force numerically or with the aid of empirical models.

---

[3] The origin of the "*chromo*" in *chromo*dynamics is explained in §14.2.3.

Chromodynamics and the Strong Nuclear Force

The *chromodynamic force* is a powerful force that binds *quarks* together into nucleons such as protons and neutrons. Residual, short-range *strong nuclear interactions* between nucleons bind nuclei together, just as residual electromagnetic interactions lead to forces between electrically neutral atoms that bind molecules together.

The strong nuclear force between nucleons depends upon their separation, their relative velocities, their relative angular momentum, and even on the orientations of their spins (protons and neutrons have spin 1/2 like the electron). This complicated force between two nucleons is often described by empirical formulae with many *fit parameters* (see, for example, [68] and references therein).

At the largest distances where it is detectable, the strong interaction potential between two nucleons at rest takes the simple form of a Yukawa interaction (14.1) with a range $b \cong 1.4 \times 10^{-15}$ m and a strength about 10 times that of electromagnetism,

$$V_{\text{strong}}(r) = -\frac{1}{4\pi\epsilon_0}\frac{g^2_{\text{strong}}}{r}e^{-r/b}\,, \tag{14.5}$$

with $g^2_{\text{strong}} \approx 10e^2$, where $e = 1.602 \times 10^{-19}$ C is the proton's electric charge.[4] The unit of distance 1 femtometer $= 10^{-15}$ m, abbreviated 1 fm, is a characteristic unit for strong interaction phenomena. It is also known as *1 Fermi* in honor of the Italian theoretical physicist Enrico Fermi. The strong interaction force between two (chromodynamically neutral) nucleons at large distances is mediated by the exchange of *pi-mesons* or **pions**, which are themselves chromodynamically neutral massive bound states of quarks and antiquarks. This is different from the long-range residual electromagnetic forces between electrically neutral atoms, which arise from exchange of multiple massless photons and have a polynomial form rather than the characteristic exponential suppression of the Yukawa potential.

Note the minus sign in eq. (14.5): the force is attractive. The form given in eq. (14.5) holds (approximately) at separations greater than about 1.5 fm. Below that, the forces between nucleons become stronger, but they do not have the simple exponential form of eq. (14.5).

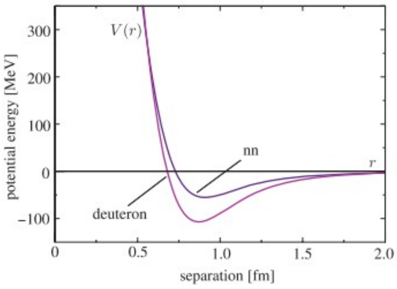

Figure 14.3 The nucleon–nucleon strong interaction potential in two configurations [68]. Roughly speaking, the curve marked *deuteron* is the potential that holds together a proton and a neutron into a bound state called a **deuteron**, while the one marked *nn* is the potential between two neutrons, which is not strong enough to bind a state. Note that while the two potential functions are quite different at ∼ 1 fm, they have the same asymptotic form (14.5) as $r \to \infty$.

Although the strength, and even the sign, of the nucleon–nucleon potential varies depending upon the nucleons' relative angular momentum, spin, and momentum, the nucleon–nucleon interaction is, on average, strong and attractive at distances greater than ∼0.7 fm. At still shorter distances, the nucleon–nucleon force turns strongly repulsive, preventing nucleons from coming too close to one another. Figure 14.3 shows the neutron–neutron potential and the proton–neutron potential; in the latter case, the configuration is the one in which the nucleons can form a bound state, the *deuteron*. Although they look quite different at 1 fm, both potentials reduce to eq. (14.5) with the same strength at large distances. At their minima near 0.8 fm, the potentials shown take values of roughly −50 MeV and −100 MeV. This means that energy in amounts measured in *millions* of electron volts per nucleon is in principle available in nuclear interactions. The depth of the potential is not, however, a good measure of the binding of nuclei. The reason for this is that the potential is very negative only in a relatively thin spherical shell. A quantum bound state in this potential has a wavefunction that is peaked at the spherical shell where $V(r)$ is negative. The second derivative of the wavefunction in the radial direction contributes substantial positive energy in the Schrödinger equation (7.7). This positive *kinetic* contribution cancels much of the 50–100 MeV of negative potential energy, reducing the net binding energy between individual nucleons to a few MeV. The two-nucleon system has a relatively small binding energy per nucleon compared to other nuclei with a few more constituent nucleons, in part since each nucleon is only bound to one other. The deuteron, composed of a proton and a neutron, is bound by only ≈ 2.2 MeV, and the two-neutron and two-proton systems are not bound at all. We investigate the systematics of nuclear binding further in §17.

---

[4] The factor $1/4\pi\epsilon_0$ is introduced so that the (appropriately scaled) strength g^2_{strong} of the strong force can be compared with electromagnetism more easily (Problem 14.3).

14.1.4 Weak Interactions

The weak interactions start to make their appearance at roughly the same distance scale as the strong interactions. The weak interactions are characterized by a Yukawa potential energy with a strength not too different from electromagnetism, but with a range that is a factor of about 500 shorter than the range of the strong interactions, so the form of the weak potential is roughly

$$V_{\text{weak}}(r) \approx \frac{g_{\text{weak}}^2}{4\pi\epsilon_0}\frac{e^{-r/b}}{r} \tag{14.6}$$

with $g_{\text{weak}} \sim e$ but $b \approx 2.5 \times 10^{-3}$ fm. Their short range makes the weak interactions far too small to be observed at nuclear distance scales, compared to both strong and electromagnetic interactions. The Yukawa form of the weak nuclear interaction arises from the fact that the fundamental particles ($W^{\pm}$ and Z *vector bosons*) mediating this interaction are massive, rather than massless like the photon. The weak interactions would be almost entirely negligible *except for the fact that they facilitate some processes that are forbidden for all the other interactions*. These processes are described in more detail in §14.3.

Are there other forces waiting to be discovered? Perhaps. Answering this question is one of the goals of modern particle physics. The *Large Hadron Collider* (LHC) facility at the European Center for Nuclear Research (CERN) in Geneva, Switzerland is looking for as yet unknown particles and forces that become important at very short distances. Whatever they may find, it will not affect the practical contemporary energy issues we are studying in this book because any new forces that may exist are locked away deep within protons and neutrons, inaccessible to our attempts so far to liberate their energies.

We have only sketched the basic properties of the forces that control physics at the subatomic scale. Some of the information about forces accumulated so far is summarized in Table 14.1 along with other facts that appear later in this chapter. Next we turn to the players in the world of subatomic physics – the elementary particles from which the world is built.

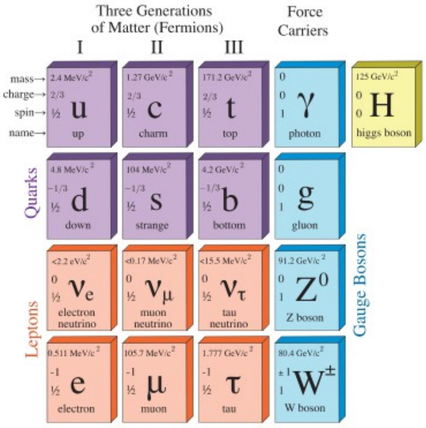

Figure 14.4 A summary of the 17 elementary particles in the Standard Model. Some of the properties of the particles are summarized in Table 14.2. The constituents of matter are shown in the first three columns, the carriers of the forces are shown in the fourth column, and the recently discovered *Higgs boson* appears in the final right-hand column. (Credit: Adapted from HolgerFiedler nach Benutzer: Murphee under CC-BY-SA 3.0 license via Wikimedia Commons)

14.2 Elementary Particles

The elementary particles in the Standard Model come in two types: the constituents of matter and the conveyers of force.[5] The archetype of the first class is the electron, and an example of the second class is the photon. It is a good idea to keep these examples in mind as the names and types of particles proliferate. For reference, Figure 14.4 gives a schematic summary of all the particles in the Standard Model, with more detail in Table 14.2.

The key to understanding the structure of Table 14.2 is the checklist of interactions in the last column. The particles that make up matter can be classified by the forces they feel. Just as electric charge indicates the extent to which a particle interacts electromagnetically, so there are "charges" for each of the other forces. *Quarks* are

---

[5] The recently discovered **Higgs particle** is the lone exception to this rule. It plays a special role in the Standard Model as the breaker of symmetries and the generator of mass. Fascinating though it is to particle physicists, we say little about the Higgs particle here since it plays no direct role in our subject.

Table 14.1 Some properties of the fundamental forces. Although energy is not explicitly listed, all the forces conserve energy. The strengths of the forces are measured relative to the chromodynamic force between quarks.

Force	Mediator	Mediator mass	Relative strength at 1 fm	Conservation laws			
				Baryon number*	Electric charge	Flavor	Parity
Gravity	Graviton	Massless	$\sim 10^{-41}$	√	√	√	√
Weak	W & Z bosons	$\sim 80\,\mathrm{GeV/c^2}$	$\sim 10^{-8}$	√	√	×	×
Electromagnetic	Photon	Massless	$\sim 10^{-2}$	√	√	√	√
Chromodynamic	Gluons	Massless	1	√	√	√	√

* Note that while all observed local processes conserve baryon number, subtle *nonperturbative* processes can violate baryon number (§21).

Table 14.2 Properties of the leptons and quarks [69]. Masses are given in units of MeV/c^2 (1 MeV/c^2= 1.783×10^{-30} kg). Note that each quark can come in three distinct *colors* corresponding to different charges under the chromodynamic force.

Name	Symbol	Mass (MeV/c^2)	Electric charge	Baryon number	Interactions			
					Strong	E&M	Weak	Gravity
Electron	e	0.510 998 92(4)	−1	0	–	√	√	√
Muon	μ	105.658 369(9)	−1	0	–	√	√	√
Tauon	τ	1776.99(29)	−1	0	–	√	√	√
Electron neutrino	ν_e	$0 < m \leq 2 \times 10^{-6}$	0	0	–	–	√	√
Mu neutrino	ν_μ	> 0	0	0	–	–	√	√
Tau neutrino	ν_τ	> 0	0	0	–	–	√	√
Up quark	u	2.3(6)	2/3	1/3	√	√	√	√
Down quark	d	4.8(4)	−1/3	1/3	√	√	√	√
Strange quark	s	95(5)	−1/3	1/3	√	√	√	√
Charm quark	c	$1.275(25) \times 10^3$	2/3	1/3	√	√	√	√
Bottom quark	b	$4.18(3) \times 10^3$	−1/3	1/3	√	√	√	√
Top quark	t	$173.2(5) \times 10^5$	2/3	1/3	√	√	√	√

"charged" with respect to chromodynamic, weak, and electromagnetic interactions. **Leptons** have no chromodynamic charge, so they do not feel the chromodynamic interactions, but all leptons interact by weak forces. Leptons are divided into **charged leptons** and **neutral leptons**, based on whether they are electromagnetically charged or neutral. All particles feel the effects of gravity.

All the particles that constitute observable matter – quarks and leptons – have spin 1/2. In §8, we discussed the division of quantum particles into *fermions* and *bosons*, the distinction being whether only one, or an arbitrary number, of particles can exist in a given quantum state. The fermionic nature of the electron is responsible for the complexity of atomic structure and the richness of chemistry. All the other leptons and all quarks are also fermions. Indeed, a fundamental theorem of relativistic quantum theory dictates that all particles with half-integral spins are fermions, while all particles with integral spins are bosons. This basic fact is discussed further in §15.5.

The particles that transmit the electromagnetic, chromodynamic, and weak forces are all spin one particles, known as **vector bosons**. The term "vector" refers to the fact that the fields associated with the gluon and the $W^\pm$ and Z are vector fields like the $\boldsymbol{E}$ and $\boldsymbol{B}$ fields associated with the photon. As mentioned earlier, the photon and gluon are massless, while the $W^\pm$ and Z bosons are massive.

The Higgs particle has spin 0, and is known as a **scalar particle** – the Higgs is the first fundamental scalar particle ever observed in nature. (The term *scalar* refers to the fact that the field of which the Higgs particle is an excitation assigns a single number – a scalar – to each point in space-time, unlike a vector field that assigns a vector to each point in space-time.) A consistent quantum theory of gravity would include a further particle associated with a quantum excitation of the gravitational field – a massless **graviton** – which would have to be a spin-2 boson.

An as yet unexplained feature of the spectrum of observed leptons and quarks is that they come in three **generations** that are almost identical except for the particle masses. The *electron* e^-, *electron neutrino* ν_e, and *up* (u) and *down* (d) quarks make up the first generation of fundamental particles. The *muon* is like a heavier version of the electron, and the *charm* (c) and *strange* (s) quarks are heavier versions of the u and d. These, together with the *muon neutrino* (ν_μ), make up the second generation. And the *top* (t) and *bottom* (b) quarks, along with the *tauon* (τ) and *τ-neutrino* (ν_τ), form a similar, but still heavier third generation. The quarks and leptons are grouped into generations in the chart of Figure 14.4.

Clearly, there is an abundance of elementary particles, many of which are difficult to produce, live only briefly before they decay, and have little if any impact on energy production or flow on Earth. Before surveying them all, we strip away the complexity and introduce the **Standard Model "lite"**, which contains the particles responsible for almost all of the phenomena we encounter in this book.

14.2.1 The Standard Model Lite: A $p\, n\, e\, \bar{\nu}_e\, \gamma$ World

For almost all practical purposes, *only five particles* play a role in the world, and one of the five usually hides in the wings, only making an occasional entrance when needed. The five key particles are the proton, neutron, electron, photon, and the (electron anti-) *neutrino*. The electron (e^-) was the first to be identified, having been discovered in the nineteenth century as the **cathode ray** in cathode-ray tubes – the same *CRT*s were later used in television sets and computer monitors. The exact date of discovery of the photon (γ) is debatable. In some sense it was "discovered" by Einstein in 1905, who introduced the concept of a quantum of the electromagnetic field when he used it to explain how light can knock electrons off the surface of metals. The proton (p) and neutron (n) were discovered during the development of nuclear physics in the first third of the twentieth century. The existence of what we now know to be the electron antineutrino ($\bar{\nu}_e$) was postulated by Austrian physicist Wolfgang Pauli in 1931, though it was not actually discovered until 1956.

In 1930, Dirac pointed out that every particle has an "opposite" or **antiparticle** with the same mass, but opposite charge. So complementing the first three particles in the *standard model lite* are the antiproton ($\bar{p}$), antineutron ($\bar{n}$), and antielectron (e^+, also known as the **positron**). The $\bar{\nu}_e$ is an *antineutrino*, so its opposite is the ν_e, the *neutrino*. The photon is unique in this list in that it is *its own antiparticle*, so there is no separate "antiphoton." Antiprotons and antineutrons play almost no role in our world. They are hard to produce and annihilate quickly into radiation when they encounter any matter. Positrons are emitted in some nuclear decays and have found use in medical diagnostics and cancer treatment. Neutrinos are produced copiously in the Sun (see §22) but pass through our world largely unnoticed. More about positrons and neutrinos can be found in §20 and §22.

The description of the world in terms of the five particles in the *Standard Model lite* is really quite simple:

Protons and neutrons bind together to form nuclei. Nucleon–nucleon forces are complicated, but nuclei are rather simple – at least at the level we encounter them. Nuclei can be described as a quantum version of "liquid drops" in which the protons and neutrons slither about. Note that while protons and neutrons are not truly fundamental particles – they are bound states of quarks and do not appear in Figure 14.4 – only experiments at very high energies can discern the structure within them, so for most practical purposes they can be thought of as primitive constituents of matter.

Electrons are attracted to nuclei by forces that are transmitted by electric and magnetic fields. Together, electrons and nuclei formed from protons and neutrons form atoms; atoms form molecules; and molecules form complex systems like us.

Photons – the quanta of the electromagnetic field – are emitted and absorbed when electrons or protons make transitions from one quantum state to another.

Electromagnetic fields play a dual role: as classical waves that can be broadcast and absorbed, and as quantized photons as already mentioned.

Antineutrinos A neutron can decay into a proton, an electron, and an electron antineutrino. This is a weak interaction known as *β-decay*. Sometimes, when protons and neutrons are bound into nuclei, this reaction is forbidden by energy conservation and instead the opposite reaction

The Standard Model "Lite"

Only five particles – the proton, neutron, electron, photon, and the electron antineutrino – are needed to provide a fairly good description of almost all phenomena in our world. Electromagnetism and gravity are the principal macroscopic forces of consequence. Weak and strong interactions operate within nuclei, which are held together by the strong nuclear interaction between nucleons (protons and neutrons).

can occur: effectively a proton can decay into a neutron, a positron, and an electron neutrino (ν_e).

Gravity acts on all these particles, even photons which are massless but carry energy.

For a short period of time – roughly the period between 1935 and 1950 – the five particles in the *Standard Model lite* were thought to be the only elementary particles in nature. In fact, this relatively complacent era in fundamental physics was over almost before it began, since the first additional particle, the *muon*, had already been detected in a cloud chamber photograph in 1937. Trying to understand the muon and the plethora of strongly interacting particles related to protons and neutrons that were made in accelerators in the 1950s led eventually to the Standard Model.

The remainder of this section provides a brief introduction to the other particles in the Standard Model.

14.2.2 Leptons

Charged leptons All six known leptons experience the weak, but not the strong interactions. Three of these leptons also carry electromagnetic charge. The electron is the lightest and most familiar of the (electromagnetically) charged leptons. We know of two other charged leptons: the **muon** (μ) with a mass of approximately 207 times the mass of the electron, and the **tauon** (τ) with a mass about 3478 times the mass of the electron. As far as we can tell, the μ and the τ are almost identical copies of the electron, except for their masses. They have the same charges, and the same kinds of interactions; they are just heavier. They are short-lived and decay into electrons, neutrinos and, occasionally, other stuff. There is good reason to believe that the electron, muon, and tauon are the only charged leptons.

Neutral leptons Each charged lepton is associated with a *neutral lepton*, called a **neutrino**. For the e there is the ν_e, for the μ, the ν_μ, and for the τ, the ν_τ. What is meant by "associated with" is explained in more detail in §14.3. Neutrinos feel only the weak force and gravity. They are very light – for many years they were thought to be massless like photons, but late last century it was discovered that they have small but nonzero masses. Their interactions are so weak that they pass through matter almost like it isn't there. To make that statement quantitative: the *mean free path* (the typical distance traveled before an interaction takes place, §20) of a 1 MeV neutrino moving through lead is roughly 1 light-year ($\sim 10^{16}$ m)!

Lepton interactions An important tool in analyzing systems of elementary particles is the existence of additional exactly or approximately *conserved charges* like the total electric charge, which remain unchanged under all, or almost all, physical processes. Each of the three lepton pairs, (e, ν_e), (μ, ν_μ), and (τ, ν_τ) is associated with a discrete *approximately* conserved quantity.[6] This quantity is called **lepton number** (L) generically: **electron number**, **muon number**, and **tauon number** (L_e, L_μ, L_τ) refer to the approximately conserved quantities associated with each of the three lepton types. The charged leptons and their associated neutrinos have lepton number $+1$, their antiparticles have lepton number -1. An example of an interaction that conserves both muon number and electron number is muon decay,

$$\mu \to e\, \bar{\nu}_e\, \nu_\mu\,. \tag{14.7}$$

The muon ($L_\mu = +1$) decays into a muon neutrino ($L_\mu = +1$), an electron ($L_e = +1$), and an electron antineutrino ($L_e = -1$). Thus the muon number is one on both sides of the equation and the total electron number is zero.

Muons are not particularly exotic. They are made by cosmic rays in the upper atmosphere and travel down well into the ground (on average), before decaying or interacting. The lifetime of the muon is about 2.2 µs, and the flux at sea level is about $200\,\text{m}^{-2}\,\text{s}^{-1}$. So hundreds have passed through you in the time it has taken you to read these words.

---

[6] A subtle phenomenon called *neutrino oscillation* allows one type of neutrino to turn into another. The phenomenon is of great interest to particle physicists, but is extremely difficult to observe and has no impact on the energy processes such as β-decay that we are interested in here. There are also more subtle effects in quantum field theory that can lead to violation of lepton number; these effects are negligible in all circumstances considered in this book.

14.2.3 Quarks and their Interactions

Quarks are massive particles that feel the chromodynamic force. While they are similar in some respects to leptons at a fundamental level, the role they play in nature is quite different. Whether or not a particle feels the chromodynamic force is determined by a "charge" – not electric charge, but similar in that particles with this charge feel the force and particles without it do not. This charge is called *color*, but it has nothing to do with visible color, which is, of course, a characteristic of electromagnetic radiation. Electric charge comes in two types, which we call *positive* and *negative*, with the property that combining positive and negative charges of equal strengths results in a system that is electrically neutral. Similarly, each type of quark comes in three versions which differ by their "color." If three quarks, one of each version, are combined, the result is neutral under chromodynamic forces. Because this resembles the rule for addition of the primary colors of light – when red, green, and blue light are combined, they yield white, or neutral light – physicists chose, somewhat whimsically, to call the chromodynamic charge **color**. The proton and the neutron are both examples of color-neutral three-quark systems. Another successful feature of the analogy is that combining a quark and antiquark also can yield a color-neutral system, in much the same way that combining a visual color with its complement gives color-neutral, i.e. white, light.

The chromodynamic forces are very strong. Furthermore, as discussed further below, gluons themselves carry color charge (unlike photons, which are electrically neutral). These effects combine in such a way that quarks can never escape from the color-neutral bound states that they form. Thus, individual quarks are never seen. Color-neutral states of three quarks are called **baryons** and bound color-neutral states of a quark and an antiquark are called **mesons**. Together, these color-neutral composite particles are known as **hadrons**.[7] Protons and neutrons are the lightest baryons. Almost all the known particles that feel the strong force fit into these two categories: baryons (or antibaryons, like the antiproton) or mesons. The exception being a handful of recently discovered and/or very short-lived states that appear to be essentially composed of two quarks and two antiquarks, or four quarks and one antiquark.

Quark Properties

Baryon number There are literally hundreds of different types of baryons, but all are unstable except for protons (and neutrons when they are bound within certain nuclei). Eventually, if you follow its life, any baryon decays into a proton or neutron plus a lot of other stuff that may include mesons, leptons, antileptons, and photons. Protons, however, do not seem to decay – ever. Searches for proton decay have come up empty, and the proton lifetime is now known to be greater than 2×10^{29} yr [69]. To account for this, physicists endow baryons with a type of "charge" called **baryon number**, which is +1 for baryons and -1 for antibaryons. So, for example, the proton and neutron have baryon number +1 and the antiproton and antineutron have baryon number -1. The stability of the proton can then be expressed as **conservation of baryon number**.[8] A baryon can decay, but among its decay products one must always find another baryon, and if you wait long enough only protons and/or neutrons will be left. Mesons, leptons, photons, and the rest have baryon number zero. A proton and an antiproton can annihilate into a cloud of mesons and photons because this conserves baryon number: $1 + (-1) = 0$.

The concept of baryon number can be attributed at a more fundamental level to quarks. Since there are three quarks in a baryon, each quark is assigned baryon number $1/3$. While quark number conservation implies conservation of baryon number, the name "baryon number" was invented long before quarks were discovered, and the name stuck. Nuclei are bound states of protons and neutrons, so they can be labeled by their baryon number. Carbon, for example, with six protons and six neutrons, has baryon number 12. The baryon number of a nucleus is thus the same thing as its *atomic mass number* in the language of chemistry. We use the terms interchangeably.

Baryon Number (Atomic Mass)

An atomic nucleus can be labeled by the number of nucleons it contains. That number is called the *baryon number* or *atomic mass*, and is usually denoted by A. A nucleus of atomic mass A contains $3A$ quarks. Baryon number is conserved in all observed processes.

---

[7] All these names are from the Greek: *hadron* = stout; *baryon* = heavy; *meson* (originally *mesotron*) = intermediate; *lepton* = slight.

[8] Some speculative ideas for physics beyond the Standard Model, such as *Grand Unified Theories*, predict a very small probability for proton decay. These ideas have not been confirmed experimentally. Also, as for leptons, subtle processes can give rise to very small violations of baryon number; while negligible for the purposes of energy physics, these processes may have been involved in the early universe in producing the presently observed asymmetry between matter and antimatter (§21).

Quark charges and colors, gluons Aside from the fact that they are never seen in isolation, perhaps at first sight the most bizarre property of quarks is that their electric charges are either $+\frac{2}{3}e$ or $-\frac{1}{3}e$, where $-e$ is the electron's charge. When quarks were originally proposed in 1964 by American physicists Murray Gell-Mann and George Zweig, the idea that a particle could have *fractional electric charge* was considered strange if not silly. Now there is plenty of evidence for these charge assignments, and the only oddity is that fractional charges are not observed directly because the allowed, color neutral, combinations of quarks and antiquarks always have charges that are integer multiples of e.

Given that they are never seen in isolation, how can we be certain that quarks have fractional charge, or indeed, that quarks exist at all? The reason is that when electrons or other particles that do not feel the strong force are scattered from protons or other nuclei, the pattern of scattering depends on the nature and distribution of the constituents of the baryon(s). In the late 1960s American physicists Jerome Friedman, Henry Kendall, and Richard Taylor scattered electrons from protons and observed scattering patterns that could only be accounted for if protons were made of pointlike spin-1/2 particles with electric charges that are third integral fractions of the electron's charge. Physicists now agree that quarks are just as "real" as electrons, even though the nature of chromodynamic force sequesters them permanently inside protons and neutrons.

The gluons that mediate the chromodynamic force couple to color charges in much the same way that a photon couples to electric charge, but in addition, gluons themselves are colored. Two beams of light pass through one another because photons do not scatter significantly from one another.[9] Gluons not only do not pass through one another, they interact with one another strongly by emitting and absorbing more gluons, and those interact by emitting and absorbing more gluons, *ad infinitum*. This is why chromodynamic forces are so complicated.

Flavor On top of all the previous complications, quarks come in six distinct types, more or less in parallel to the six types of leptons (remember (e, ν_e), (μ, ν_μ), and (τ, ν_τ)). The six types are called **up** (u), **down** (d), **charm** (c), **strange** (s), **top** (t), and **bottom** (b). They differ in electric charge: three (u, c, t) have charge $+\frac{2}{3}e$ and three (d, s, b) have charge $-\frac{1}{3}e$. The properties of the quarks, to the extent they are known, are listed in Table 14.2. Note that they all have electric charge, so they feel electromagnetic forces. They all feel the weak force as well.

These six different types of quarks are known as different **flavors** of quarks. The name "flavor" is even more fanciful than "color." It has no content except to allow physicists to discuss an abstract concept in simple words. Note that the six flavors of quarks can be divided into the three *generations* of matter as discussed above, with up and down quarks in the first generation, charm and strange in the second generation, and top and bottom in the third generation, with each generation progressively more massive than the previous.

The chromodynamic interactions of quarks conserve flavor. The number of u quarks (minus the number of u antiquarks), for example, does not change in a chromodynamic interaction. In contrast, the weak interactions allow quarks to change their flavors. Thus, for example, a weak interaction can enable a d quark to emit an electron and an electron antineutrino and turn into a u quark – a transformation not otherwise possible. These transformations are important in nuclear energy processes, and are described in §14.3.

The quark structure of protons and neutrons Protons and neutrons are the lightest baryons. The **proton** is a bound state of two u quarks and one d quark. The sum of the electric charges is $2 \times \frac{2}{3} - \frac{1}{3} = 1$. The **neutron** is a bound state of two d quarks and one u quark, with electric charge $\frac{2}{3} - 2 \times \frac{1}{3} = 0$. This structure is illustrated in Figure 14.5. The proton is lighter than the neutron because the u quark is slightly lighter than the d quark. The masses of the u and d quarks are tiny, which at first sight may seem very strange: how can objects of mass $M \approx 940\,\text{MeV}/c^2$ be made of only three particles with masses of $\sim$ 2–5 MeV/c^2 each? Where does all the mass come from? The answer lies in quantum mechanics and the concept of zero-point energy, which was briefly mentioned in §9.2.1. Recall that in each of the potentials that was studied (square-well and harmonic oscillator) in §7, the lowest energy state has energy greater than zero. The smaller the region to which a particle is confined, the greater its energy. For a region as small as 1 fm, the zero-point energy of a massless particle is ~300 MeV (Problem 14.5). The proton contains three such particles, each with a zero-point energy of about 300 MeV, so the energy of a proton at rest is ~900 MeV; by Einstein's $E = mc^2$, that energy contributes 900 MeV/c^2 to its mass.

The visible matter in the universe consists of nuclei and electrons. The nuclei in turn consist of protons and neutrons. The mass of an electron is ~1/2000th that of a

---

[9] There is a tiny quantum effect called *light-by-light scattering*, where a photon briefly materializes as an electron-positron pair, which then interacts with the other photon. This effect is so small that it has not been observed directly.

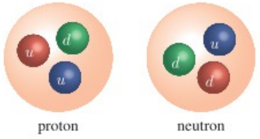

Figure 14.5 A cartoon of a proton and neutron showing the dominant quarks: uud in the proton and ddu in the neutron. The quarks are colored to remind us that all three colors must be present to make a color-neutral hadron. In actuality, protons and neutrons are described by quantum states that include fluctuating gluon fields and quark–antiquark pairs, though this complexity does not affect the nuclear reactions relevant to nuclear energy processes.

Mass in the Visible Universe

Almost all of the visible mass in the universe is found in the rest masses of protons (hydrogen nuclei), neutrons, and the nuclei they compose. This mass, in turn, is a manifestation of the quantum zero-point energy of almost-massless quarks confined to the interior of nucleons.

proton or neutron. So we conclude that most of the mass of the visible universe is due to the quantum zero-point energy of bound quarks!

Although protons and neutrons have excited states, the energies emitted and absorbed in the nuclear reactions of interest to us here are not great enough to excite the quarks in protons or neutrons. Protons and neutrons can therefore, to a good approximation, be regarded as persistent, unstructured objects whose identity does not change inside a nucleus. The internal quark substructure of protons and neutrons is manifested in the complicated structure of the strong nuclear interactions.

14.2.4 Force Carriers

As summarized earlier, the chromodynamic, weak, and electromagnetic forces each are mediated by spin one *vector bosons*. Each of the vector bosons has its own features and character. The *photon* is most visible because it is massless and carries no charge, so that it propagates freely through space mediating the long-range electromagnetic force. The gluon, while also massless, is itself *charged* under the chromodynamic interactions, so that it cannot propagate freely. Even in the absence of quarks or leptons, gluons can in principle bind together into color-free massive states known as *glueballs*. Up to now, however, no glueball has been convincingly identified experimentally. The Z^0 and $W^\pm$ vector bosons that mediate the weak interactions are massive, and thus weak interactions are intrinsically short-range forces.

14.2.5 The Higgs Boson

The final particle in the standard model is the *Higgs boson*, or *Higgs particle*. Originally predicted in 1964, this particle was found experimentally in 2013. Though this particle does not play a direct role in any energy-related processes, it is a central component of the Standard Model. It is responsible for *electroweak symmetry breaking*, the mechanism that gives rise to masses for the $W^\pm$ and Z bosons and differentiates the weak interactions from the closely related electromagnetic interaction. The Higgs particle is also associated with the phenomenon that gives rise to quark and lepton masses.

14.3 The Weak Interactions and β-decay

We have alluded several times to the crucial role that the weak interactions play in the universe. Their fundamental practical importance is that they allow protons to turn into neutrons and *vice versa*. In this section we take a more careful look at this and related processes.

14.3.1 Discovery of β-decay

In the early twentieth century physicists observed that some nuclei emit electrons and change their chemical identity. A simple, illustrative, and important example is the decay of a rare form of potassium into calcium or argon. Potassium is an atom with 19 electrons bound to a nucleus with 19 protons and usually 20 neutrons. This nucleus is stable. About one in ten thousand potassium nuclei contains 21 neutrons rather than 20, giving the nucleus a baryon number (atomic mass number) of 40. An atom with this nucleus at its core has all the chemical properties of ordinary potassium, but it weighs about 2.5% more due to the extra neutron. What is special about potassium-40 (^{40}K in standard notation, §17.1.2) is that it is unstable. It decays with a lifetime of greater than a billion years.

About 88% of the time that the nucleus of a ^{40}K atom decays, it emits an electron, thereby increasing its nuclear charge by one unit. This process turns it into a form of calcium, ^{40}Ca. At first, physicists did not know what particle was emitted in this process. They called the emitted particle a β-ray and they called the decay a **beta decay** Soon it became clear that the emitted particle was an ordinary electron. But a new puzzle arose: the electron did not always come out with the same energy. According to quantum mechanics, the decay should have taken one quantum state of fixed energy to another, and the electron's energy should have been determined by the difference of the energies of the two states. Even if the transition left the calcium nucleus in one of several excited energy basis states, the energy of the electron would have been limited to one of a few definite values. Instead the electrons' energies measured in many ^{40}K decays were found to vary continuously between zero and a maximum that equaled the difference of nuclear energies.[10] It seemed that energy was leaking away. Further experiments showed that momentum and angular momentum were not being conserved in β-decay either. In 1931, Wolfgang Pauli speculated that an *unobserved* neutral particle was being emitted *with the electron*, and it was carrying off the missing energy, momentum, and angular momentum. To have been overlooked, the neutral particle would have to have had *very weak interactions with ordinary matter*. Fermi named it "a little neutral one" or *neutrino* in Italian. This was the first time (but not the last) that a physicist predicted the existence of a new elementary particle. Further experiments confirmed that Pauli was right and that the reaction that was taking place is

$$^{40}\text{K} \to {}^{40}\text{Ca} + e^- + \bar{\nu}_e\,. \qquad (14.8)$$

Many nuclei undergo similar decays.

14.3.2 β-decay in the Standard Model

When physicists of the mid twentieth century figured out that the nucleus is a bound state of protons and neutrons, they developed a more universal description of what is happening in ^{40}K and other β-decays. In such decays, a neutron is decaying into a proton,

$$n \to p + e^- + \bar{\nu}_e\,. \qquad (14.9)$$

The proton remains bound by the strong nuclear force to the nucleus, but the electron and the neutrino are emitted. And when physicists of the late twentieth century understood that the neutron and proton are bound states of quarks, they realized that, at a deeper level still, a d quark is decaying into a u quark by a weak interaction,

$$d \to u + e^- + \bar{\nu}_e\,. \qquad (14.10)$$

Since quarks are confined to the interiors of the proton and neutron, the observed reaction is

$$n(udd) \to p(uud) + e^- + \bar{\nu}_e\,. \qquad (14.11)$$

Weak Interactions Violate Flavor Conservation

The strong interactions appear to conserve flavor absolutely, but weak interactions allow quarks of one flavor to turn into quarks of any other flavor, as long as the quark electric charge changes by ± 1 and the overall reaction conserves baryon number, electric charge, and lepton number. The transformations between u and d quarks lead to β-decay and related processes in nuclei,

$$\begin{aligned} d &\to u + e^- + \bar{\nu}_e, \\ u &\to d + e^+ + \nu_e, \\ u + e^- &\to d + \nu_e. \end{aligned}$$

The Standard Model gives quite a simple description of what is happening at the quark level. The modifications due to the details of nuclear structure, however, are very important in determining the lifetime of any particular nucleus that can undergo β-decay. Some nuclei that can β-decay have lifetimes that are longer than the age of the universe. The free neutron β-decays to the proton with a lifetime of about 10 minutes, and there are many nuclei with β-decay lifetimes of less than a microsecond. We do not attempt to develop the theory of β-decay here in any detail. Lifetimes for β-decay processes in which we are interested can be looked up online [70].

The fact that quark flavor is not conserved ($d \to u$) in β-decay confirms that the weak interactions are at work. There are many different types of weak interactions, but the only ones important for our purposes are the one given in eq. (14.10) and a few variations mentioned below. These reactions always conserve electric charge, baryon number, and lepton number as well as the other usual conserved quantities – energy, momentum, and angular momentum – but quark flavor is not conserved. The fact that weak interactions enable reactions that would otherwise be forbidden is the reason that we care about them. When they give small corrections to otherwise allowed processes, as they do under most circumstances, they are usually too small to be noticed.

14.3.3 Processes Related to β-decay

^{40}K β-decays to ^{40}Ca 88% of the time. The other 12% of the time it undergoes a related process that turns it into ^{40}Ar. In this case the nuclear charge must decrease by one unit (argon has 18 protons and 18 electrons). From what

---

[10] Actually the experiments were performed on different, more abundant nuclei with shorter lifetimes. We chose ^{40}K because it both β-decays *and electron captures* (see below) and it plays a role in geothermal energy (see §32).

Example 14.1 What Force Was Responsible For That?

Interactions among particles must satisfy the conservation laws that are respected by the type of interaction that is at work. This fact – together with the hierarchy that the strong nuclear interaction is much stronger than electromagnetism, which in turn is much stronger than the weak interactions – makes it possible to identify what force is at work in important processes. In general, the rate at which a quantum process occurs depends on the strength of the coupling, so most strong nuclear interaction processes occur much more quickly than those mediated by weak interactions. (Note that gravity is too weak to drive any measureable reaction among particles or nuclei.)

Some important examples:

- When neutrinos or antineutrinos appear, the weak interactions must be at work, because neutrinos do not couple to the strong or electromagnetic interactions.
- When photons appear, electromagnetism must be at work because photons only interact electromagnetically.
- If protons change into neutrons or *vice versa*, the weak interactions must be at work.

Consider, for example, hydrogen fusion into helium, which is known to be the Sun's primary energy source. Four protons fuse to form one helium nucleus, known also as an α-**particle**, which consists of two protons and two neutrons, as well as two positrons (needed to conserve electric charge). A first guess for the reaction might be

$$4p \to \alpha + 2e^+ \quad (?)$$

This reaction conserves baryon number and electric charge. Naively it looks like a strong nuclear interaction, which should go very quickly. One wonders why the Sun has lived so long. Closer inspection, however, reveals that two protons have turned into neutrons and that electron number is not conserved. These features indicate both that a weak interaction is involved, and that two neutrinos must be produced. A corrected version of the reaction reads

$$4p \to \alpha + 2e^+ + 2\nu_e \,.$$

The reaction can only proceed as rapidly as the weakest force involved permits, so despite the fact that protons and neutrons are involved, the time scale for hydrogen burning in the Sun is set by the weak interactions, which is a good thing for life on Earth.

we have learned about the weak interactions of quarks, we might guess that the reaction could be

$$^{40}\mathrm{K} \to \, ^{40}\mathrm{Ar} + e^+ + \nu_e \quad (?) \tag{14.12}$$

where at the microscopic level $u \to d + e^+ + \nu_e$. This is a good guess, which satisfies all the rules like lepton number and baryon number conservation. This kind of reaction is called β^{+}_{-}*decay* or *positron emission*, but it is *not* in fact how ^{40}K decays to ^{40}Ar. A quick check of the masses of the ^{40}K and ^{40}Ar nuclei reveals that there is not enough energy released in the nuclear reaction to create the rest mass of the positron, 511 keV/c^2. (We explain how to do calculations like this in §17.) Instead, the ^{40}K nucleus *captures* an electron from the surrounding cloud to produce the reaction

$$^{40}\mathrm{K} + e^- \to \, ^{40}\mathrm{Ar} + \nu_e \,, \tag{14.13}$$

which satisfies all the rules of the weak interactions. This process is called *electron capture* or *K-capture* ("*K*" because the electron is captured from the innermost atomic shell, known to chemists as the *K*-shell). This reaction can proceed even if the rest mass of ^{40}Ar is *greater* than that

Important β-decay Processes

The summary of interesting β-decay and related processes for nucleons is

β^- decay	$n \to p + e^- + \bar{\nu}_e,$
β^+ decay	$p \to n + e^+ + \nu_e,$
electron capture	$p + e^- \to n + \nu_e.$

The processes are described here in terms of protons and neutrons, but the fundamental processes involve quarks. In applications to nuclear physics, the protons and neutrons are usually bound in nuclei.

of ^{40}K, as long as the sum of the ^{40}K rest mass plus the electron's rest mass exceeds the rest mass of ^{40}Ar. Many nuclei decay by β^+-decay and/or electron capture, with lifetimes that vary from very short to longer than the age of the universe.

Discussion/Investigation Questions

14.1 Physicists searching to see if the proton decays have looked for the reaction $p \rightarrow e^+\gamma$. Which of the conservation laws explored in this chapter does this decay violate?

14.2 Gravity is a long-range force proportional to the masses of the interacting bodies. Physicists have long searched to see if there might be a long-range force that is proportional to baryon number. Think about the composition of atoms and propose a "thought experiment" that could detect such a force.

14.3 Two possible nuclear fusion reactions are $d + d \rightarrow {}^4\text{He} + \gamma$ and $d + d \rightarrow {}^3\text{He} + p$, where d is deuterium, an atom with a nucleus composed of a proton bound to a neutron. ^{3}He and ^{4}He are helium atoms with nuclei consisting of two protons and one neutron (^{3}He) or two protons and two neutrons (^{4}He). Both of these reactions satisfy energy conservation. Which do you think occurs more quickly and why? (This question and others like it arise when considering fuel for nuclear fusion on Earth.)

14.4 A *baryon* frequently encountered in particle physics experiments is known as the Λ (*"Lambda"*). Its quark content is uds. Sometimes the Λ decays by the process $\Lambda \rightarrow n\gamma$, where n is a neutron (ddu) and γ is a photon. What interactions must be active in this decay?

14.5 The tauon τ decays often to a muon μ, which in turn decays to an electron. How many neutrinos, and of which type are produced in this sequence of weak decays.

Problems

14.1 A rocket fuel should have high energy density (per kilogram) because the weight of the propellant is an important consideration. A favorite fuel is liquid hydrogen plus liquid oxygen. What is the energy density (J/kg) of a stoichiometric mixture of H_2(l) and O_2(l) (assuming they combine to form water in the gaseous state)? The strong nuclear force, in principle, allows the same stoichiometric mixture of two hydrogen atoms and one oxygen atom to fuse to form an *isotope* of neon, ^{18}Ne, giving off 4.52 MeV in the process. If this reaction were the source of power for the rocket, what would be the energy density of the fuel?

14.2 In principle, and in the absence of electromagnetic or any other non-gravitational interactions, an electron and a proton should form a "gravitational atom," bound by the force of gravity. We know that the energy of the ground state of the ordinary hydrogen atom is given by eq. (14.4). Show that the ground state energy of gravitationally bound "hydrogen" is given by $E_{\text{grav}} = -\frac{1}{2}G_N^2 m_p^2 m_e^3/\hbar^2$ and evaluate this numerically.

14.3 Show that the combination of constants $g_{\text{strong}}^2/(4\pi\epsilon_0\hbar c)$, where g_{strong} is defined in eq. (14.5), is dimensionless. It is taken as a dimensionless measure of the strength of an interaction. Compute this quantity for electromagnetism ($g \rightarrow e$), where it is known as the *fine structure constant* and denoted by α.

14.4 Which of the following interactions are consistent with the conservation laws for baryon number, electric charge, and the three lepton numbers? Don't worry about energy conservation. (A bar denotes an antiparticle. See Question 14.4 for information about the Λ particle.)

$$\begin{array}{ll}
p \rightarrow n + e + \nu_e & p \rightarrow n + \bar{e} + \bar{\nu}_e \\
\tau \rightarrow \mu + \bar{\nu}_\mu + \nu_\tau & \bar{\tau} \rightarrow \mu + \bar{\nu}_\mu + \nu_\tau \\
\nu_\mu + p \rightarrow \bar{\mu} + n & \nu_\mu + n \rightarrow \mu + p \\
\Lambda \rightarrow p + e + \bar{\nu}_e & \Lambda \rightarrow n + \nu_e + \bar{\nu}_e
\end{array}$$

14.5 Einstein's energy–momentum relation for a particle of mass m with momentum $\boldsymbol{p}$ is $E = \sqrt{\boldsymbol{p}^2c^2 + m^2c^4}$. Estimate the uncertainty in the x, y, and z components of the momentum of a quark confined in a (cubic) box of side length $L = 1$ fm using the Heisenberg uncertainty principle $\Delta p_{x,y,z} \gtrsim \hbar/L$ (Box 7.6). Approximate $\langle \boldsymbol{p}^2 \rangle$ by $(\boldsymbol{\Delta p})^2$, then show that for a quark of mass 5 MeV/c^2, $E \approx |\boldsymbol{p}|c$ and that the zero-point energy of three quarks is of order 900 MeV, the rest energy of a proton.

14.6 To get a sense of the potential practical relevance for energy purposes of one aspect of as-yet-undiscovered physics, consider proton decay. Making the most general assumptions about the nature of its decay, the lifetime of the proton is currently bounded by $\tau_{\text{proton}} > 2.1 \times 10^{29}$ y. Assume that the lifetime is in fact 3×10^{29} y, and that all of the proton's rest energy emitted in the decay can be captured and put to use. Estimate the rate of useful power output from proton decay of a cubic kilometer of hydrogen gas at NTP.

and the restriction of γ_1 onto l_j with fixed points A and A_j. Since these two fixed points are corresponding under π_{l_j}, the two involutions commute (see, *e.g.*, [46, Exercise 5.4.1]). Therefore, when the points $X, Y \in l_j$ are conjugate w.r.t. π, *i.e.*, $Y = \pi_{l_j}(X)$, then $\gamma_1(Y) = \gamma_1 \circ \pi_{l_j}(X) = \pi_{l_j} \circ \gamma_1(X)$. This means that $\gamma_1(X)$ and $\gamma_1(Y)$ are also conjugate w.r.t. π or, in other words, the induced involutions of π and π' are the same.

With regard to the skew involution γ_2 with axes l and $l^* := \pi^*(l)$, we choose two different, but mutually conjugate points A and A' on l and show that γ_2 is the product of the two harmonic homologies with centers A and A' and respective axes $\pi(A)$ and $\pi(A')$.

Under the product of the two homologies, all points on $\pi(A) \cap \pi(A') = l^*$ remain fixed, but so do all points on $l = [A, A']$, since the restrictions of both harmonic homologies to the line l are involutions with the same fixed points A and A'. Furthermore, the two harmonic homologies commute since the center of one homology lies in the axial plane of the other. Consequently, the product of the two homologies is involutive and biaxial, and therefore, the skew involution with the axes l and l^*. ■

In the particular case $\pi = \pi_{\mathcal{Q}}$, we can state:

Corollary 4.2.7 *Each quadric $\mathcal{Q}$ remains fixed under all harmonic homologies with a point $A \notin \mathcal{Q}$ as center and its polar plane w.r.t. $\mathcal{Q}$ as axial plane.*

If l and its polar line l^* w.r.t. $\mathcal{Q}$ are skew, then the skew involution with axes l and l^* maps $\mathcal{Q}$ onto itself.

Collineations which keep a quadric $\mathcal{Q}$ fixed are called *automorphisms* of $\mathcal{Q}$.

Quadrics in the real projective space

Let $A_0A_1A_2A_3$ be a self-polar tetrahedron of an elliptic or hyperbolic polarity π in the real projective space $\mathbb{P}^3(\mathbb{R})$. Then, each of its triangles is self-polar w.r.t. the induced polarity in the spanned plane ε, and this planar polarity can be elliptic or hyperbolic. We recall (note [46, p. 266]):

Lemma 4.2.8 *If $A_1A_2A_3$ is a self-polar triangle of a polarity π_ε in a real projective plane ε, then, in the case of an elliptic polarity, the involution of conjugate points on each side of the triangle is elliptic, while for a hyperbolic polarity, exactly on two sides the induced involutions are hyperbolic.*

We denote these two types of self-polar triangles by (eee) and (ehh), where 'e' stands for an elliptic involution and 'h' for a hyperbolic one (see [46, p. 278, Fig. 7.14]).

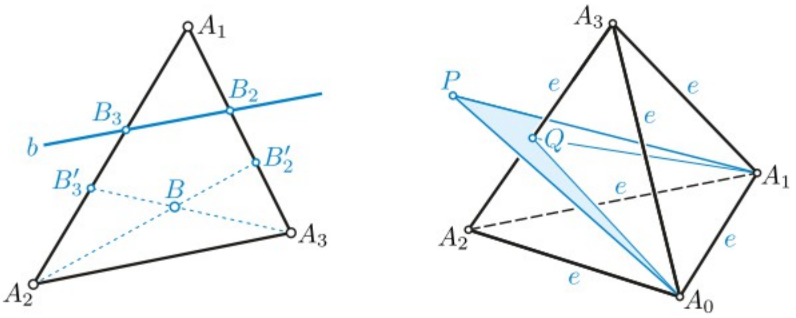

FIGURE 4.5. Left: Induced involutions of conjugate points on the sides of a self-polar triangle; Right: The point P is supposed to be self-conjugate.

Proof: We define π_ε by a self-polar triangle $A_1A_2A_3$ and an additional pair $B \mapsto b$ of pole and polar line, where $A_1, \dots, B$ is a quadrangle and $A_1, A_2, A_3 \notin b$. Then, on the side $[A_1, A_2]$, the involution of conjugate points maps A_1 onto A_2 and the intersection B_3 with b onto the point B_3' being aligned with B and A_3 (Figure 4.5, left). A positive cross-ratio $\operatorname{cr}(A_1, A_2, B_3, B_3')$ of the two pairs characterizes hyperbolic involutions, *i.e.*, real self-conjugate points on $[A_1, A_2]$. The same applies to the other sides. Due to the theorems of Ceva and Menelaos, the product of the cross-ratios on the three sides must be negative, which results in the two cases. ■

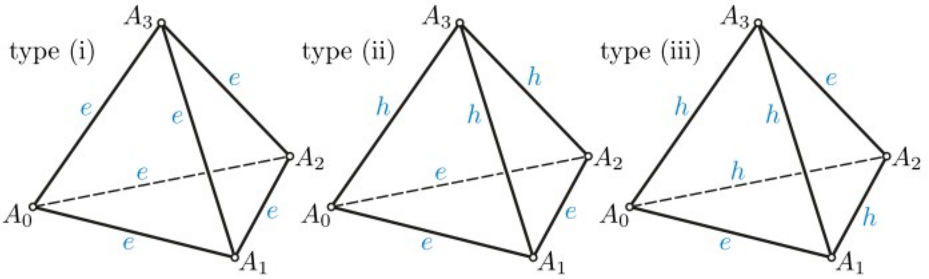

FIGURE 4.6. Induced involutions of conjugate points on the edges of a self-polar tetrahedron.

By virtue of Lemma 4.2.8, for the involutions induced by any elliptic or hyperbolic polarity π on the edges of a self-polar tetrahedron $A_0 \dots A_3$ in $\mathbb{P}^3(\mathbb{R})$, there remain three possibilities (see Figure 4.6):

type (i): all involutions are elliptic;

type (ii): the involutions are elliptic on exactly three coplanar edges;

type (iii): the involutions are elliptic on exactly two opposite edges.

If π is the polarity w.r.t. a ruled quadric $\mathcal{Q}$, then each induced polarity must be hyperbolic, since each generator of $\mathcal{Q}$ meets all planes at self-conjugate points. Therefore, each self-polar triangle must be of type (ehh), and consequently, all self-polar tetrahedra are of type (iii).

Conversely, any self-polar tetrahedron of type (iii) defines self-polar lines, because there exist self-conjugate points on opposite edges (l, l^*) and, by virtue of Lemma 4.2.2, the connection of a self-conjugate point $P \in l$ with a self-conjugate point $Q \in l^*$ is self-polar.

If π is elliptic, then the induced polarity must be elliptic in each plane, too. Therefore, each self-polar tetrahedron must be of type (i).

Conversely, the induced polarities are elliptic in the planes of any self-polar tetrahedron of type (i). Suppose that there is a self-polar point P outside the faces of $A_0 \dots A_3$ (see Figure 4.5, right). Then, the induced polarity in the plane $\varepsilon := [A_0, A_1, P]$ must be hyperbolic. Together with A_0 and A_1, the point of intersection $Q := \varepsilon \cap [A_2, A_3]$ forms a self-polar triangle of π_ε of type (ehh). This yields a self-conjugate point on the side $[Q, A_0]$ in the plane $[A_0, A_2, A_3]$, which contradicts our assumption.

What remains now is that all self-polar tetrahedra of oval quadrics must be of type (ii). We summarize:

Theorem 4.2.8 *All self-polar tetrahedra of ruled quadrics in $\mathbb{P}^3(\mathbb{R})$ are of type* (iii) *and those of oval quadrics are of type* (ii).

Let π be any elliptic or hyperbolic polarity in $\mathbb{P}^3(\mathbb{R})$ with a self-polar tetrahedron $A_0 \dots A_3$. When the vertices $A_0, \dots, A_3$ are used as base points of a coordinate frame, then the π representing matrix $\mathbf{M}$ already has diagonal form $\operatorname{diag}(a_{00}, \dots, a_{33})$ with $a_{00}, \dots, a_{33} \neq 0$, since $\pi_{\mathcal{Q}}\colon (1,0,0,0)\mathbb{F} \mapsto (1:0:0:0)\mathbb{F}$, and so on. By (4.6), the two points $X = (x_0 : x_1 : 0 : 0)$ and $X' = (x'_0 : x'_1 : 0 : 0)$ on $[A_0, A_1]$ are conjugate w.r.t. π if, and only if,

$$a_{00} x_0 x'_0 + a_{11} x_1 x'_1 = 0.$$

This symmetric bilinear form characterizes the induced involution on $[A_0, A_1]$, which, in the case $a_{00} a_{11} > 0$, is elliptic and otherwise hyperbolic. The same holds for all other edges of the tetrahedron.

If π is the polarity w.r.t. an oval quadric $\mathcal{Q}$, we can assume that the involutions on the edges through A_3 are hyperbolic. Now, we define the unit point such that the planes connecting one side of the triangle $A_0 A_1 A_2$ with E intersect the opposite edge at a self-conjugate point.

This means, *e.g.*, that the point $[A_0, A_1, E] \cap [A_2, A_3]$ with coordinates $(0 : 0 : 1 : 1)$ is self-conjugate, which implies that $a_{22} + a_{33} = 0$ and, similarly, $a_{00} + a_{33} = a_{11} + a_{33} = 0$.

If the induced involution on an edge through A_3, say on $[A_2, A_3]$, is elliptic, we specify the plane $[A_0, A_1, E]$ such that the conjugate point of $X = (0 : 0 : 1 : 1)$ is the fourth harmonic point w.r.t. A_2 and A_3, hence $X' = (0 : 0 : 1 : -1)$, which implies $a_{22} - a_{33} = 0$, and so on. Finally, we may set $a_{33} = -1$, which gives rise to the following standard forms.

Theorem 4.2.9 *For each polarity π in $\mathbb{P}^3(\mathbb{R})$, there is a coordinate frame such that the representing matrix $\mathbf{M}$ has one of the following forms:*

$$\mathbf{M} = \begin{cases} \operatorname{diag}(1,1,1,1) & \Leftrightarrow \quad \pi \text{ is elliptic,} \\ \operatorname{diag}(1,1,1,-1) & \Leftrightarrow \quad \pi = \pi_{\mathcal{Q}} \text{ and } \mathcal{Q} \text{ is oval,} \\ \operatorname{diag}(1,1,-1,-1) & \Leftrightarrow \quad \pi = \pi_{\mathcal{Q}} \text{ and } \mathcal{Q} \text{ is ruled.} \end{cases}$$

For the sake of completeness, we shall mention that even a symmetric 4×4 matrix $\mathbf{M}$ with rank $r < 4$ defines a symmetric relation called *conjugacy* between two points $\mathbf{p}\mathbb{R}$ and $\mathbf{q}\mathbb{R}$ by the condition (4.6), $\mathbf{p}^{\mathrm{T}}\mathbf{M}\,\mathbf{q} = 0$. There is a $(3-r)$-dimensional space of *singular points* $\mathbf{s}\mathbb{R}$ satisfying $\mathbf{M}\,\mathbf{s} = \mathbf{0}$. Singular points are conjugate to each point in $\mathbb{P}^3(\mathbb{R})$. When conjugacy is restricted to an $(r-1)$-dimensional space of non-singular points, then for $r = 3$, we obtain pairs of conjugate points w.r.t. a planar polarity and for $r = 2$ we obtain pairs of an elliptic or hyperbolic involution.

Theorem 4.2.10 *The set of points in $\mathbb{P}^3(\mathbb{R})$ satisfying $\mathbf{x}^{\mathrm{T}}\mathbf{M}\,\mathbf{x} = 0$ with a symmetric 4×4 matrix $\mathbf{M}$ of rank $r \leq 3$ is a singular quadric $\mathcal{Q}$.*
When $\mathbf{M}$ has rank deficiency 1, i.e., $r = 3$, this is a quadratic or imaginary cone with the apex at the singular point. In the case $r = 2$, we obtain either two real or two complex conjugate planes intersecting at the line of singular points. For $r = 1$, the set of singular points is a plane, which equals the set of self-conjugate points.
In the case of $r = 3$, it is the sets of tangent planes of a conic that are dual to the singular point quadrics; for $r = 2$, it is pairs of line bundles; and for $r = 1$, it is single line bundles.

Euclidean geometry in the projective setting

When the real projective space $\mathbb{P}^3(\mathbb{R})$ is introduced as the projective closure of the Euclidean 3-space $\mathbb{E}^3$, then it is endowed with additional structures. Below, we analyse some of them.

The orthogonality in $\mathbb{E}^3$ defines a bijectivity between bundles of parallel lines l and pencils of parallel planes ε orthogonal to l. This induces, in the plane ω at infinity, a bijective mapping $\nu\colon \mathcal{P}_\omega \to \mathcal{L}_\omega$ with $(l \cap \omega) \mapsto (\varepsilon \cap \omega)$ for $l \perp \omega$. If l runs through a pencil $\mathcal{L}_{A,\varphi}$ of lines, the corresponding planes $\varepsilon \perp l$ are parallel to lines f perpendicular to φ. Hence, ω is a correlation. Since the orthogonality $l \perp f$ between two lines is symmetric, the conjugacy between $l \cap \omega$ and $f \cap \omega$ is symmetric, too. Consequently, orthogonality in $\mathbb{E}^3$ induces a polarity ν in ω, which is called the Euclidean *absolute polarity.*

No real line can be orthogonal to itself. Therefore, the absolute polarity in ω is elliptic. In the complex extension, the self-conjugate points form the *absolute conic* j, which satisfies

$$x_0 = 0 \quad \text{and} \quad x_1^2 + x_2^2 + x_3^2 = 0, \tag{4.9}$$

when using homogeneous Cartesian coordinates $(x_0 : x_1 : x_2 : x_3) = (1 : x : y : z)$. Finite imaginary lines which meet j are called *isotropic* as well as finite planes tangent to j. Pairs of orthogonal lines in any pencil $\mathcal{L}_{A,\varepsilon}$ form an involution with fixed lines passing through the absolute circle points of ε. Hence, the absolute conic j comprises the absolute circle points of all finite planes ε in $\mathbb{E}^3$.

We recall LAGUERRE's formula from page 76: If l_1 and l_2 are two lines in the pencil $\mathcal{P}_{A,\varepsilon}$ and i and $\overline{i}$ are the two complex conjugate isotropic lines in this pencil, then the measure α of the angle enclosed by l_1 and l_2 is related to the cross ratio of the four lines by

$$\operatorname{cr}(l_1, l_2, i, \overline{i}) = e^{2\mathrm{i}\alpha}, \text{ where } \alpha = \sphericalangle\, l_1 l_2. \tag{4.10}$$

The dual formula holds for two intersecting planes $\varepsilon_1, \varepsilon_2$ and the two isotropic planes $\iota, \overline{\iota}$ through the line $\varepsilon_1 \cap \varepsilon_2$ in the form

$$\operatorname{cr}(\varepsilon_1, \varepsilon_2, \iota, \overline{\iota}) = e^{2\mathrm{i}\alpha}, \text{ where } \alpha = \sphericalangle\, \varepsilon_1 \varepsilon_2. \tag{4.11}$$

Collinear transformations κ which map the plane ω onto itself, are called *affine transformations*. If κ sends all pairs of orthogonal lines again to orthogonal lines, then κ is called a *similarity*. In this case, the restriction of κ to the plane ω keeps the absolute conic j fixed. Consequently, by virtue of LAGUERRE's formula, all angle measures between lines or planes remain fixed, too. Each triangle if mapped onto a similar triangle, *i.e.*, scaled with a certain factor, and this scaling factor is the same for all distances. In other words, for each similarity κ in $\mathbb{E}^3$, there exists a scaling factor f_κ with $\overline{\kappa(A)\kappa(B)} = f_\kappa \cdot \overline{AB}$. Similarities with scaling factor $f_\kappa = 1$ preserve all distances and are called *motions*, whether they are continuous transformations or discrete.

Important examples of motions are the *reflections in planes*. They are special harmonic homologies where the center is the ideal point orthogonal to the plane of the mirror. The *reflection in a line* g is a skew involution with axes g and g^*, where g^* is the ideal line of all planes orthogonal to g. Rotations about the axis g are examples of uniaxial collineations.

Affine and Euclidean classification of quadrics

From the viewpoint of the projective space $\mathbb{P}^3(\mathbb{F})$, the affine space $\mathbb{A}^3(\mathbb{F})$ can be defined by appointing any plane ω to be the 'plane at infinity' and focusing on elements outside ω, *i.e.*, on finite points, lines, and planes. Affine transformations are collineations which keep the plane at infinity fixed. In order to classify quadrics $\mathcal{Q}$ in the real affine space $\mathbb{A}^3(\mathbb{R})$, we have to study the relation of $\mathcal{Q}$ and $\pi_\mathcal{Q}$ to the plane ω.

If ω is self-conjugate, then the quadric $\mathcal{Q}$ is a *paraboloid*. Each finite line l through the point of contact with ω is called a *diameter line* of $\mathcal{Q}$. Its polar line l^* lies in ω, and the skew involution with the axes l and l^*, which maps $\mathcal{Q}$ onto itself, is an *affine reflection* in l. This characterizes l as an axis of affine symmetry. Each plane through l is the axial plane of an affine reflection which also leaves the paraboloid invariant.

Paraboloids can be oval or ruled and accordingly, they are called *elliptic* or *hyperbolic*. In the latter case, the paraboloid intersects ω along two lines, taken from different reguli. Therefore, all finite generators of each regulus of $\mathcal{Q}$ are parallel to a fixed plane.

If the pole M of ω is finite, then M is called the *center*, and the quadric is a *central quadric*. The harmonic homology with the center M and axis ω, which maps $\mathcal{Q}$ onto itself, is the reflection in M and shows that M is a center of symmetry. When $MA_1A_2A_3$ is a self-polar tetrahedron, then the edges through M form a *triplet of conjugate diameters.* The polar line of the diameter line $l_1 = [M, A_1]$ is $l_1^* = [A_2, A_3]$ at infinity. The affine reflection in l maps $\mathcal{Q}$ onto itself.

When the induced polarity in ω is elliptic, $\mathcal{Q}$ is an *ellipsoid.* The self-polar tetrahedra are of type (ii). Each line through M is an edge of a self-polar tetrahedron and carries two real points of $\mathcal{Q}$.

A hyperbolic polarity in ω belongs to a *hyperboloid* $\mathcal{Q}$. In this case, the tangent cone with apex M contacts the hyperboloid along its curve at infinity; this cone is called *asymptotic cone.* It depends on the type of the self-polar tetrahedra whether the hyperboloid $\mathcal{Q}$ is oval or ruled. In the first case, each triplet of conjugate diameters contains only one axis with real points of $\mathcal{Q}$, while the existence of a tetrahedron of type (iii) yields two axes with real points. Accordingly, the hyperboloids are two-sheeted or one-sheeted, respectively. Quadratic cones with an apex at infinity are, of course, quadratic *cylinders.*

It can be shown that, for each regular quadric in $\mathbb{A}^3(\mathbb{R})$, there exists a coordinate frame such that the equation can be reduced to one of the normal forms, as listed in Theorem 3.1.1, but where all coefficients α_i are equal to 1.

When classifying quadrics w.r.t. Euclidean transformations, we must additionally analyse the relation between the quadrics and the absolute polarity in ω.

In the case of a paraboloid $\mathcal{Q}$, let U denote its point of contact with ω. The absolute polar u of U has a polar line u^* w.r.t. $\mathcal{Q}$, and this is the *axis* of the paraboloid $\mathcal{Q}$, because the skew involution with axes u and u^* is the *reflection* in u^*, which maps the paraboloid onto itself. There are two cases to be distinguished:

(i) Either there are exactly two tangents t_1, t_2 at U which are polar w.r.t. $\mathcal{Q}$ and at the same time conjugate w.r.t. the absolute polarity. Then, the planes $[t_1, u^*]$ and $[t_2, u^*]$ are the only planes of symmetry. The reflection in each of these planes maps the paraboloid onto itself.

(ii) When the absolute polarity as well as $\pi_{\mathcal{Q}}$ induce the same involution in the pencil of lines $\mathcal{L}_{U,\omega}$ or, in other words, when the complex conjugate lines of intersection between an elliptic paraboloid and ω are tangents of the absolute conic, then each plane through u^* is a plane of symmetry, and $\mathcal{Q}$ is a paraboloid of revolution.

In the case of central quadrics $\mathcal{Q}$, the induced polarity in ω and the absolute polarity share at least one common self-polar triangle $A_1A_2A_3$ (see [46, p. 278]). Then, the diameter lines $[M, A_i]$ are axes of symmetry of $\mathcal{Q}$, and the self-polar tetrahedron is called the *principal self-polar tetrahedron* of $\mathcal{Q}$. In the following two cases, the axes of $\mathcal{Q}$ are not unique:

(i) When the quadric $\mathcal{Q}$, which can also be imaginary, has a two-point contact with the absolute conic, each real point A_1 on the common chord is a point of a principal self-polar tetrahedron, and $\mathcal{Q}$ is a surface of revolution, an ellipsoid or a hyperboloid.

(ii) When the induced polarity π_ω is the absolute polarity, then, in the case of a hyperbolic polarity $\pi_{\mathcal{Q}}$, the quadric $\mathcal{Q}$ is a *sphere*.

Finally, a few words about elliptic polarities π: On each line l through the pole M of ω, the induced involution is elliptic. Consequently, there exist two points $P, P' \in l$ which are conjugate w.r.t. π and symmetric w.r.t. M. The harmonic homology γ with center M and axial plane ω is the reflection in M and leaves π invariant, which means $\widehat{\gamma} \circ \pi \circ \gamma = \pi$, hence $\widehat{\gamma} \circ \pi = \pi \circ \gamma$. In this case, the product $\pi' := \pi \circ \gamma$ is also self-adjoint, since

$$\widehat{\pi}' \circ \pi' = (\widehat{\pi} \circ \widehat{\gamma}) \circ (\pi \circ \gamma) = \widehat{\pi} \circ \pi = \mathrm{id}_{\mathcal{P}}.$$

The point M is also the pole of ω w.r.t. this composed polarity π'. If, on any line l through M, the points P and P' are conjugate w.r.t. π and symmetric w.r.t. M, then $\pi' = \pi \circ \gamma$ maps P via P' to the plane $\pi(P')$ which passes through P. Hence, P is self-conjugate w.r.t. π'. This holds for each diameter line l. Therefore, the self-polar tetrahedra are of type (ii), and π' is the polarity w.r.t. an ellipsoid with center M. Thus, we proved

Theorem 4.2.11 *Each elliptic polarity in the projective extension of* $\mathbb{E}^3$ *is the commutative product of the polarity w.r.t. an ellipsoid* $\mathcal{Q}$ *and the reflection in the center of the ellipsoid. This composition is called the anti-polarity w.r.t.* $\mathcal{Q}$*.*

If the ellipsoid $\mathcal{Q}$ is given in standard form, then the respective symmetric matrices $\mathbf{M}_{\mathcal{Q}}$ of $\mathcal{Q}$ and $\mathbf{M}$ of the elliptic polarity are

$$\mathbf{M}_{\mathcal{Q}} = \operatorname{diag}\left(-1, \frac{1}{a^2}, \frac{1}{b^2}, \frac{1}{c^2}\right) \quad \text{and} \quad \mathbf{M} = \operatorname{diag}\left(1, \frac{1}{a^2}, \frac{1}{b^2}, \frac{1}{c^2}\right)$$

In the literature, the ellipsoid $\mathcal{Q}$ is sometimes called the *real representative* of the imaginary quadric, associated with the elliptic polarity.

Since the field of complex numbers is algebraically closed, in the complex extension of $\mathbb{P}^3(\mathbb{R})$, every polarity π with a real symmetric transformation matrix $\mathbf{M}$ defines a quadric as the set of self-conjugate points. With each complex point P, the complex conjugate $\overline{P}$ is also self-conjugate. In the case of an elliptic polarity π, we call this quadric *empty* or *imaginary*.

Moreover, in the complex extension, every quadric is ruled, and it contains pairs of complex conjugate generators. When the polarity π is elliptic, the generators must be complex of the second kind, since otherwise pairs of complex conjugate generators would intersect at a real self-conjugate point. This means that complex conjugate generators of an imaginary quadric belong to the same regulus. On the other hand, the generators of oval quadrics are imaginary of the first kind, and the pairs of complex conjugate generators belong to different reguli. In particular, the generators of a sphere are isotropic. The intersection of a sphere with any tangent plane is a null circle consisting of two complex conjugate isotropic lines of the first kind.

If a polarity is elliptic and the induced polarity in ω equals the absolute polarity, we call the corresponding imaginary quadric of self-conjugate points an *imaginary sphere*. Its generators are isotropic of the second kind.

- **Exercise 4.2.1** Equations of a ruled quadric.

Find a coordinate transformation which transforms the equation $x_0x_3 - x_1x_2 = 0$ of a ruled quadric, as given in Theorem 4.2.5, to the standard form $x_0^2 + x_1^2 - x_2^2 - x_3^3 = 0$ given in Theorem 4.2.9.

- **Exercise 4.2.2** Polarity w.r.t. a ruled quadric.

Prove the following statements:

(i) *Let an arbitrary line l intersect a generator e of the ruled quadric $\mathcal{Q}$. Then, also the polar line l^* of l w.r.t. $\mathcal{Q}$ intersects the generator e.*

(ii) *If the four sides of the (non-planar) quadrangle $A_1 \dots A_4$ are generators of $\mathcal{Q}$, then the two diagonals $[A_1, A_3]$ and $[A_2, A_4]$ are polar w.r.t. $\mathcal{Q}$.*

• Exercise 4.2.3 Two pairs of polar lines.

Prove the following statement concerning the complex extension of $\mathbb{P}^3(\mathbb{R})$: *Let* (g, g^*) *and* (h, h^*) *be two pairs of polar lines. Then, the four lines* g, g^*, h, h^* *belong to a regulus if, and only, if they intersect two different self-polar lines* e_1 *and* e_2.

• Exercise 4.2.4 Reducible intersection of two quadrics.

Prove the following statement: *If two quadrics* $\mathcal{Q}_1, \mathcal{Q}_2$ *in* $\mathbb{P}^3(\mathbb{R})$ *contact each other at two points* P, Q, *and the common chord* $l = [P, Q]$ *and the intersection* $l^* = \tau_P \cap \tau_Q$ *of the corresponding tangent planes are skew, then all common points of the quadrics are located in two planes through* l, *which can also coincide or be complex conjugate. This is true also when one or both quadrics are quadratic cones.*

Hint: Choose a coordinate frame with the first two base points at P and Q and the two remaining base points on l^*. Common points of $\mathcal{Q}_1$ and $\mathcal{Q}_2$ satisfy all linear combinations of the quadrics' equations. There is a linear combination of the representing symmetric matrices with zeros in the first two lines and rows (see also Theorem 6.9.2).

• Exercise 4.2.5 Proof of Theorem 2.4.4.

Prove the statements of Theorem 2.4.4 concerning cones (or cylinders) passing through two different conics c and d of a regular quadric $\mathcal{Q}$.

Hint: Let l denote the line of intersection between the planes of c and d, and select any point $C \in l$ in the exterior of $\mathcal{Q}$ as the center of a projection into the polar plane γ of C. Then in the image plane γ, there are one or two centers V of planar harmonic homologies which map the contour of $\mathcal{Q}$ onto itself and exchange the contour points of c with those of d. Each homology can be continued to a harmonic homology in the 3-space which preserves $\mathcal{Q}$ and sends c to d. This confirms that its center V is the apex of a quadratic cone through c and d.

The last statement in Theorem 2.4.4 follows by dualization.

• Exercise 4.2.6 Projective generation of quadrics in projective 3-space.

Given two different points P, Q in $\mathbb{P}^3(\mathbb{F})$, let $\kappa\colon \mathcal{L}_P \to \mathcal{E}_Q$ be a projective correlation between the bundles with respective carriers P and Q. Then, the set of points of intersection $X = x \cap \kappa(x)$ is a regular or singular quadric. Conversely, each quadric can be generated in this way.

Hint: Choose a coordinate frame with $P = (1:0:0:0)$ and $Q = (0:0:0:1)$. Note that for describing a quadric in the form $\mathbf{x}^{\mathrm{T}} \mathbf{A}\, \mathbf{x} = 0$, the matrix A need not be symmetric.

B. Odehnal et al., *The Universe of Quadrics*,
https://doi.org/10.1007/978-3-662-61053-4_4

The projective space is the proper setting for many properties of quadrics and associated polarities. It will be shown that, in the real projective 3-space, there are only two types of quadrics to be distinguished, ruled and non-ruled quadrics. With regard to polarities, there are three, apart from null polarities. The affine classification of quadrics can be done by analyzing their relative position to the plane at infinity.

In this chapter, we expect the reader to be already familiar with the basics of Projective Geometry in the plane as presented in [46, chapters 5–7].

4.1 Three-dimensional Projective Geometry

Models of projective spaces

To begin with, we give a short overview of the axiomatic approach to the projective 3-space $\mathbb{P}^3$, called projective space for short. It consists of a set $\mathcal{P}$ of *points*, a set $\mathcal{L}$ of *lines*, and a set $\mathcal{E}$ of *planes*. Lines and planes are always considered as sets of points. Sometimes we emphasize this by calling them a *range of points*. Similarly, planes are considered as sets of points and lines, and we speak sometimes of a *field of points* or *field of lines*.

The set of planes through some line g is called *pencil of planes* $\mathcal{E}_g$ with the *carrier* or *axis* g. The set of lines through some point V is called *bundle* or *star of lines* $\mathcal{L}_V$, and the set of planes through V is the *bundle* or *star of planes* $\mathcal{E}_V$ with the *carrier* or *vertex* V. For a *pencils of lines*, *i.e.*, the set of lines through some point V in some plane ε, we use the notation $\mathcal{L}_{V,\varepsilon}$. Again, the point V is the *vertex* or *carrier* and ε is the *carrier plane* of this pencil. We use the symbols $\mathcal{P}_\varepsilon$ and $\mathcal{L}_\varepsilon$ for the sets of points and lines in the plane ε, respectively.

If, for some point $P \in \mathcal{P}$ and some line $l \in \mathcal{L}$, the relation $P \in l$ holds, we say that P *is contained in* the line l, P *is incident with* l, P *lies on* l, l *goes through* P, or l *passes through* P. A similar wording is used for the *incidence* $P \in \varepsilon$ of the point P with the plane ε and for the incidence $l \subset \varepsilon$ of the line l with ε. Any set of points on the same line is called *collinear* or *aligned*. Lines or planes through the same point are called *concurrent*, points and lines in the same plane are *coplanar*, and planes through the same line are *coaxial*.

The following list of *axioms* makes the triple $(\mathcal{P}, \mathcal{L}, \mathcal{E})$ a *three-dimensional projective space* or *projective 3-space* $\mathbb{P}^3$.

(A1) Any two different points $P \neq Q$ can be joined by a unique line $l = [P, Q]$, the *connecting* or *spanned* line.

(A2) Any point P and any line l with $P \notin l$ can be joined with a unique plane $[P, l]$, the *connecting* or *spanned* plane.

(A3) For any line l and plane ε with $l \not\subset \varepsilon$, there exists a unique common point $l \cap \varepsilon$, the *point of intersection* or *piercing point.*

(A4) There exist five points such that no four of them are coplanar. We call this quintuple a *fundamental figure* of $\mathbb{P}^3$.

Two projective spaces $\mathbb{P}^3 = (\mathcal{P}, \mathcal{L}, \mathcal{E})$ and $\mathbb{P}^{3\prime} = (\mathcal{P}', \mathcal{L}', \mathcal{E}')$ are called *isomorphic* if there exist bijective mappings $\kappa : \mathcal{P} \to \mathcal{P}'$, $\kappa^* : \mathcal{L} \to \mathcal{L}'$, and $\widehat{\kappa} : \mathcal{E} \to \mathcal{E}'$ such that each incidence $P \in l$, $P \in \varepsilon$, or $l \subset \varepsilon$ in $\mathbb{P}^3$ holds if, and only if, the respective incidence $\kappa(P) \in \kappa^*(l)$, $\kappa(P) \in \widehat{\kappa}(\varepsilon)$, or $\kappa^*(l) \subset \widehat{\kappa}(\varepsilon)$, holds in $\mathbb{P}^{3\prime}$. We also say that in this case the triples $(\mathcal{P}, \mathcal{L}, \mathcal{E})$ and $(\mathcal{P}', \mathcal{L}', \mathcal{E}')$ are *models* of the same abstract projective 3-space.

Below we present two three-dimensional projective spaces. As will be shown, the first is isomorphic to a particular case of the second.

(i) **The projectively closed Euclidean 3-space.** Similarly to the projective closure of the Euclidean plane in [46, p. 180], we begin with the Euclidean 3-space $\mathbb{E}^3$. We assign to each class of parallel lines in $\mathbb{E}^3$ a unique *ideal point* or *point at infinity* and define that each line out of this class passes through this ideal point. The set of all ideal points of the 3-space is called *ideal plane* or *plane at infinity.* If we concentrate only on lines parallel to a given plane ε, the set of associated ideal points is called *ideal line* or *line at infinity* of the plane ε. Obviously, parallel planes share their line at infinity.

Now, we define $\mathcal{P}$ as the union of the set of points of $\mathbb{E}^3$ and the set of all ideal points. $\mathcal{L}$ is the union of the set of lines of $\mathbb{E}^3$ with the set of ideal lines. Finally, we obtain $\mathcal{E}$ as the set of planes of $\mathbb{E}^3$, which is extended by the plane at infinity. It is easy to verify that the triple $(\mathcal{P}, \mathcal{L}, \mathcal{E})$ satisfies all axioms (A1) to (A4). The extended space is called the *projectively closed Euclidean 3-space* or the *real projective space*, and we denote it by $\mathbb{P}^3(\mathbb{R})$. Points, lines, and planes belonging to $\mathbb{E}^3$ are called *finite* or *proper* in the projective closure $\mathbb{P}^3(\mathbb{R})$.

Connecting the finite point P with an ideal point Q means drawing a parallel through P to some line of the class associated with Q. In order to obtain the connection of two different ideal points P and Q, we choose any finite point V. Then, $[P,Q]$ is the ideal line of the plane spanned by the lines $[V,P]$ and $[V,Q]$. The point of intersection of any finite line l with the plane at infinity is the ideal point of l. The line of intersection of any finite plane ε with the plane at infinity is the ideal line of ε.

(ii) **The vector space model of a projective space.** Let $\mathbb{F}$ be an arbitrary (commutative) field and $\mathbb{F}^4$ a four-dimensional vector space over $\mathbb{F}$. It can be shown that the set $\mathcal{P}$ of one-dimensional subspaces, the set $\mathcal{L}$ of two-dimensional subspaces, and the set $\mathcal{E}$ of three-dimensional subspaces of $\mathbb{F}^4$ defines a projective 3-space. We call it the *vector space model* of a projective space and denote it by $\mathbb{P}^3(\mathbb{F})$.

If point P is spanned by the non-zero vector $\mathbf{p} \in \mathbb{F}^4$, then, instead of $P = \{\lambda\mathbf{p} \,|\, \lambda \in \mathbb{F}\}$, we write $P = \mathbf{p}\mathbb{F}$ or sometimes only $P = \mathbf{p}$ for short. The line l spanned by the points $\mathbf{p}\mathbb{F}$ and $\mathbf{q}\mathbb{F}$ is written briefly as $l = \mathbf{p}\mathbb{F} + \mathbf{q}\mathbb{F}$, which means $l = \{\lambda_1\mathbf{p} + \lambda_2\mathbf{q} \,|\, (\lambda_1, \lambda_2) \in \mathbb{F}^2\}$, provided that $\mathbf{p}$ and $\mathbf{q}$ are linearly independent, which means that the two points are different. Similarly, for three linearly independent vectors $\{\mathbf{p}, \mathbf{q}, \mathbf{r}\}$, the plane spanned by the three corresponding points is denoted $\varepsilon = \mathbf{p}\mathbb{F} + \mathbf{q}\mathbb{F} + \mathbf{r}\mathbb{F}$.

Any basis $(\mathbf{b}_0, \dots, \mathbf{b}_3)$ of $\mathbb{F}^4$ gives rise to coordinates for each vector in $\mathbb{F}^4$ and also *homogeneous coordinates* for each point $P = \mathbf{p}\mathbb{F}$ in $\mathbb{P}^3(\mathbb{F})$, according to the rule

$$P = (x_0 : x_1 : x_2 : x_3) \iff \mathbf{p} = x_0\mathbf{b}_0 + \dots + x_3\mathbf{b}_3.$$

Apparently, the coordinates of points are only unique up to a common non-vanishing scalar.

Now, we show that the choice of a basis yields also homogeneous coordinates for each plane: The set of solutions of any linear equation

$$u_0x_0 + u_1x_1 + u_2x_2 + u_3x_3 = 0 \quad \text{with} \quad (u_0, \dots, u_3) \neq (0, \dots, 0)$$

is three-dimensional, and therefore, a plane of $\mathbb{P}^3(\mathbb{F})$. Conversely, a point $\mathbf{x}\mathbb{F}$ belongs to the plane $\varepsilon = \mathbf{p}\mathbb{F} + \mathbf{q}\mathbb{F} + \mathbf{r}\mathbb{F}$ if, and only if, the vectors $\{\mathbf{p}, \mathbf{q}, \mathbf{r}, \mathbf{x}\}$ are linearly dependent. In this case, the system of linear equations

$$\begin{aligned} u_0p_0 + \ \dots \ + u_3p_3 &= 0\\ u_0q_0 + \ \dots \ + u_3q_3 &= 0\\ u_0r_0 + \ \dots \ + u_3r_3 &= 0\\ u_0x_0 + \ \dots \ + u_3x_3 &= 0 \end{aligned}$$

with the unknowns $(u_0, \dots, u_3)$ has a one-dimensional solution, and $\mathbf{x}$ must satisfy the last linear equation. We call the coefficients $(u_0 : \dots : u_3)$ *homogeneous plane coordinates* of ε and write also $\varepsilon = \mathbf{u}\mathbb{F}$, if $\mathbf{u} := (u_0, \dots, u_3)$.[1] Using the notation $\langle \cdot , \cdot \rangle$ for the standard scalar product, we can state:

Lemma 4.1.1 *Point* $\mathbf{x}\mathbb{F}$ *lies in the plane* $\mathbf{u}\mathbb{F}$ *if, and only if,* $\langle \mathbf{u}, \mathbf{x} \rangle = 0$.

A change of the basis in $\mathbb{F}^4$ yields new coordinates for each point. Due to a standard result of Linear Algebra, there is a regular 4×4 *transformation matrix* $\mathbf{T}$ such that for each point the *old* coordinates $(x_0 : \dots : x_3)$ and the *new* ones $(x'_0 : \dots : x'_3)$ are related in matrix form by

$$\begin{pmatrix} x'_0 \\ \vdots \\ x'_3 \end{pmatrix} = \mathbf{T} \begin{pmatrix} x_0 \\ \vdots \\ x_3 \end{pmatrix}.$$

Because of the homogeneity of the point coordinates, the transformation matrix $\mathbf{T}$ is unique only up to a non-vanishing scalar. Note that we still retain the convention introduced in Chapter 3 of writing coordinate vectors as columns.

Instead of choosing a basis of $\mathbb{F}^4$ for coordinatizing the projective space $\mathbb{P}^3(\mathbb{F})$, we can proceed in a more geometric way by specifying any fundamental figure $(A_0, \dots, A_3, E)$ in $\mathbb{P}^3(\mathbb{F})$:

If $A_i = \mathbf{a}_i\mathbb{F}$ for $i = 0, \dots, 3$, then $\{\mathbf{a}_0, \dots, \mathbf{a}_3\}$ is a basis of $\mathbb{F}^4$. This yields for the fifth point $E = \mathbf{e}\mathbb{F}$ a representation

$$\mathbf{e} = \lambda_0\mathbf{a}_0 + \dots + \lambda_3\mathbf{a}_3 \quad \text{with} \quad \lambda_0 \dots \lambda_3 \neq 0.$$

Now, we use $\mathbf{a}'_i = \lambda_i\mathbf{a}_i$ as the new coordinate vector of A_i for each $i \in \{0, \dots, 3\}$. The new basis $\{\mathbf{a}'_0, \dots, \mathbf{a}'_3\}$ brings about a coordinatization of $\mathbb{P}^3(\mathbb{F})$ with the following properties.

---

[1] In the language of Linear Algebra, planes are one-dimensional spaces in the dual space of $\mathbb{F}^4$, which can also be introduced in a coordinate-free way as the space of linear forms over $\mathbb{F}^4$.

Theorem 4.1.1 *For each fundamental figure* $(A_0,\dots,A_3,E)$ *in* $\mathbb{P}^3(\mathbb{F})$, *there is a coordinate frame such that* $A_0 = (1:0:0:0)$, $\dots$, $A_3 = (0:0:0:1)$ *and* $E = (1:1:1:1)$. *The points* $A_0,\dots,A_3$ *are called base points of this frame, and point* E *is the unit point.*

Finally, we show that, in the projectively closed Euclidean 3-space, we can introduce homogeneous coordinates as well. This will confirm that this projective space is isomorphic to the projective 3-space over the field of real numbers, which justifies the introduced notation $\mathbb{P}^3(\mathbb{R})$.

It is quite natural to start with a Cartesian coordinate frame in the Euclidean 3-space $\mathbb{E}^3$, though the same procedure could be performed with affine coordinates: If (x_P, y_P, z_P) are the coordinates of any (finite) point P, we extend them by adding 1 as the first coordinate, and we permit that these four coordinates can be multiplied with any factor $\lambda \in \mathbb{R}\setminus\{0\}$.[2] If Q is the point at infinity of a line with direction vector (x_Q, y_Q, z_Q), then we insert 0 as additional coordinate at the beginning. Of course, the direction vector is unique only up to a non-vanishing scalar. Thus, we assigned to each point in the projective extension of $\mathbb{E}^3$ four homogeneous coordinates.

Conversely, from any given coordinates $(x_0:\dots:x_3)$ with $(x_0,\dots,x_3) \neq (0,\dots,0)$, we can retrieve the original point: In the case $x_0 \neq 0$, we get

$$(x,y,z) = \left(\frac{x_1}{x_0}\,,\ \frac{x_2}{x_0}\,,\ \frac{x_3}{x_0}\right).$$

In the case $x_0 = 0$, the vector $(x_1,x_2,x_3) \neq (0,0,0)$ gives the direction of the point at infinity.

We call these particular homogeneous coordinates *homogeneous Cartesian coordinates*. In the language of $\mathbb{P}^3(\mathbb{R})$, the base points of this coordinate frame are the origin and the ideal points of the coordinate axes. The unit point has the Cartesian coordinates $(x,y,z) = (1,1,1)$.

First consequences of the axioms

From the four axioms of projective 3-spaces (A1)–(A4) we can deduce a sequence of statements, as listed below.

---

[2] The same extension of coordinates was already used in Chapter 3 when extended coefficient matrices of linear mappings and quadrics were introduced.

- If $P, Q \in \varepsilon$, then $[P, Q] \subset \varepsilon$, and vice versa.

- For any three non-collinear points P, Q, R, *i.e.*, for each *triangle*, there exists a unique plane ε with $P, Q, R \in \varepsilon$, which is denoted by $[P, Q, R]$ and called the *connecting* or *spanned* plane.

- Each plane contains at least a *quadrangle*, *i.e.*, four coplanar points such that no three of them are collinear.

- Any two different planes ε, ψ have exactly one line in common, the *line of intersection* $l = \varepsilon \cap \psi$.

- If two different lines g, h share a point, then they are coplanar, hence spanning a plane $[g, h]$. Conversely, any two different but coplanar lines have exactly one point in common, the *point of intersection*.

Thus, we can state:

- For each plane ε in $\mathbb{P}^3$, the incident points and lines, *i.e.*, the sets $\mathcal{P}_\varepsilon$ and $\mathcal{L}_\varepsilon$, form a projective plane (see, *e.g.*, [46, Sec. 5.1]).

Each set of four non-coplanar points $\{O, P, Q, R\}$ is called a *tetrahedron* with the six *edges* $[O, P], \dots, [Q, R]$. Let ε denote the plane $[P, Q, R]$. Then, the mapping

$$\pi\colon\ \mathbb{P}^3 \setminus \{O\} \to \mathcal{P}_\varepsilon,\ X \mapsto \pi(X) = [X, O] \cap \varepsilon,$$

is called a *projection* with *center* O and *image plane* ε.

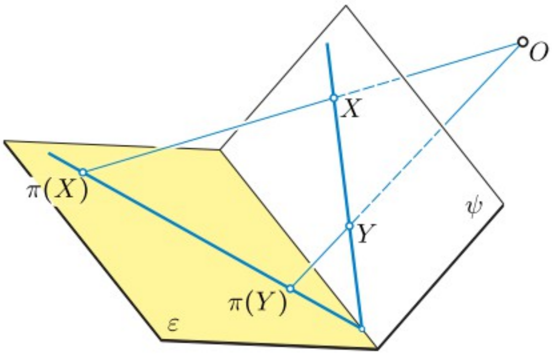

FIGURE 4.1. The projection $\pi\colon X \mapsto \pi(X)$ with center O and image plane ε.

The restriction of the projection π to any plane ψ not passing through O is bijective and preserves the collinearity of points (Figure 4.1). Hence, this is a collineation $\mathcal{P}_\psi \to \mathcal{P}_\varepsilon$. As a consequence, for any two planes ε, ψ

in $\mathbb{P}^3$, the induced projective planes are isomorphic in the sense of [46, p. 179].

- Conversely, if for two different planes ε, ψ in $\mathbb{P}^3$ there is a collineation $\lambda\colon\ \mathcal{P}_\varepsilon \to \mathcal{P}_\psi$, where each point of the line of intersection $\varepsilon \cap \psi$ remains fixed, then λ is the restriction of a projection.
- There exist pairs of *skew* lines in $\mathbb{P}^3$, *i.e.*, lines g, h having no point in common and being non-coplanar.

In each projective space $\mathbb{P}^3$, there exist five planes such that no four share a point. For example, given a fundamental figure $\{P_0, \dots, P_4\}$, the five planes $[P_0, P_1, P_2]$, $[P_1, P_2, P_3]$, $\dots$, $[P_4, P_0, P_1]$ have this property. Hence, similar to projective planes [46, p. 182], for each three-dimensional projective space $\mathbb{P}^3$, we can state the

Principle of Duality. *Any valid theorem formulated in terms of points, lines, planes, connection, intersection, and incidence remains true if we interchange the words points and planes, intersection and connection, but keep lines as lines and all incidences between points, lines, or planes.*

In other words, if $\mathbb{P}^3 = (\mathcal{P}, \mathcal{L}, \mathcal{E})$ is a projective space, then $\widehat{\mathbb{P}}^3 = (\mathcal{E}, \mathcal{L}, \mathcal{P})$ is also a projective space provided that we switch $\in$ and $\ni$ as well as $\subset$ and $\supset$. The space $\widehat{\mathbb{P}}^3$ is called the *dual space* of $\mathbb{P}^3$. When any statement is dualized, the obtained new result is called the *dual*.

The proof of the principle of duality consists in verifying that, from the axioms (A1) to (A4), all respective dual statements can be concluded, and this has already been done above.

In this spatial duality, the fields of points correspond to stars of planes, and the fields of lines (or ruled planes) to stars of lines. Therefore, for all points V, the pair $(\mathcal{E}_V, \mathcal{L}_V)$ is a projective plane, as well as $(\mathcal{L}_V, \mathcal{E}_V)$.

We recall that a projective plane is called a *Fano plane* if the axiom of FANO holds, *i.e.*, for each quadrangle the three diagonal points are not collinear. Similarly, we call a projective 3-space a *Fano space* if it contains a Fano plane.

Since any two planes are isomorphic, all quadrangles in a Fano space have a diagonal triangle. The principle of duality in the plane guarantees that, for the dual of a quadrangle, a *quadrilateral*, the three diagonals are never concurrent. It can be shown that $\mathbb{P}^3(\mathbb{F})$ is a Fano plane if, and only if, the characteristic of the field $\mathbb{F}$ is different from two (note [46, p. 184]. Otherwise, we speak of an *Anti-Fano plane*.

In this book, we will mainly focus on Fano planes without specifying so. Only in very exceptional cases, we will assume that this axiom does not hold.

For the axiomatic approach to projective planes, two other axioms are important, the axiom of DESARGUES and the axiom of PAPPUS (note [18], [46, p. 185–187], or [57]).

The first one states that if two triangles are perspective to a point, then their sides are perspective to a line. In other words, if, for two given triangles $P_1P_2P_3$ and $Q_1Q_2Q_3$, the points P_i, Q_i are collinear with a point (*perspector*) Z for $i = 1, 2, 3$, then the pairs of sides $([P_1, P_2], [Q_1, Q_2])$, $([P_2, P_3], [Q_2, Q_3])$, and $([P_3, P_1], [Q_3, Q_1])$ are concurrent with a line (*perspectrix*) a.

The axiom of Desargues guarantees the existence of perspective collineations in the plane. Furthermore, it can be proved that any Desarguesian plane is isomorphic to a projective plane $\mathbb{P}^2(\mathbb{F})$ over a field $\mathbb{F}$ which needs not be commutative (see [18]).

The situation in projective spaces is quite different:

- In each plane of a projective 3-space, the axiom of Desargues holds.

Proof: Suppose that the two triangles $\overline{P_1}\,\overline{P_2}\,\overline{P_3}$ and $Q_1Q_2Q_3$ in different planes are perspective w.r.t. $\overline{Z}$ (Figure 4.2). Then, the points $\{\overline{Z}, \overline{P_1}, \overline{P_2}, Q_1, Q_2\}$ are coplanar. Therefore, the sides $[\overline{P_1}, \overline{P_2}]$ and $[Q_1, Q_2]$ share a point A_3 on the line of intersection $a = [\overline{P_1}, \overline{P_2}, \overline{P_3}] \cap [Q_1, Q_2, Q_3]$. A cyclic permutation of the subscripts reveals that the sides of the two triangles are perspective w.r.t. a.

If two triangles $P_1P_2P_3$ and $Q_1Q_2Q_3$ belong to the same plane π and are perspective w.r.t. a point Z, we can confine ourselves to the case that the seven points $P_1, \dots, Q_1, \dots, Z$ are mutally different. Now, we interpret the scene as a projection of the spatial situation. This means that we choose a point $O \notin \pi$ and, on the line $[O, Z]$, another point $\overline{Z} \neq O, Z$. Then, there exist the points $\overline{P_i} = [O, P_i] \cap [\overline{Z}, Q_i]$ for $i = 1, 2, 3$, which do not belong to π. This results in a triangle $\overline{P_1}\,\overline{P_2}\,\overline{P_3}$ which is perspective to $Q_1Q_2Q_3$ w.r.t. $\overline{Z}$. Due to the spatial version of Desargues's theorem, the sides of these two triangles are perspective w.r.t. $a = [\overline{P_1}, \overline{P_2}, \overline{P_3}] \cap \pi$. The point of intersection $[P_1, P_2] \cap [\overline{P_1}, \overline{P_2}]$ must coincide with $A_3 = [P_1, P_2] \cap [Q_1, Q_2]$, which, after cyclic permutation of the subscripts, proves the original planar version. ■

Finally, we call a projective space a *Pappian space*, if it contains a Pappian plane. Again, the isomorphy between any two planes guarantees that each plane is Pappian.

A standard result from the theory of projective planes states that each Pappian plane is isomorphic to a projective plane $\mathbb{P}^2(\mathbb{F})$ over a commu-

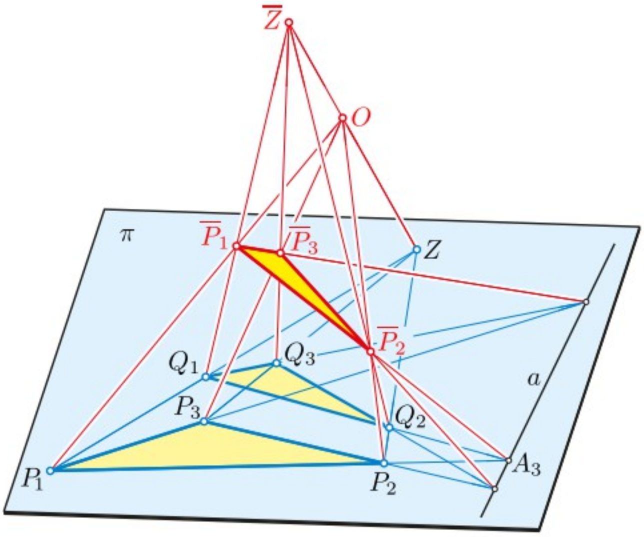

FIGURE 4.2. Proof of Desargues's theorem for the perspective triangles $P_1P_2P_3$ and $Q_1Q_2Q_3$ via the spatial version with the triangle $\overline{P}_1\overline{P}_2\overline{P}_3$.

tative field $\mathbb{F}$ (see [18]). Hence, the projective space $\mathbb{P}^3(\mathbb{F})$, as introduced above, is Pappian.

Collineations, perspectivities, and projectivities

Definition 4.1.1 A *collineation* $\kappa : \mathbb{P}^3 \to \mathbb{P}^{3\prime}$ between two projective spaces is a mapping that sends points to points and satisfies the following two conditions:

(1) Collinear points are mapped to collinear points.

(2) The mapping is one-to-one and onto.

Apparently, each isomorphism of $\mathbb{P}^3 = (\mathcal{P}, \mathcal{L}, \mathcal{E})$ to $\mathbb{P}^{3\prime} = (\mathcal{P}', \mathcal{L}', \mathcal{E}')$ defines a collineation $\kappa\colon \mathcal{P} \to \mathcal{P}'$. However, the converse is also true:

- Each collineation $\mathbb{P}^3 \to \mathbb{P}^{3\prime}$, defined as a mapping $\kappa\colon \mathcal{P} \to \mathcal{P}'$, induces an isomorphism between the two spaces, and hence the bijections $\kappa^*\colon \mathcal{L} \to \mathcal{L}'$ and $\widehat{\kappa} : \mathcal{E} \to \mathcal{E}'$. Each incidence in $\mathbb{P}^3$ is equivalent to the incidence between the corresponding elements in $\mathbb{P}^{3\prime}$.

For a proof, the reader is referred to the literature, *e.g.*, to [18].

This result reveals that the restriction of any collineation $\kappa\colon \mathbb{P}^3 \to \mathbb{P}^{3\prime}$ to each plane ε of $\mathbb{P}^3$ is a (planar) collineation $\mathcal{P}_\varepsilon \to \mathcal{P}_{\widehat{\kappa}(\varepsilon)}$. The duality guarantees that the same is true for corresponding stars $\mathcal{E}_S$ and $\mathcal{E}_{\kappa(S)}$.

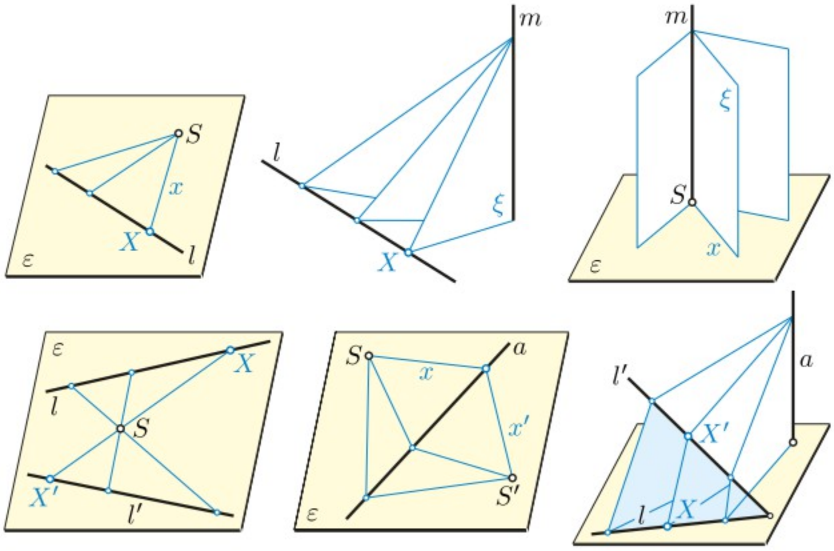

FIGURE 4.3. Perspectivities in the projective space: First row, from left to right: $l(X) \doublebarwedge S_\varepsilon(x)$, $l(X) \doublebarwedge m(\xi)$, and $S_\varepsilon(x) \doublebarwedge m(\xi)$; second row, from left to right: $l(X) \overset{S}{\doublebarwedge} l'(X')$, $S_\varepsilon(x) \overset{a}{\doublebarwedge} S'_\varepsilon(x')$, and $l(X) \overset{a}{\doublebarwedge} l'(X')$.

Now, we are going to extend perspectivities and projectivities from the projective plane to the projective 3-space.

Definition 4.1.2 Let $\mathcal{P}_l$, $\mathcal{L}_{S,\varepsilon}$ and $\mathcal{E}_m$ be, respectively, a range of points, a pencil of lines, and a pencil of planes. Any bijection between any two of these sets is called a *perspectivity* if corresponding elements are incident (Figure 4.3). We denote them for short $l \doublebarwedge S_\varepsilon$, $l \doublebarwedge m$, and $S_\varepsilon \doublebarwedge m$, respectively, or more extensively, by indicating corresponding elements, in the form

$$l(X) \doublebarwedge S_\varepsilon(x), \quad l(X) \doublebarwedge m(\xi), \quad S_\varepsilon(x) \doublebarwedge m(\xi),$$

or in opposite order.

Any composition of finitely many perspectivities is called a *projectivity* and usually expressed with the symbol $\barwedge$.

If, in particular, the lines l and l' are coplanar with S, we call the composition $l(X) \barwedge S_\varepsilon(x) \barwedge l'(X')$ a perspectivity $l \overset{S}{\barwedge} l'$ with *center* S. Similarly, we speak of a perspectivity $S_\varepsilon \overset{a}{\barwedge} S'_\varepsilon$ with the *axis* a for two coplanar pencils or pencils with a common carrier, when either $S_\varepsilon(x) \barwedge a(X) \barwedge S'_\varepsilon(x')$ or $S_\varepsilon(x) \barwedge a(\xi) \barwedge S_{\varepsilon'}(x')$, respectively. Finally, we speak of a perspectivity between two pencils of planes $l \overset{a}{\barwedge} l'$ with the axis a when $l(\xi) \barwedge a \barwedge l'(\xi')$ and the carriers l and l' are coplanar.

The perspectivities, as defined above in the projective 3-space, are extensions of those related to the projective plane. Therefore, the set of projectivities between ranges of points or pencils of lines seems to be larger than that of the planar counterparts. However, a detailed case analysis reveals that each 3-space projectivity between coplanar ranges of points or pencils of lines is also a projectivity in the sense of planar Projective Geometry. This justifies keeping the same notations. Furthermore, the *fundamental theorem* of plane geometry is still valid. This means (note [46, p. 190]):

Lemma 4.1.2 *In a Pappian projective space, any projectivity between ranges of points, or pencils of lines or planes, is uniquely defined by three pairs of corresponding elements.*

The following lemma is also an extension of a result from plane geometry.

Lemma 4.1.3 *A projectivity between two different ranges of points with coplanar carriers is a perspectivity if, and only if, the common element remains fixed.*

The same holds for projectivities between different pencils of lines that are either in a common plane or share a common center. Finally, a similar statement is valid for projectivities between two different pencils of planes with intersecting carriers.

On the other hand, we can adopt, from the vector model $\mathbb{P}^3(\mathbb{F})$, the statement (note [46, Theorem 5.4.1]):

Lemma 4.1.4 *Each projectivity between ranges of lines in $\mathbb{P}^3(\mathbb{F})$ can be described by a bijective linear mapping between the corresponding two-dimensional subspaces of $\mathbb{F}^4$.*

In this sense, the group $\mathrm{PGL}(l)$ of projective mappings of any line l onto itself in the projective space is not bigger than that in the projective plane. It equals the factor group $\mathrm{GL}(\mathbb{F},2)/\mathrm{D}(\mathbb{F})$ of the general linear group, where $\mathrm{D}(\mathbb{F})$ is the group of dilations, represented by all scalar multiples of the unit matrix $\mathbf{I}_2$ (note [46, Theorem 5.4.2]).

Definition 4.1.3 We call a collineation *projective* if its restriction to a range of points or to a pencil of lines or planes is a projectivity.

It is easy to verify that the restriction of a projective collineation to all ranges of points or pencils of lines or planes is a projectivity. Hence, the restriction to any plane is projective, too, and the projective collineations $\mathbb{P}^3 \to \mathbb{P}^3$ form a group.

From the projective plane, we recall that under projective collineations all *cross ratios* remain unchanged ([46, Theorem 5.3.1]), which in the vector model can be defined in the following way:

If, on the line $l = [A,B] = \mathbf{a}\mathbb{F} + \mathbf{b}\mathbb{F}$, two more points are given as $C = (\lambda_1\mathbf{a} + \lambda_2\mathbf{b})\mathbb{F}$ and $D = (\mu_1\mathbf{a} + \mu_2\mathbf{b})\mathbb{F}$, then

$$\mathrm{cr}(A,B,C,D) := \frac{\lambda_2}{\lambda_1}\frac{\mu_1}{\mu_2}. \tag{4.1}$$

We call $(\mu_1 : \mu_2)$ *projective coordinates* of the point D w.r.t. the coordinate frame with the *base points* A and B and the *unit point* $(\mathbf{a}+\mathbf{b})\mathbb{F}$.

Similarly, a quadrangle $A_0A_1A_2E$ defines in its spanned plane a projective coordinate frame with the *base points* $A_i = \mathbf{a}_i\mathbb{F}$, $i = 0,1,2$, and the *unit points* $E = (\mathbf{a}_0 + \mathbf{a}_1 + \mathbf{a}_2)\mathbb{F}$, which assigns to any point $P = (x_0\mathbf{a}_0 + x_1\mathbf{a}_1 + x_2\mathbf{a}_2)\mathbb{F}$ the homogeneous triplet $(x_0 : x_1 : x_2)$ as coordinates.

A fundamental theorem of Projective Geometry over commutative fields states:

Theorem 4.1.2 *Each projective collineation $\mathbb{P}^3(\mathbb{F}) \to \mathbb{P}^3(\mathbb{F})$ of a Pappian projective space onto itself can be described by a bijective linear mapping $f\colon \mathbb{F}^4 \to \mathbb{F}^4$. This mapping is unique up to a scalar.*

Conversely, any linear mapping $f : \mathbb{F}^4 \to \mathbb{F}^4$ induces a projective collineation $\kappa\colon \mathbb{P}^3(\mathbb{F}) \to \mathbb{P}^3(\mathbb{F})$ with $\mathbf{p}\mathbb{F} \mapsto f(\mathbf{p})\mathbb{F}$.

We learn from the real projective plane that, in the real projective space $\mathbb{P}^3(\mathbb{R})$, each collineation is projective.

By the same token, all collineations in $\mathbb{P}^3(\mathbb{F}) \to \mathbb{P}^3(\mathbb{F})$ are induced by bijective semilinear mappings $\mathbb{F}^4 \to \mathbb{F}^4$, *i.e.*, by the compositions of linear mappings with automorphisms of $\mathbb{F}$ (see, *e.g.*, [18, 57]). A standard example of a non-projective collineation in the complex extension $\mathbb{P}^3(\mathbb{C})$ of the real projective space $\mathbb{P}^3(\mathbb{R})$ is the *complex conjugation* ι, which replaces each coordinate by its complex conjugate value. This conjugation is involutive and exchanges each non-real point P, line g, or plane ε with its respectively *complex conjugate* element $\overline{P} = \iota(P)$, $\overline{l} = \iota^*(l)$, or $\overline{\varepsilon} = \widehat{\iota}(\varepsilon)$. Elements which remain fixed under ι are called *real*, as they are already included in $\mathbb{P}^3(\mathbb{R})$. Otherwise, we call them *non-real* or *imaginary*. Therefore, $P = \mathbf{p}\mathbb{F}$ is imaginary if, and only if, the vectors $\{\mathbf{p}, \overline{\mathbf{p}}\}$ are linearly independent. In this case, the connection of P and $\overline{P}$ is real. For the same reason, two different complex conjugate planes ε and $\overline{\varepsilon}$ contain a single real line, the line of intersection $\varepsilon \cap \overline{\varepsilon}$.

The situation for lines is slightly different: If a line contains two different real points, then it is real. However, the converse is also true: If the line $l = \mathbf{p}\mathbb{F} + \mathbf{q}\mathbb{F}$ remains fixed under the conjugation, which means that $l = \overline{\mathbf{p}}\,\mathbb{F} + \overline{\mathbf{q}}\,\mathbb{F}$, where both pairs of vectors $(\mathbf{p}, \overline{\mathbf{p}})$ and $(\mathbf{q}, \overline{\mathbf{q}})$ are linearly independent, then the two points $R = (\mathbf{p} + \overline{\mathbf{p}})\mathbb{F}$ and $S = (\mathbf{p} - \overline{\mathbf{p}})\mathbb{F}$ on l are real. Moreover, the two points R and S must be different.

For imaginary lines l and $\overline{l}$, there are two possibilities:

- Either, they intersect each other. Then, they share a real point and span a real plane. We call them *imaginary of the first kind.*
- Or, the lines l and $\overline{l}$ are skew. Then, l neither includes a real point nor does it belong to a real plane. Line l is called *imaginary of the second kind.*

Perspective collineations

Suppose that a collineation κ in the projective space $\mathbb{P}^3$ keeps all points of a plane ζ fixed. Then, this collineation is projective by Definition 4.1.3. Moreover we can prove:

Lemma 4.1.5 *If under a collineation $\kappa\colon \mathbb{P}^3 \to \mathbb{P}^3$ all points of a plane ζ remain fixed, then there exists a point Z with the property that all lines and planes through Z remain fixed, too, and vice versa.*

Proof: If a point $Z \notin \zeta$ remains fixed, *i.e.*, $\kappa(Z) = Z$, then each line g through Z is a connection of Z with another fixed point $g \cap \zeta$, and therefore, a fixed line. Furthermore, each plane through Z is the connection of two fixed lines.

There remains the case that, for all points $P \notin \zeta$, we have $\kappa(P) \neq P$. Then, the line $p = [P, \kappa(P)]$ is fixed, since its image $\kappa^*(p)$ is the connection of $\kappa(P)$ with the fixed point $p \cap \zeta$. For any other point $Q \notin p, \zeta$ the fixed line $q = [Q, \kappa(Q)]$ is coplanar with p, since $g = [P, Q]$ and $\kappa^*(g) = [\kappa(P), \kappa(Q)]$ meet at the point $g \cap \zeta$. The point $Z := p \cap q$ remains fixed as the intersection of two fixed lines. Hence, $Z \in \zeta$.

Each line x through Z must be fixed, too, since, in the case $x \notin \zeta$ and $x \neq p$, it contains any point $Q \notin \zeta, p$, and, by the same argument as used above, x equals the fixed line $[Q, \kappa(Q)] = q$.

The converse statement holds due to duality. ■

Definition 4.1.4 A collineation κ which keeps each point of a plane ζ and each plane through a point Z fixed is called *perspective collineation* with the *center* Z and the *axis* or *axial plane* ζ.

In the case $Z \in \zeta$, the collineation κ is called *elation* and otherwise *homology*.

All perspective collineations which share the center Z and the axis ζ form a group. We denote it by $\mathrm{PK}(Z, \zeta)$. A standard result of Projective Geometry states that the commutativity of this group is equivalent to the validity of the Pappus theorem.

Suppose that a perspective collineation $\kappa \in \mathrm{PK}(Z, \zeta)$, *i.e.*, with center Z and axis ζ, has another fixed point $P \neq Z$, $P \notin \zeta$. Then, each point $Q \notin [P, Z]$ remains fixed as the intersection of two fixed lines $[Q, Z]$ and $[Q, P]$. However, each point R on the fixed line $[P, Z]$ is also the intersection with another fixed line $[R, Q]$, and therefore, fixed. Hence, κ is the identity mapping $\mathrm{id}_{\mathbb{P}^3}$.

Lemma 4.1.6 *Any perspective collineation with center Z and axis ζ is uniquely defined by a pair of corresponding points P, P' collinear with Z and $P, P' \notin \zeta$.*

Proof: If there were two perspective collineations $\kappa, \lambda \in \mathrm{PK}(Z, \zeta)$ with $P \to P'$, then the product $\lambda^{-1} \circ \kappa$ keeps P fixed. This implies $\lambda^{-1} \circ \kappa = \mathrm{id}_{\mathbb{P}^3}$ and, consequently, $\kappa = \lambda$. ■

Homologies in the plane have a *characteristic cross ratio* defined by the pairs of corresponding points, the center, and the collinear point on the axis. The analogue in 3-space is also valid: For all points $X \neq Z$, $X \notin \zeta$, the cross ratio

$$\delta = \operatorname{cr}\bigl(Z, X_\zeta, X, \kappa(X)\bigr), \quad \text{where} \quad X_\zeta = \zeta \cap [Z, X],$$

is the same, since the restriction to any plane through Z has a characteristic cross ratio, and any two planes through Z share a line through Z (note Figure 4.4, left). A homology is involutive if, and only if, its characteristic cross ratio is -1. In this case, the pairs $(X, \kappa(X))$ are harmonic w.r.t. Z and the axis ζ; we speak of a *harmonic homology*.

Suppose that in a Pappian projective space $\mathbb{P}^3$, a projective collineation κ has a fundamental figure of fixed points $P_0, \dots, P_4$. Then, the restriction to the plane $\varepsilon = [P_0, P_1, P_2]$ has a quadrangle of fixed points, since $\varepsilon \cap [P_3, P_4]$ also remains fixed. Thus, this restriction is the identity, and the collineation κ is perspective with two more fixed points outside the axis ε. This yields $\kappa = \mathrm{id}_{\mathbb{P}^3}$. An immediate consequence is formulated below.

Theorem 4.1.3 *In Pappian projective spaces, for any two fundamental figures $P_0, \dots, P_4$ and $P'_0, \dots, P'_4$, there exists exactly one projective collineation with $P_i \mapsto P'_i$ for $i = 0, \dots, 4$.*

In other words, projective collineations act sharply transitive on fundamental figures. Since Pappian projective spaces are isomorphic to projective spaces over commutative fields, this result can also be concluded from Theorem 4.1.2.

After introducing a coordinate frame in $\mathbb{P}^3(\mathbb{F})$, each projective collineation $\kappa\colon (x_0 : \dots : x_3) \mapsto (x'_0 : \dots : x'_3)$ can be written in matrix form as

$$\kappa: \begin{pmatrix} x'_0 \\ \vdots \\ x'_3 \end{pmatrix} = \mathbf{M} \begin{pmatrix} x_0 \\ \vdots \\ x_3 \end{pmatrix}, \tag{4.2}$$

where $\mathbf{M}$ is a regular 4×4 matrix. Suppose that the image point lies in the plane with coordinates $(u'_0 : \dots : u'_3)$, which can be written in matrix form as $\mathbf{u}'^{\mathrm{T}}\mathbf{x}' = 0$. The coordinates $(u_0 : \dots : u_3)$ of the preimage satisfy the linear equation $\bigl(\mathbf{u}'^{\mathrm{T}}\mathbf{M}\bigr)\,\mathbf{u} = 0$. Therefore, the associated transformation of planes is given by

$$\widehat{\kappa}: \begin{pmatrix} u'_0 \\ \vdots \\ u'_3 \end{pmatrix} = \bigl(\mathbf{M}^{-1}\bigr)^{\mathrm{T}} \begin{pmatrix} u_0 \\ \vdots \\ u_3 \end{pmatrix}. \tag{4.3}$$

A point $(x_0 : \ldots : x_3)$ remains fixed under κ if, and only if, there exists $\lambda \in \mathbb{R} \setminus \{0\}$ with

$$\lambda \begin{pmatrix} x_0 \\ \vdots \\ x_3 \end{pmatrix} = \mathbf{M} \begin{pmatrix} x_0 \\ \vdots \\ x_3 \end{pmatrix}, \quad \text{and hence} \quad (\mathbf{M} - \lambda \mathbf{I}_4) \begin{pmatrix} x_0 \\ \vdots \\ x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ \vdots \\ 0 \end{pmatrix}$$

with $\mathbf{I}_4$ as unit matrix. This reveals that λ must be an eigenvalue of the matrix $\mathbf{M}$. Once an eigenvalue λ is found, it depends on the rank of the matrix $(\mathbf{M} - \lambda \mathbf{I}_4)$ whether we get a fixed point, a line, or a plane consisting of fixed points only. A k-fold eigenvalue effects a rank deficiency of at least 1 and at most k.

Note that, for each eigenvalue λ of $\mathbf{M}$, the reciprocal $1/\lambda$ is an eigenvalue of $\mathbf{M}^{-1}$, since $\det(\mathbf{M} - \lambda \mathbf{I}_4) = 0$ is equivalent to $\det[\mathbf{M}^{-1}(\mathbf{M} - \lambda \mathbf{I}_4)] = \det(\mathbf{I}_4 - \lambda \mathbf{M}^{-1}) = 0$, which defines fixed planes of $\widehat{\kappa}^{-1}$ and $\widehat{\kappa}$.

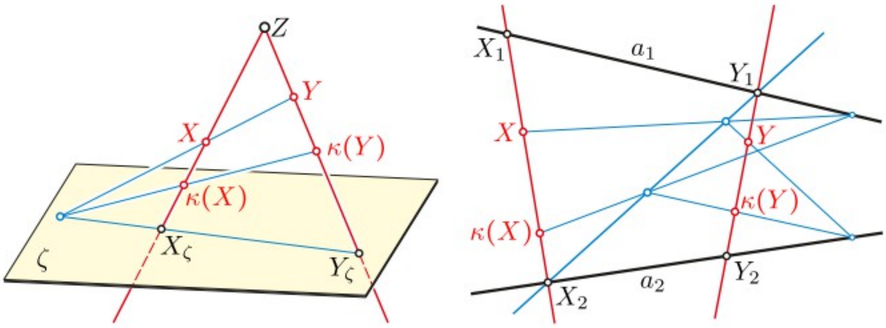

FIGURE 4.4. Left: characteristic cross ratio $\mathrm{cr}(Z, X_\zeta, X, \kappa(X))$ of a homology; Right: characteristic cross ratio $\mathrm{cr}(X_1, X_2, X, \kappa(X))$ of a biaxial collineation with axes a_1 and a_2.

In this way, we can classify projective collineations at hand of their configuration of fixed points. An appropriate tool, provided in Linear Algebra, is the Jordan normal form (see, *e.g.*, [53, 108]). For an algebraically closed field $\mathbb{F}$, there are already 13 different types to be distinguished, together with the identity $\mathrm{id}_{\mathbb{P}^3}$ (compare with (5.6) in Chapter 5). Otherwise, we obtain much more types. For example, in the real projective space, there are projective collineations without any fixed point, since the spectrum of $\mathbf{M}$ may consist of two pairs of complex conjugate eigenvalues.

Below, we concentrate on three types of projective collineations.

(i) The fixed points of a projective collineation κ can form a tetrahedron $A_0, \dots, A_3$. In this case, the restriction to each edge of the tetrahedron is a hyperbolic projectivity. If the fixed points are chosen as base points of a coordinate frame, we obtain a diagonal matrix $\mathbf{M}$ as analytic representation of κ.

(ii) If a projective collineation $\kappa \neq \mathrm{id}_{\mathbb{P}^3}$ has, besides a fixed tetrahedron, another fixed point F, then F must be located either in a face or on an edge. In the first case, κ is perspective. In the second case, κ has a line consisting of fixed points only, and the collineation is called *uniaxial*.

(iii) It is even possible that κ has two skew lines a_1 and a_2 with fixed points. We call such a collineation *biaxial* with the axes a_1 and a_2. Here all transversals, meeting both axes, remain fixed, and the restriction to each line is a hyperbolic projectivity. The restriction to any plane through one of the axes is a homology, and any plane through a_1 shares with any plane through a_2 a transversal. Therefore, the characteristic cross ratios in all these planes and on all transversals are the same. We call

$$\delta := \mathrm{cr}\left(X_1, X_2, X, \kappa(X)\right) \text{ with } X_i \in a_i,\ i = 1, 2, \tag{4.4}$$

the *characteristic cross ratio* of the biaxial collineation (Figure 4.4, right). The involutive case with $\delta = -1$ is sometimes called a *skew involution*.

• **Exercise 4.1.1** Projective collineations are products of perspective collineations.

Prove the following theorem: *In Pappian projective spaces, each projective collineation is the product of four perspective collineations at most.*

Hint: Reduce it to the two-dimensional analogue.

• **Exercise 4.1.2** Perspective collineation in vector form.

Prove that any perspective collineation κ in $\mathbb{P}^3(\mathbb{F})$ with center $\mathbf{z}\mathbb{F}$ and axis $\mathbf{u}\mathbb{F}$ can be represented as $\kappa\colon \mathbf{x}\mathbb{F} \mapsto \mathbf{x}'\mathbb{F}$, where $\mathbf{x}' = \mathbf{x} + \langle \mathbf{u}, \mathbf{x} \rangle \mathbf{z}$, provided that $1 + \langle \mathbf{u}, \mathbf{z} \rangle \neq 0$.

Metric relations between curvature radii and tangential distances

Curves can also be defined as envelopes of one-parameter families of lines. Each line is uniquely defined by a unit normal vector $\mathbf{n} = (\cos\varphi, \sin\varphi)$ and the oriented distance $d(\varphi)$ to the origin of the coordinate system such that $d\mathbf{n}$ is the position vector of the line's pedal point with respect to the origin. The function $d(\varphi)$ is called the *support function* of the curve.

The curvature and the support function of an ellipse fulfill a simple relation:

Theorem 3.2.1 *The curvature function κ and the support function d of an ellipse with semimajor axis a and semiminor axis b are related via*

$$\kappa = \frac{d^3}{a^2b^2}. \tag{3.19}$$

Proof: We shall have in mind that $x = a\cos t$ and $y = b\sin t$ (cf. (2.12)) holds for any point on the ellipse

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1. \tag{3.20}$$

After eliminating $\cos t$ and $\sin t$ from the curvature function given in (3.17), we arrive at an algebraic expression for the curvature:

$$\kappa(t) = \frac{a^4b^4}{\sqrt{(b^4x^2 + a^4y^2)^3}}. \tag{3.21}$$

Via the velocity vector of the ellipse at some point $P = (\xi, \eta)$, we obtain the Hesse normal form of the tangent at P as

$$t_P : \quad \frac{-b^2\xi\, x - a^2\eta\, y + a^2b^2}{\sqrt{b^4\xi^2 + a^4\eta^2}} = 0. \tag{3.22}$$

If we insert $\xi = \eta = 0$, we obtain the signed distance of t_P to the center of the ellipse,

$$d(x,y) = \frac{a^2b^2}{\sqrt{b^4x^2 + a^4y^2}} \tag{3.23}$$

Note that x and y in (3.23) have to fulfill (3.20). Combining (3.21) and (3.23) we can eliminate the nasty square root and obtain (3.19). ■

- **Exercise 3.2.2** Analyze the curvature function of the ellipse given in (3.19) and show that the vertices of the ellipse appear where the support function is stationary.

- **Exercise 3.2.3** Derive the analogous formula to (3.19) for hyperbolas.

A deeper result relating the curvature radii with metric values is due to the French mathematician JOSEPH LIOUVILLE (1809–1882) and given in

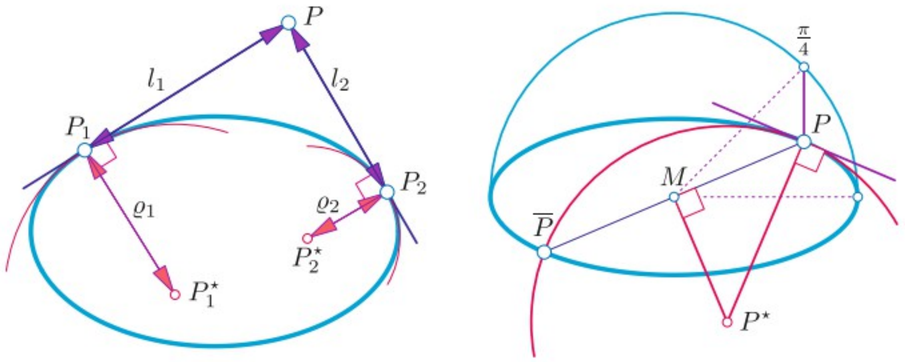

FIGURE 3.12. Left: The cube of the ratio $l_1 : l_2$ equals the ratio $\varrho_1 : \varrho_2$ of the curvatures at the two contact points P_1 and P_2. Right: For the particular point P, the osculating circle o_P meets the ellipse c at the antipode $\overline{P}$ of P.

Theorem 3.2.2 *Let P be an exterior point of a conic c. The two tangents from P to c touch at P_1 and P_2. Let $l_1 = \overline{P_1P}$ and $l_2 = \overline{P_2P}$ and let further $\varrho_1 = \kappa_1^{-1}$ and $\varrho_2 = \kappa_2^{-1}$ be the curvature radii of the conic at P_1 and P_2. Then,*

$$\frac{\varrho_1}{\varrho_2} = \left(\frac{l_1}{l_2}\right)^3$$

holds independently of the choice of P and the conic.

• **Exercise 3.2.4** Give a proof of Theorem 3.2.2 by assuming P_1 and P_2 are arbitrary points on an ellipse / hyperbola / parabola with the parametrizations

$$\text{ellipse} \quad \left(a\frac{1-t^2}{1+t^2}, b\frac{2t}{1+t^2}\right), \quad \text{hyperbola} \quad \left(a\frac{1+t^2}{1-t^2}, b\frac{2t}{1-t^2}\right), \quad \text{parabola} \quad \left(2qt^2, 2qt\right)$$

with $a, b, p \in \mathbb{R}$. Compute the intersection P of the tangents at P_1 and P_2, the distances $\overline{P_1P}$ and $\overline{P_2P}$, and the curvatures at the respective points on the conic.

In Figure 3.12 (left), the metric values mentioned in Theorem 3.2.2 are marked. Though Figure 3.12 shows only the case of an ellipse, Theorem 3.2.2 holds for hyperbolas and parabolas as well.

Figure 3.12 (right) shows another curious result. There are four points P on the ellipse (corresponding to the parameter values $t = \pm\frac{\pi}{4}$ and $t = \pm\frac{3\pi}{4}$ in the trigonometric parametrization (2.12)) whose osculating circles meet the ellipse in a pair $(P, \overline{P})$ of opposite points. In this special case, the center $P^\star$ of the osculating circle lies on the diameter line which is orthogonal to the diameter $[P, \overline{P}]$.

- **Exercise 3.2.5** Find a proof for the facts illustrated in Figure 3.12 (right).

- **Exercise 3.2.6** Vertices of a hyperbola. Show that there are two vertices $V_1 = (a, 0)$ and $V_2 = (-a, 0)$ on the hyperbola

$$h: \frac{x^2}{a^2} - \frac{y^2}{b^2} = 1 \quad \text{with} \quad ab \neq 0$$

by using the two parametrizations

$$\mathbf{h}(t) = (\pm a \cosh t, b \sinh t), \quad t \in \mathbb{R}$$

and compute the curvature (cf. the curvature plot in Figure 3.13)

$$\kappa = \mp \frac{ab}{(a^2 \sinh^2 t + b^2 \cosh^2 t)^{\frac{3}{2}}}.$$

The radius of the osculating circle at V_1 and V_2 equals $\varrho_1 = \varrho_2 = \frac{b^2}{a}$. As shown in Figure 3.14 (left), the centers $V_1^\star$ and $V_2^\star$ of the osculating (hyperosculating) circles at the hyperbola's vertices can be constructed in a simple way, provided that the vertex and at least one asymptote is known.

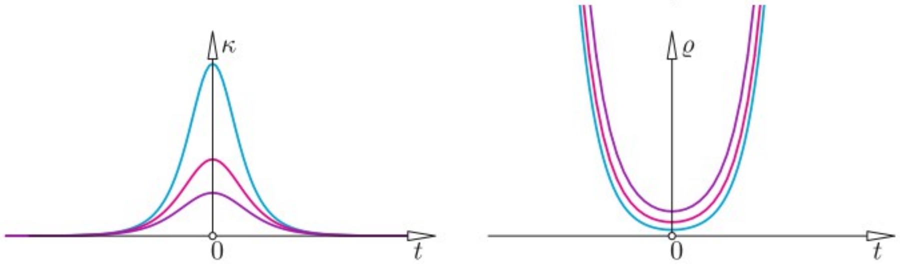

FIGURE 3.13. Curvature plot and the curvature radius function of the hyperbola for three different ratios of the semimajor and semiminor axes: 3 : 2 (blue), 1 : 1 (magenta), and 3 : 4 (violet).

- **Exercise 3.2.7** Vertex of a parabola. A parabola $p:\ x^2 = 2qy$ (with $q \in \mathbb{R} \setminus \{0\}$) can be given in parametric form as

$$\mathbf{p}(t) = (2qt, 2qt^2), \quad t \in \mathbb{R}.$$

Thus, the curvature radius function $\varrho = \frac{1}{\kappa}$ reads

$$\varrho = q(1 + 4t^2)^{\frac{3}{2}}.$$

Show that p has only one vertex $V = (0, 0)$ which corresponds to $t = 0$. The radius of the osculating circle at V equals $\varrho_0 = q$.

In Section 4.2 (Theorem 4.2.3, page 145) we learn that the *subnormals* (the orthogonal projections of the normal's segment between the curve and its principal axis onto the latter) of conics are linear functions in the abscissa. The parabola is more special: The subnormal is constant, and thus, independent of the point on the parabola as shown in Figure 3.14.

-7 - ?

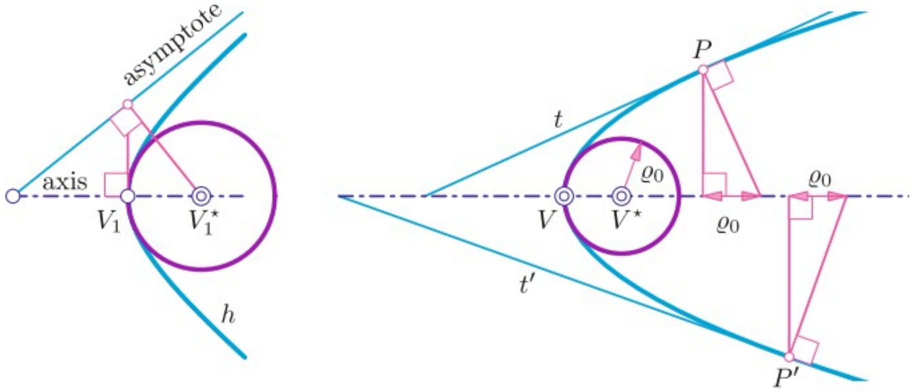

FIGURE 3.14. Left: The construction of the center $V_1^\star$ of the hyperbola's osculating circle at the vertex V_1. Right: The radius ϱ_0 of the osculating circle at a parabola's vertex V can be found if a line element, *i.e.*, a point $P \neq V$ plus incident tangent, is known.

Evolute of an ellipse

What about the osculating circle o_P for a generic point $P = \mathbf{c}(t_0)$ of an ellipse c? Assume that o is such a circle with center $P^\star$ (with coordinate vector $\mathbf{c}^\star$ and radius R). Locally, that means, in a sufficiently small neighborhood of a generic point $P = \mathbf{c}(t_0)$ on the ellipse c, the circle and the ellipse share the point, the tangent, and the curvature.

We can express these three conditions algebraically: The first condition yields

$$\langle \mathbf{c}(t) - \mathbf{c}^\star, \mathbf{c}(t) - \mathbf{c}^\star \rangle|_{t=t_0} = R^2,$$

i.e., a circle through $\mathbf{c}(t)$ (at any t) with the yet unknown center $\mathbf{c}^\star$ and radius R. Note that both, center and radius are constant at a certain point $P = \mathbf{c}(t_0)$. We differentiate once with respect to t and obtain

$$\langle \dot{\mathbf{c}}(t), \mathbf{c}(t) - \mathbf{c}^\star \rangle|_{t=t_0} = 0 \quad \Longrightarrow \quad \langle \mathbf{e}_1, \mathbf{c}(t) - \mathbf{c}^\star \rangle = 0 \tag{3.24}$$

where $(\mathbf{e}_1, \mathbf{e}_2)$ is the Frenet frame at P. The last equation tells us that the desired circle o is tangent to c at $P = \mathbf{c}(t_0)$, for its radius vector $\mathbf{c}(t) - \mathbf{c}^\star$ is perpendicular to the tangent t_P of c at P that aims in the direction $\dot{\mathbf{c}}(t)$ or $\mathbf{e}_1$. Thus, the center $P^\star$ of o is a point on the curve's normal at P.

We differentiate once again. With $\dot{\mathbf{c}} = v\kappa\mathbf{e}_2$ and $\langle \mathbf{e}_1, \mathbf{e}_1 \rangle = 1$, we find

$$v\langle \kappa\mathbf{e}_2, \mathbf{c}(t) - \mathbf{c}^\star \rangle|_{t=t_0} + v = 0 \tag{3.25}$$

which yields

$$\mathbf{c}^\star = \mathbf{c} + \frac{1}{\kappa}\mathbf{e}_2. \tag{3.26}$$

At this point we recall that, by virtue of (3.16), κ can be expressed in terms of the derivatives of the parametrization $\mathbf{c}(t)$ (with an arbitrary parameter t which does not necessarily agree with the arc length parameter).

We learned that $\mathbf{c}^\star$ is the center of the osculating circle or the *center of curvature*. The term *osculation* is explained for pairs of conics in a completely different way in Definition 6.4.1 (see Section 6.3) although the two separate approaches lead to the same circle.[10]

If t runs through the entire interval $J = [0, 2\pi[$, then $\mathbf{c}(t)$ parametrizes the ellipse and $\mathbf{c}^\star(t)$ parametrizes a curve called the *evolute of the ellipse.* The tangents of the evolute are the normals of the ellipse which follows from $\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{c}^\star = v\mathbf{e}_1 - \frac{\dot{\kappa}}{\kappa^2}\mathbf{e}_2 - \frac{v\kappa}{\kappa}\mathbf{e}_1 = -\frac{\dot{\kappa}}{\kappa^2}\mathbf{e}_2$. Figure 3.15 shows some ellipses together with their evolutes.

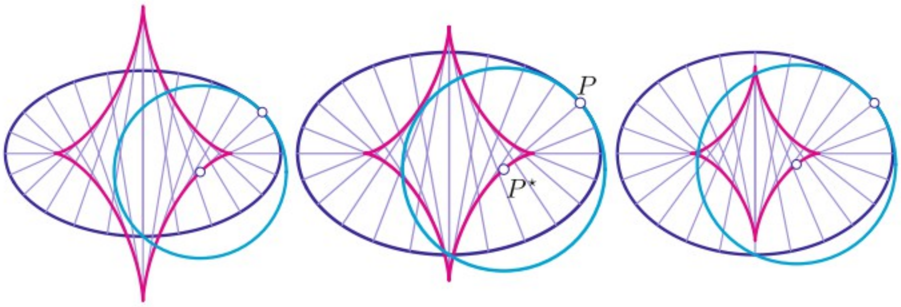

FIGURE 3.15. Evolutes of different ellipses being the envelopes of the ellipses' normals. The cusps of the evolute correspond to the vertices of the ellipse.

---

[10] Two C^r curves c and d are said to be in n-th order contact (with $n \le r$) if there exist parametrizations of both curves such that the derivatives of c and d agree up to order n. Sometimes this is called a C^n-contact. Two C^r curves are said to be in G^n-contact (geometric continuity of order $n \le r$) if the span of the first n derivative vectors of both curves agree. C^n-contact always implies G^n-contact, the converse is not true.

The projective differential geometric version deals with the first $n+1$ derivative points starting with $c(t_0)$ and $d(t_0)$ as the first derivatives.

We insert the parametrization (2.12) of the ellipse c into (3.26) and obtain a parametrization of the evolute as

$$\mathbf{c}^{\star}(t) = \frac{a^2 - b^2}{ab}\left(b\cos^3 t, -a\sin^3 t\right), \quad t \in J. \tag{3.27}$$

The evolute of an ellipse is an algebraic curve of degree six and class[11] four. The parametric representation (3.27) fulfills the algebraic equation

$$\left(\frac{x}{\alpha}\right)^{\frac{2}{3}} + \left(\frac{y}{\beta}\right)^{\frac{2}{3}} = 1 \tag{3.28}$$

with $\alpha = \frac{a^2-b^2}{a}$ and $\beta = \frac{a^2-b^2}{b}$ which is equivalent to the polynomial equation

$$\left((a^2-b^2)^2 - (a^2x^2+b^2y^2)\right)^3 - 27a^2b^2x^2y^2(a^2-b^2)^2 = 0.$$

The evolute of an ellipse has four cusps which are the centers of curvature of the four vertices, see Figure 3.15.

The scaling $(x, y) \mapsto (x', y') = \left(\frac{x}{\alpha}, \frac{y}{\beta}\right)$ transforms (3.28) into the *astroid* with the equation

$$x'^{\frac{2}{3}} + y'^{\frac{2}{3}} = 1.$$

For a generic point P on the ellipse $\mathbf{c}(t)$, there exists also an elementary construction of the center of curvature $P^{\star} = \mathbf{c}^{\star}(t)$, cf. Figure 3.16 (left):

Lemma 3.2.2 *Draw the tangent t_P and the normal n_P at $P \in c$. The normal intersects the principal axis in the point 1. The line parallel to t_P through 1 meets the ellipse's diameter through P in the point 2. The line $[2, P^{\star}]$ is parallel to the auxiliary axis of c, and $P^{\star}$ is the center of curvature which has to lie on the curve's normal n_P.*

Proof: We can verify the construction shown in Figure 3.16 (left) by a simple computation. We start with the trigonometric parametrization of c given in (2.12) and set $P = (a\cos t, b\sin t)$. For fixed t_0 we find a point P on c. Then, the tangent t_P and the normal n_P of e at P are given by the Cartesian equations

$$t_P: \ \frac{x\cos t}{a} + \frac{y\sin t}{b} = 1 \quad \text{and} \quad n_P: \ -\frac{x\sin t}{b} + \frac{y\cos t}{a} = \frac{b^2-a^2}{ab}\cos t\sin t.$$

---

[11] The class of a planar algebraic curve is, roughly speaking, the number of tangents to the curve that can be drawn from a generic point to the curve. In Section 7.5, we shall obtain the evolute of a conic as the image of the set of the conic's tangents under a quadratic Cremona transformation. Then, it will be immediately clear why the class of the evolute is four.

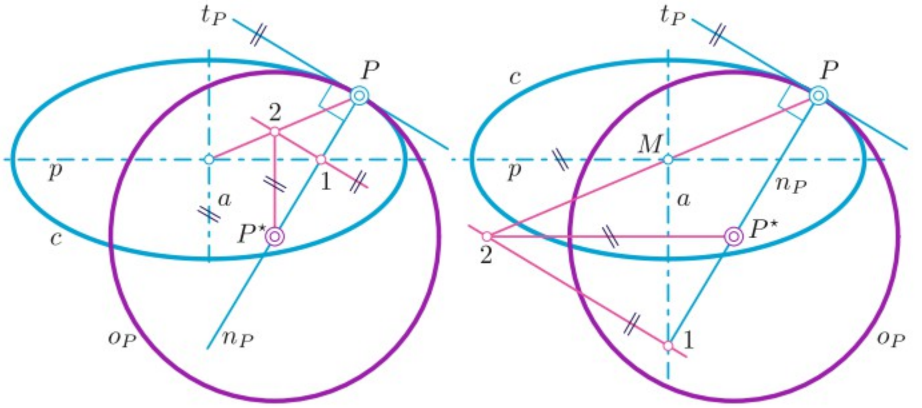

FIGURE 3.16. Two constructions of the center of curvature of an ellipse c. The construction also works if we interchange the roles of the axes.

The normal n_P and the principal axis with equation $y = 0$ meet at 1 with coordinates

$$\left(\frac{a^2 - b^2}{a}\cos t, 0\right),$$

and thus, the line l parallel to the tangent t_P has the equation

$$l:\ \frac{x\cos t}{a} + \frac{y\sin t}{b} = \frac{a^2 - b^2}{a^2}\cos^2 t.$$

The diameter through P is given by $xb\sin t - ya\cos t = 0$. Therefore, its intersection 2 with l has the same x-coordinate as $P^\star$

$$x_{P^\star} = \frac{a^2 - b^2}{a}\cos^3 t$$

which, inserted into the normal's equation, yields $y_{P^\star}$, and thus, $\mathbf{p}^\star(t)$ agrees with $\mathbf{c}^\star$ from (3.27). ■

• **Exercise 3.2.8** Alternative curvature construction. In Figure 3.16 (right), we can see that there is a second construction that leads to the center $P^\star$ of curvature for a generic point P on the ellipse c. Show that this construction leads to the same $P^\star$, *i.e.*, it is equivalent to the first construction given above.

Theorem 3.2.3 *When in the case of an ellipse or a hyperbola c the tangent t_P and the normal n_P at a generic point $P \in c$ intersect the principal axis at points 1, $1'$ and the auxiliary axis at 2, $2'$, then the signed distances to P and the center $P^\star$ of curvature satisfy*

$$\overline{P1} : \overline{P2} = \overline{P^\star 1'} : \overline{P^\star 2'}. \tag{3.29}$$

• **Exercise 3.2.9** Proof of Theorem 3.2.3. Show that the construction of $P^\star$ from Theorem 3.2.3 as shown in Figure 3.17 is equivalent to that given in Theorem 3.2.2.

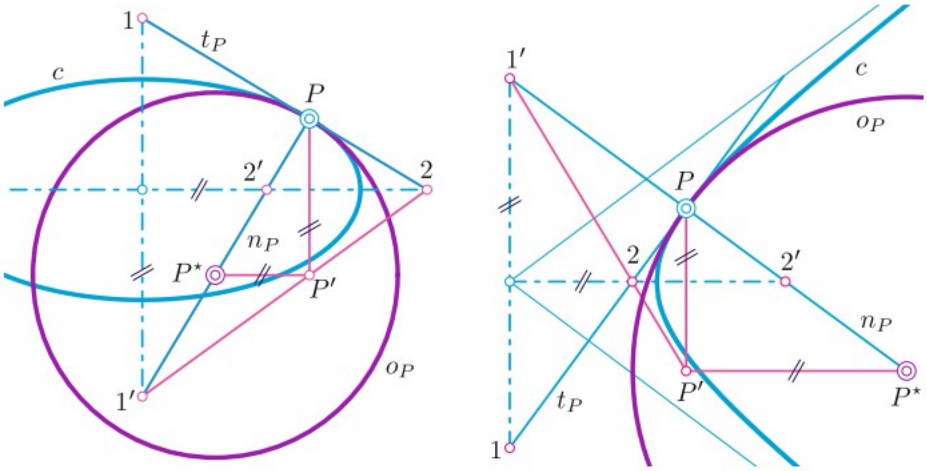

FIGURE 3.17. An alternative constructive approach to the centers of curvature of ellipses and hyperbolas. P divides the segment 12 on t_P at the same ratio as $P^\star$ does with $1'2'$ on n_P.

• **Exercise 3.2.10** Evolute of an ellipse as the envelope of the ellipse's normals. Show that the evolute of an ellipse can be found as the envelope of its normals. Start with the equations of lines depending on $t \in [0, 2\pi[$

$$n_P: \ -\frac{x \sin t}{b} + \frac{y \cos t}{a} = \frac{b^2 - a^2}{ab} \cos t \sin t$$

and intersect the lines n_P with their derivatives $\dot{n}_P$ (with respect to t). The points $n_P \cap \dot{n}_P$ are precisely the points of the ellipse's evolute.

• **Exercise 3.2.11** Evolutes of hyperbola and parabola as envelopes. Find the evolute of a hyperbola and a parabola as the envelopes of the normals.

The evolute of a parabola

Assume that we are given a parabola $p\colon\ x^2 = 2qy$ (with $q \in \mathbb{R}\setminus\{0\}$) which can be parametized as

$$\mathbf{p}(t) = (2qt, 2qt^2), \quad t \in \mathbb{R}. \tag{3.30}$$

We insert (3.30) into (3.26) and find a parametrization of its evolute

$$\mathbf{p}^\star(t) = q(-8t^3, 6t^2 + 1) \tag{3.31}$$

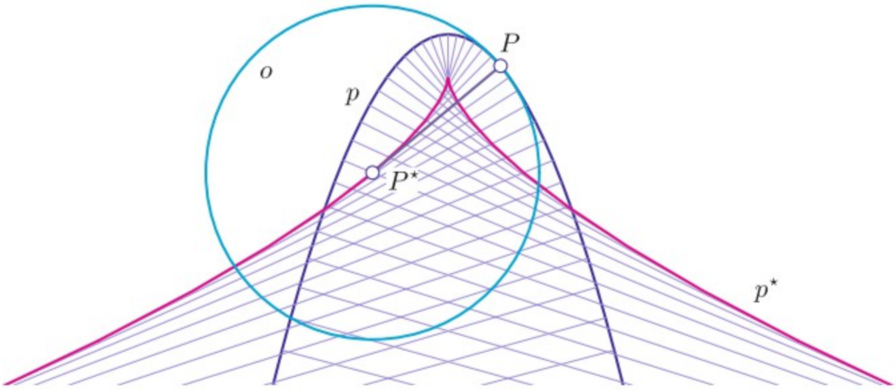

FIGURE 3.18. The evolute of a parabola as the envelope of the parabola's normals.

which is even polynomial, and thus, it can be written as a Bézier curve (see Section 8.2). This curve is sometimes called a *semicubical parabola*. An example of a parabola's evolute can be seen in Figure 3.18.

The curve given in (3.31) is algebraic and of degree three and of class three, although it is the evolute of a parabola. Its only cusp is the point $(q, 0)^{\mathrm{T}}$ which is the center of the osculating circle at the vertex. An implicit equation of the parabola's evolute from (3.31) reads

$$8(y-q)^3 - 27qx^2 = 0$$

which can be found by eliminating t from $x = -8qt^3$ and $y = 6qt^2 + q$.

• **Exercise 3.2.12** Center of curvature for a generic point on a parabola Assume $P \in p$ is a generic point (not the vertex). We can find the center $P^\star$ of p's osculating circle at P in two different ways shown in Figure 3.19:

The construction shown on the left-hand side of Figure 3.19 is the analogue to the construction of the center of curvature of the ellipse (cf. Figure 3.16). The parabola's normal n_P at P meets the axis of the parabola at a point D. There we draw the parallel to the tangent t_P. In the case of the ellipse, the point P has to be joined with the center of the curve. In the present case of the parabola, there is no center. However, there is a diameter through P, *i.e.*, the line parallel to the parabola's axis which meets the aforementioned parallel to the tangent at the point 2, such that $[2, C]$ is orthogonal to all diameters of p, especially to its axis.

Prove this by direct computation.

Theorem 3.2.4 *The normal n_P at any point P of a parabola meets the parabola's directrix at a point D. If $P^\star$ is the parabola's center of curvature*

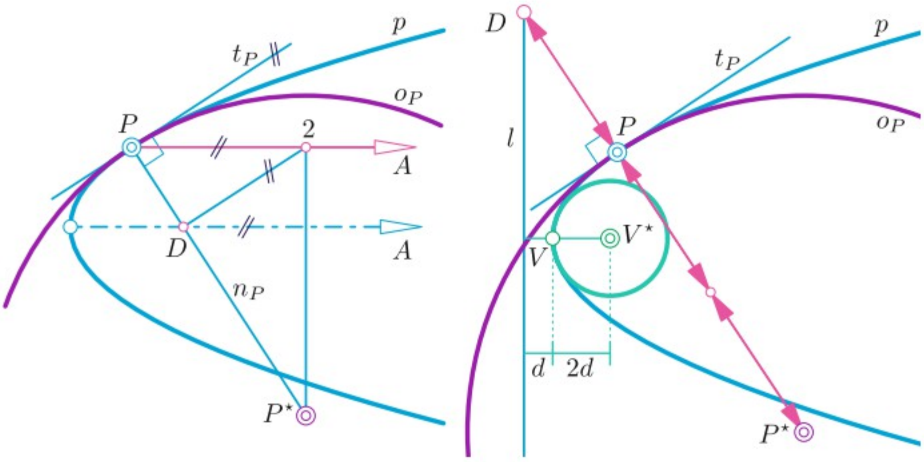

FIGURE 3.19. Two constructions of the center of curvature of parabolas.

at P, then the lengths of the segments DP and $DP^\star$ fulfill

$$\overline{DP} : \overline{DP^\star} = 1 : 3.$$

• **Exercise 3.2.13** Alternative approach to the center of curvature. The construction in Figure 3.19, right, for the center $P^\star$ of curvature of a parabola is also valid at the vertex (cf. Theorem 3.2.4). Give a proof of Theorem 3.2.4.

Evolute of a hyperbola

With the preparations from the previous sections, it is easily verified that the evolute of the hyperbola parametrized by

$$(\pm a \cosh t, b \sinh t), \quad t \in \mathbb{R}$$

admits the parametrization

$$\frac{a^2 + b^2}{ab} \left(\pm b \cosh^3 t, \mp a \sinh^3 t \right), \quad t \in \mathbb{R}.$$

An implicit equation of the evolute of the hyperbola reads either

$$\left(\frac{ax}{a^2 + b^2} \right)^{\frac{2}{3}} - \left(\frac{by}{a^2 + b^2} \right)^{\frac{2}{3}} = 1 \quad \text{or} \quad \left(1 - \frac{a^2x^2 - b^2y^2}{(a^2 + b^2)^2} \right)^3 = 27 \frac{(abxy)^2}{(a^2 + b^2)^4}.$$

Like the evolute of the ellipse, the evolute of a hyperbola is a sextic curve of class four. It has two real cusps being the centers of the osculating

Chapter 1

Properties of Radiation

1.1 Preamble

Early studies of the properties of electric and magnetic fields, their interplay and the resulting emission of radiation, led to formation of several fundamental laws by Carl F. Gauss (1777–1855), Michael Faraday (1791–1867), André M. Ampère (1775–1836), and James C. Maxwell (1831–1879). These were presented in a compact differential formalism by Maxwell (1865), which are referred to as Maxwell's equations:

$$\nabla \cdot \mathbf{D}(\mathbf{r}, t) = \rho(\mathbf{r}, t), \tag{1.1}$$

$$\nabla \cdot \mathbf{B}(\mathbf{r}, t) = 0, \tag{1.2}$$

$$\nabla \times \mathbf{E}(\mathbf{r}, t) = -\frac{\partial \mathbf{B}(\mathbf{r}, t)}{\partial t}, \tag{1.3}$$

$$\nabla \times \mathbf{H}(\mathbf{r}, t) = \mathbf{J}(\mathbf{r}, t) + \frac{\partial \mathbf{D}(\mathbf{r}, t)}{\partial t}. \tag{1.4}$$

The electric $\mathbf{E}(\mathbf{r}, t)$ and the magnetic fields $\mathbf{B}(\mathbf{r}, t)$, are time dependent and can be specified at every point in space and time, in which $\mathbf{r}(= x, y, z)$ denotes the position vector, t is the time, $\mathbf{J} = \sigma\mathbf{E}$, the electric current density, $q(= 1.6 \times 10^{-19}$ C) the elementary charge, $\mathbf{E}$ and $\mathbf{B}$, the electric field strength and the magnetic induction, respectively, $\mathbf{H} = \mathbf{B}/\mu$, the magnetic field, $\mathbf{D} = \epsilon\mathbf{E}$, the

electric displacement, ρ, the volume density of free charge, ϵ, μ, and σ the respective dielectric permittivity, the magnetic permeability, and conductivity of the medium, "×," the cross product, and

$$\nabla = \mathbf{i}\frac{\partial}{\partial x} + \mathbf{j}\frac{\partial}{\partial y} + \mathbf{k}\frac{\partial}{\partial z}. \tag{1.5}$$

represents a linear vector differential operator.

The unit of the electric field intensity, $\mathbf{E}$, is expressed as volt (V) m^{-1}, and that for the magnetic flux density $|\mathbf{B}|$ (in tesla; $\mathrm{T} = \mathrm{Wb\ m}^{-2}$). Equation (1.1) represents Gauss' theorem in electrostatics. Equation (1.2) tells that whatever might be the origin of $\mathbf{B}$, be it static magnetic poles or conduction current, the divergence is zero. Equation (1.3) is an outcome of Faraday's law of electromagnetic induction, which states that a changing magnetic field produces an electric field. Equation (1.4) originates from the circuital form of Ampère's law subject to satisfying the equation of continuity. What follows from circuital form of Ampère's law is

$$\nabla \times \mathbf{H} = \mathbf{J}. \tag{1.6}$$

From equation (1.6), one may obtain, $\nabla \cdot (\nabla \times \mathbf{H}) = 0$, which is an identity. That is

$$\nabla \cdot \mathbf{J} = 0, \tag{1.7}$$

which is the equation of continuity in a restricted sense of steady charge.

The equation of continuity actually is

$$\nabla \cdot \mathbf{J} + \frac{\partial \rho}{\partial t} = 0. \tag{1.8}$$

On using equation (1.1), one can rewrite equation (1.8)

$$\nabla \cdot \mathbf{J} + \frac{\partial}{\partial t}(\nabla \cdot \mathbf{D}) = 0. \tag{1.9}$$

Therefore,

$$\nabla \cdot \left(\mathbf{J} + \frac{\partial D}{\partial t}\right) = 0. \tag{1.10}$$

Using equation (1.10), Maxwell modified equation (1.6), by introducing the additional term, $\partial \mathbf{D}/\partial t$ on the right hand side (RHS), named it the displacement current density to obtain equation (1.4), which is also known as Ampère–Maxwell law.

© 2015 by Taylor & Francis Group, LLC

By taking surface integral on both sides of equation (1.4) and converting the left hand side (LHS) into a line integral, one obtains the magnetomotive force (MMF) as $\oint_1 \mathbf{H} \cdot d\mathbf{l}$. That is

$$\oint_1 \mathbf{H} \cdot d\mathbf{l} = \int_s \left(\mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \right) \cdot d\mathbf{S}. \tag{1.11}$$

The first term on the RHS indicates that MMF originates from current carrying conductor; this was postulated by Ampère and observed by Oersted. The second term indicates that time variation of the flux of electric displacement vector is a source of MMF. This reflects a symmetry of nature because it shows that as according to Faraday's law of electromagnetic induction, variation in the flux of magnetic induction gives rise to electromotive force (EMF), the variation of the flux of electric induction vector gives rise to MMF.

An exact description of electromagnetic radiation and its behavior requires a knowledge of Maxwell's electromagnetic field equations that describe the temporal and spatial dependence of electromagnetic fields and provide good agreement with observed phenomena over a wide range of frequencies in the spectrum. Equations (1.3) and (1.4) in free space (i.e., $\rho = 0$, $\mathbf{J} = 0$, $\epsilon = 0$), may be written as

$$\nabla \times \mathbf{E}(\mathbf{r}, t) = -\mu_0 \frac{\partial \mathbf{H}(\mathbf{r}, t)}{\partial t}, \tag{1.12}$$

$$\nabla \times \mathbf{H}(\mathbf{r}, t) = \epsilon_0 \frac{\partial \mathbf{E}(\mathbf{r}, t)}{\partial t}, \tag{1.13}$$

in which $\mu_0 (= 4\pi k = 4\pi \times 10^{-7}$ henrys (H).m^{-1}) is the permeability in free space (vacuum) and $\epsilon_0 (= 8.8541 \times 10^{-12}$ farads (F).m^{-1}) the permittivity in vacuum.

The curl of equation (1.12) is expressed as

$$\nabla \times \nabla \times \mathbf{E}(\mathbf{r}, t) = -\mu_0 \epsilon_0 \frac{\partial^2 \mathbf{E}(\mathbf{r}, t)}{\partial t^2}, \tag{1.14}$$

with $\nabla \times \nabla \times \mathbf{E} = \nabla(\nabla \cdot \mathbf{E}) - \nabla^2 \mathbf{E}$. Since $\nabla \cdot \mathbf{E} = 0$, in free space, one may derive the wave equation as

$$\nabla^2 \mathbf{E}(\mathbf{r}, t) - \mu_0 \epsilon_0 \frac{\partial^2 \mathbf{E}(\mathbf{r}, t)}{\partial t^2} = 0, \tag{1.15}$$

$$\nabla^2 \mathbf{E}(\mathbf{r}, t) - \frac{1}{c^2} \frac{\partial^2 \mathbf{E}(\mathbf{r}, t)}{\partial t^2} = 0. \tag{1.16}$$

© 2015 by Taylor & Francis Group, LLC

Similarly, one may derive for **B**,

$$\nabla^2\mathbf{B}(\mathbf{r}, t) - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}[\mathbf{B}(\mathbf{r}, t)] = 0. \tag{1.17}$$

The permittivity constant ϵ_0 and the permeability constant μ_0 in a vacuum are related to the speed of light, c

$$c = \frac{1}{\sqrt{\mu_0\epsilon_0}} \approx 3 \times 10^8 \text{ meter (m)/second (s)}. \tag{1.18}$$

The above expressions (1.16–1.17) are known as the electromagnetic wave equations, which indicate that electromagnetic disturbances (waves) are propagated through free space. This result gives rise to Maxwell's electromagnetic theory of light. The propagation velocity, $v(= 1/\sqrt{\epsilon\mu})$, of the waves obey the wave equations; in free space $v = c = 1/\sqrt{\mu_0\epsilon_0}$.

The union of electromagnetic theory with optics began when these equations described waves traveling at the velocity of light. However, the development of quantum theory of light at the dawn of the last century, dealing with absorption and emission, cannot be described with just Maxwell's equations. While interpreting the spectrum of electromagnetic radiation emitted by a blackbody, Max Karl Ernst Ludwig Planck (1858–1947) postulated that the oscillating electric charges which gives rise to light emission can have discrete energies (Planck, 1900). The name, blackbody, comes from the assumption that the body absorbs at every frequency and hence would look black at low temperature. The radiation emitted by a body as a result of its temperature is called thermal radiation. All bodies emit thermal radiation to their surroundings and absorb such radiations from them where the rates depend upon the temperature difference.

The nature of the spectrum of thermal radiation is continuous for matter in a condensed state (i.e. solid and liquid) and is strongly dependent on temperature. Generally speaking, the detailed nature of the radiation spectrum depends somewhat on the composition of the body. However, experiments show that there is one class of hot bodies that emits thermal spectra of universal character. These are called black bodies, which have surfaces absorbing all the thermal radiation incident upon them (in the ideal case) and re-radiate energy, which is characteristic of these radiating systems.

© 2015 by Taylor & Francis Group, LLC

However, one cannot explain the radiation emitted from such bodies on the basis of the laws of classical physics. Following Planck's suggestions, Albert Einstein (1879–1955) put forward that light is not distributed in continuous waves, but travels as a finite number of points of energy quanta, called *lichtquanten*, which are localized at points in space and move without dividing and can be absorbed or generated only in complete units (Einstein, 1905a). They travel at the speed of light and have properties like energy $\hbar\omega$, zero rest mass, momentum, spin $\hbar/2$, with $\hbar = h/(2\pi)$, $h(= 6.626096 \times 10^{-34}$ joules (J) seconds (s) $= 4.136 \times 10^{-15}$ eVs) as Planck's constant. This gave way to a term, photon, introduced by a chemist Gilbert Newton Lewis (1875–1946; Lewis, 1926), which eventually led to the development of quantum theory.

In fact, the birth of quantum mechanics is intimately linked with the theories and discoveries relating to the nature of light. Sir Isaac Newton (1642–1727) had described light as a stream of particles, what was termed as corpuscular (little particles) theory. This view had been superseded by the wave picture of light (Huygens' wavefront theory), a picture that culminated in the electromagnetic theory of Maxwell.

The energy of a photon depends on the radiation frequency, ν, of the light; the shorter the wavelength, the more energy each of these quanta has, the longer the wavelength the smaller the energy of the quanta. There are photons of all energies from high-energy gamma rays to low-energy infrared and radio waves. Photons are bosons,[a] having zero mass and rest energy and one unit of spin. Planck postulated that radiation of frequency, ν, can exchange energy with matter in units of $h\nu$. In other words, radiation of frequency, ν,

---

[a] Bosons, named after Satyendra Nath Bose (1894–1974), are particles (integer spin) that are associated with integral multiples of $\hbar$. These particles account for the phenomena of laser (acronym for light amplification by stimulated emission of radiation) (see Section 3.2), superconductivity, and superfluidity. Unlike in the case of fermions, which were named after Enrico Fermi (1901–1954), the particles with spin having odd multiples of $(1/2)\hbar$ obeying Pauli's exclusion principle, bosons can go into the ground state. A photon is a boson, whereas an electron is a fermion. Pauli's exclusion principle states that no two electrons in an atom can have identical quantum number; each energy level can accommodate a maximum of two electrons, one with spin-up $(+1/2)$ and the other with spin-down $(-1/2)$.

© 2015 by Taylor & Francis Group, LLC

behaves like a particle, called a photon, of energy,

$$E = h\nu = \frac{h\omega}{2\pi} = \hbar\omega, \tag{1.19}$$

and momentum, defined by the product of the mass of a particle and its linear velocity, $\mathbf{p}$, is given by,

$$\mathbf{p} = \hbar\boldsymbol{\kappa} = m\mathbf{c}, \tag{1.20}$$

with $\kappa = \omega/c = 2\pi\nu/c = 2\pi/\lambda$ as the wave number, $\boldsymbol{\kappa}(= \kappa\hat{\mathbf{s}})$ the wave vector in medium in the direction of propagation, $\hat{\mathbf{s}}$, ω the angular frequency, λ the wavelength, and c the velocity of light in a vacuum.

Equations (1.19) and (1.20) connect particle properties $(E, \mathbf{p})$ to the corresponding wave properties (ω, κ).

Angular momentum The angular momentum of a system of particles is due to both the spin of individual particles and their orbital momentum (Marcuse, 1980). The spin angular momentum is represented by electrons rotating about their own axes; it comes in units of $\hbar/2$, with $\hbar \equiv h/2\pi$ as the Planck constant divided by 2π. The orbital angular momentum for an atomic electron may be visualized in terms of a vector model where the angular momentum vector is seen as precessing about a direction in space. The total angular momentum is written as

$$\mathbf{J} = \mathbf{L} + \mathbf{S}, \tag{1.21}$$

where $\mathbf{J} = \sqrt{j(j+1)}\hbar$,

$$j = \begin{cases} 0,\ 1,\ 2,\ \cdots & \text{boson,} \\ 1/2,\ 3/2,\ 5/2, & \text{fermion,} \end{cases}$$

which is either an integer or a half integer, $\mathbf{L}$ and $\mathbf{S}$ the orbital and spin angular momentum respectively, which are quantized according to the following rules

$$\mathbf{L} = \sqrt{l(l+1)}\hbar \qquad \mathbf{S} = \sqrt{s(s+1)}\hbar,$$

l is an integer and s takes integer or half integer values depending on the particles. Spin angular momentum consists of two orthogonal states; on the other hand, the orbital angular momentum consists of an infinite number of orthogonal states.

© 2015 by Taylor & Francis Group, LLC

Quantum theory A number of observations had been made towards the end of the nineteenth century establishing the velocity of light independent of the velocity of the source or of the observer. This result could not be explained by classical theory. Einstein (1905b) introduced the special theory of relativity. He extended and improved Maxwell's theory by modifying the foundations of classical mechanics to remove the apparent contradictions between mechanics and electrodynamics. This theory has completely changed the concepts of space and time. He showed that space and time are closely linked and affect each other. Space, time, simultaneity, mass are all relative, but speed of light is absolute being independent of the notion of the source and the observer. The mass-energy equivalence described by the equation, $E = mc^2$, arose from the theory of relativity, where he explained the varying kinetic energies of an object emitting radiation by considering the amount of the object's change in kinetic energy, as being equivalent to change in its mass.

However, in making the transition from Planck's quantized oscillators to quanta of radiation, Einstein introduced the idea of corpuscular behavior of radiation, the revival of which posed a severe conceptual problem, one of reconciling wave and particle like behavior of radiation. Quantum theory of atomic structure, proposed by Niels Henrik David Bohr (1885–1962), known as Bohr's hypothesis, in 1913 and the discovery of dual nature of electromagnetic radiation (wave-particle duality), predicted by Louis de Broglie (1892–1987), what is referred to as de Broglie's hypothesis (de Broglie, 1925), led to the development of quantum mechanics.

Wave-particle duality Wave and particle natures are dual. When one is exhibited, the other remains suppressed. If radiation can exhibit particle nature, a particle can also show wave nature. Following this argument, de Broglie stated that equations (1.19) and (1.20) would hold for a material particle, such as an electron. From wave nature of particle, de Broglie showed that the wavelength of a particle is directly related to the Planck constant and inversely proportional to the mass and velocity of the particle; the larger the object or faster it is moving, the shorter the wavelength. The

© 2015 by Taylor & Francis Group, LLC

de Broglie equations are

$$\lambda = \frac{h}{p} = \frac{h}{\gamma m_0 v} = \frac{h}{m_0 v}\sqrt{1 - \frac{v^2}{c^2}}, \tag{1.22}$$

$$\nu = \frac{E}{h} = \frac{\gamma m_0 c^2}{h} = \frac{m_0 c^2}{h}\frac{1}{\sqrt{1 - v^2/c^2}}, \tag{1.23}$$

in which m_0 designates the particle's rest mass, v the velocity of the particle, c the speed of the light in a vacuum, and $\gamma(\equiv 1/\sqrt{1 - v^2/c^2})$ the Lorentz factor.

These two equations (1.22 and 1.23) relate the wavelength, λ, of a particle to its momentum and the frequency of the wave associated with the particle to the total energy of the particle, respectively. For instance, an electron with an accurately measured value of mass and charge could undergo diffraction in a manner similar to that of light waves.

Poynting vector The energy density of a photon, w in a volume V is given by

$$\mathrm{w} = \frac{\hbar\omega}{\mathrm{V}}. \tag{1.24}$$

Equation (1.24) states that if a plane wave with an energy quantum is contained in a volume, V. The momentum density is expressed as

$$\frac{\mathbf{p}}{\mathrm{V}} = \frac{\mathbf{S}}{c^2} = \frac{\mathrm{w}}{c}\frac{\boldsymbol{\kappa}}{\kappa} = \frac{\hbar\omega/c}{\mathrm{V}}\frac{\boldsymbol{\kappa}}{\kappa} = \frac{\hbar\boldsymbol{\kappa}}{\mathrm{V}}, \tag{1.25}$$

where

$$\mathbf{S}(\mathbf{r}, t) = \mathbf{E}(\mathbf{r}, t) \times \mathbf{H}(\mathbf{r}, t), \tag{1.26}$$

is the Poynting vector, which represents the energy flux of an electromagnetic field having the units of energy per unit area per unit time (J m^{-2} s^{-1}); it is named after its inventor John Henry Poynting (1852–1914).

Uncertainty principle Planck's constant also occurs in statements of Werner Heisenberg's (1901–1976) uncertainty principle (Heisenberg, 1927) which is an important consequence of the wave-particle duality of matter and radiation and is inherent to the quantum description of nature (Beiser, 1973, and references therein). This

© 2015 by Taylor & Francis Group, LLC

provides a lower bound on the product of the standard deviations of two conjugate variables, such as position and momentum for a system or the angular momentum and angular displacement for a system or the energy and time for a moving particle. This principle applies to all conjugate variables and also to the notion of the wave packet. A pair of physical variables describing a quantum-mechanical system such that their commutator is a nonzero constant are also known as complementary variables. The precision in measurement of one of them destroys the possibility of measurement of the other. There is a minimum for the product of the uncertainties of these two measurements

$$\begin{aligned} \Delta x \Delta p &\geq \frac{\hbar}{2}, \\ \Delta L_z \Delta \phi &\geq \frac{\hbar}{2}, \\ \Delta E \Delta t &\geq \frac{\hbar}{2}, \end{aligned} \tag{1.27}$$

where the uncertainty is given as the standard deviation of the measured value from its expected value. Uncertainty should not be construed as a limitation of measurement on the measuring device. It is an inadequacy inbuilt in the process of measurement. The product of two uncertainties is always greater than, or at best, the same as $\hbar/2$.

Schrödinger's equation If there is a wave, there must be a wave equation. Erwin Schrödinger (1887–1961) developed the wave-particle duality equation (Schrödinger, 1926)

$$i\hbar \frac{\partial \Psi}{\partial t} = \hat{H}\Psi, \tag{1.28}$$

in which $i = \sqrt{-1}$, Ψ is the time-dependent wave function, and in one dimension

$$\hat{H} = \frac{-\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + V(x), \tag{1.29}$$

is the Hamiltonian operator, a quantum mechanical operator introduced by Schrödinger in quantum mechanics, representing the energy of the system, which is the sum of kinetic and potential energies.

© 2015 by Taylor & Francis Group, LLC

Operating on the wave function, Ψ, with the Hamiltonian produces Schrödinger's equation. In the time independent Schrödinger's equation, the operation may produce specific values for the energy called energy eigen values, for example

$$\hat{H}\Psi_n = E_n\Psi_n, \tag{1.30}$$

where the functions, Ψ_n, are called eigen functions (or wave functions), possessing the properties that they are single valued, finite everywhere, and also their first derivatives with respect to their variables are continuous everywhere; E the multiplying factor, called eigen value.

For each value of n, there is a energy value and corresponding wave function. Equation (1.29) is a partial differential equation elucidating how the quantum state of some physical system changes with time. The first term on the RHS is the operator associated with kinetic energy and the second term the potential energy. The most precise computations are performed quantum mechanically by calculating the potential precisely and solving this equation. However, the least precise calculations are performed classically, neglecting quantization and using Newton's laws. A semi-classical computation, in which an atom's energy levels that are associated with attraction of the electrons to the nucleus, as well as with the effects of the angular momentum of the electrons, are computed quantum mechanically, but additional effects, such as light waves, are treated classically is an intermediate case. The observations associated with blackbody radiation, which is derived quantum mechanically, the photoelectric effect (see Section 2.1), and other related phenomena associated with the emission or transformation of light could be understood if the energy of light is discontinuously distributed in space. Advantages in technology have also led to matter wave interference experiments being demonstrated successfully with electrons, neutrons, atoms, and molecules.

Quantum statistics Light is quantized, and the statistics of the photons results in uncertainties of the amplitude and the phase of the light field. A quantum state can be occupied by several particles, what is referred to as quantum statistics. This applies to indistinguishable particles. Max Born (1882–1970) formulated the now-standard interpretation of the probability density function for

© 2015 by Taylor & Francis Group, LLC

$\Psi\Psi^*$ in Schrödinger's equation of quantum mechanics (Born, 1926). A probability amplitude is, in general, a complex number whose modulus squared represents a probability or probability density; probability amplitudes may also correspond to probabilities of discrete outcomes. For example, the values taken by a normalized wave function, Ψ, are amplitudes, since $\Psi\Psi^* = |\Psi(x)|^2$ provides the probability density at position x. Probability amplitudes, defined as complex-number-valued function of position, may also correspond to probabilities of discrete outcomes. It is a quantity whose value is a definite complex number at any point in space. The probability of finding the particle described by the wave function (e.g., an electron in an atom) at that point is proportional to square of the absolute value of the probability amplitude. That the physical meaning of the wave function is probabilistic was proposed by Max Born.

1.1.1 *Planck's Law*

At the turn of the last century, Rayleigh and Jeans made a calculation of the energy density, $E_\nu(T)$, of cavity radiation using classical arguments. The radiated energy from a blackbody may be considered to be produced by standing wave or resonant modes of the cavity. By considering the radiation inside a cavity of absolute temperature T whose walls are perfect reflectors to be a series of standing electromagnetic waves. The number of independent standing waves, $G(\nu)d\nu$ in the frequency interval between ν and $d\nu$ per unit volume in the cavity is

$$G(\nu)d\nu = \frac{8\pi\nu^2 d\nu}{c^3}. \tag{1.31}$$

The average total energy, $\bar{\mathcal{E}}$, of these waves in thermal equilibrium at a temperature T can be found out using classical kinetic theory and equipartition law,[a] i.e., assigning an average energy, $\bar{\mathcal{E}}$ per standing wave

$$\bar{\mathcal{E}} = k_\mathrm{B}T, \tag{1.32}$$

---

[a] The theorem of equipartition of energy states that the mean energy per degree of freedom of an entity, for example, a molecule of an ideal gas, which is a member of a system of such entities in thermal equilibrium at the temperature, T, is $1/2k_\mathrm{B}T$.

© 2015 by Taylor & Francis Group, LLC

in which $k_B (= 1.380662 \times 10^{-23}\ \text{J K}^{-1})$ is Boltzmann's constant, to each mode of vibration.

The amount of radiation emitted in a given frequency range should be proportional to the number of modes in that range. They showed that the number of modes was proportional to the square of the frequency. The energy density is related to the spectral distribution of blackbody radiation (spectral radiancy), $B_\nu(T)$, of the spectrum emitted by the hole on the cavity by the following equation

$$\begin{aligned} E_\nu(T)d\nu = \mathcal{E}G(\nu)d\nu &= \frac{4\pi}{c}B_\nu(T)d\nu \\ &= \frac{8\pi\nu^2 k_B T}{c^3}d\nu, \end{aligned} \tag{1.33}$$

which has units of energy per unit volume per unit frequency (J m^{-3} Hz^{-1}).

The number of standing waves in the frequency interval times the average energy of the modes divided by the volume of the cavity gives the average energy per unit volume in the frequency interval ν to $\nu + d\nu$, i.e., the energy density $E_\nu(T)$. The spectral radiancy is defined in such a way that $B_\nu(T)d\nu$ equals the energy emitted per unit time in radiation of frequency in the interval of ν to $\nu + d\nu$ from a unit area of surface at absolute temperature, T. Rayleigh and Jean's result was not successful to justify the experimental results pointing out serious conflict between classical physics and experimental observations. They considered a cavity with metallic walls heated uniformly to temperature T. The walls emit electromagnetic radiation in the thermal range of frequencies. This happens due to the accelerated motions of the electrons in the metallic walls arising from the thermal agitation. In this treatment, the oscillations of the electrons were not considered, instead, attention was focused on the behavior of the standing electromagnetic waves inside the cavity. However, Rayleigh-Jeans' law laid the foundation in understanding of the equilibrium radiation from a blackbody (Rayleigh, 1900, 1905; Jeans, 1905).

Planck considered the energy as a discrete variable instead of a continuous variable. Like the speed of light, c, that sets an upper limit on any physical velocity; Planck's constant, h, turned out to be a universal constant which sets a lower limit on action (linear

© 2015 by Taylor & Francis Group, LLC

momentum multiplied by distance). This constant opened up new vistas of physics. From the assumption that the electromagnetic modes in a cavity were quantized in energy, Planck (1901) obtained a radiation formula. The average energy, $\bar{\mathcal{E}}$[a] per mode (or quantum) is the energy of the quantum times the probability that it would occupy, which is given by

$$\bar{\mathcal{E}}(\nu) = \frac{h\nu}{e^{(h\nu/k_\mathrm{B}T)} - 1}, \tag{1.34}$$

where k_B is Boltzmann's constant, T the temperature in Kelvin (K), e the base of natural logarithms $(2.718\ldots)$, and ν the frequency.

The spectral energy density in the blackbody spectrum is expressed as

$$E_\nu(T)d\nu = \frac{8\pi\nu^2}{c^3}\frac{h\nu}{e^{(h\nu/k_\mathrm{B}T)} - 1}d\nu. \tag{1.35}$$

At high frequencies, $h\nu \gg k_\mathrm{B}T$ and $e^{h\nu/k_\mathrm{B}T} \rightarrow \infty$, which means the spectral energy density, $E_\nu d\nu \rightarrow 0$. There is no more ultraviolet (UV) catastrophe. At low frequencies, $h\nu \ll K_\mathrm{B}T$ and $h\nu/K_\mathrm{B}T \ll 1$, Rayleigh-Jeans' formula holds good and is valid for radio wavelengths. Following

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots,$$

and if x is small, $e^x \approx 1 + x$, one gets

$$\frac{1}{e^{(h\nu/k_\mathrm{B}T)} - 1} \approx \frac{1}{1 + \frac{h\nu}{k_\mathrm{B}T} - 1} \approx \frac{k_\mathrm{B}T}{h\nu} \qquad h\nu \ll k_\mathrm{B}T. \tag{1.36}$$

Thus at low frequencies, equation (1.35) for Planck's law is modified to as

$$E_\nu(T)d\nu \approx \frac{8\pi k_\mathrm{B}T\nu^2}{c^3}d\nu, \tag{1.37}$$

which is Rayleigh-Jeans' formula.

---

[a] The quantity, $\bar{\mathcal{E}}$, can be evaluated from the ratio of sums

$$\bar{\mathcal{E}} = \frac{\int_{n=0}^{\infty}\mathcal{E}\mathcal{P}(\mathcal{E})d\mathcal{E}}{\int_{n=0}^{\infty}\mathcal{P}(\mathcal{E})d\mathcal{E}},$$

in which $\mathcal{P}(\mathcal{E})d\mathcal{E}$ is the probability of finding a given entity of a system with energy in the interval between $\mathcal{E}$ and $\mathcal{E} + d\mathcal{E}$, when the density of states is independent of $\mathcal{E}$.

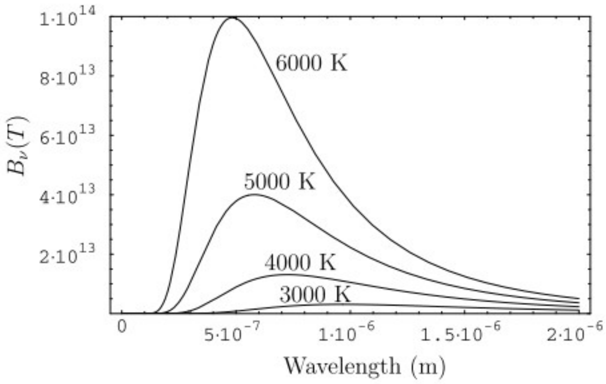

Figure 1.1 Intensity distributions of blackbody radiation at various temperatures, viz., 3000, 4000, 5000, and 6000 K. The abscissa contains the wavelengths and the ordinate depicts the intensity. The wavelength at which the curve is a maximum decreases with the increase of temperature.

A blackbody emits radiation of all wavelengths and the wavelength distribution of the radiation follows Planck's law. This pattern is characterized by

$$B_\nu(T) = \frac{2h}{c^2}\frac{\nu^3}{e^{(h\nu/k_\mathrm{B}T)} - 1}, \tag{1.38}$$

which has units of energy per unit time per unit surface area per unit solid angle per unit frequency (J s^{-1} m^{-2} Sr^{-1} Hz^{-1}).

Figure 1.1 depicts the spectral radiancy, $B_\nu(T)$, plot as function of wavelength; each curve is for a given temperature, and the peak of the curve represents the maximum emission. Stars have an overall spectrum,[a] sources of opacity both lines as well as continuum process, which is governed largely by equation (1.38).

---

[a] There are three types of spectra, such as (i) continuous spectrum that is produced by an excited dense gas radiating at all wavelengths, (ii) emission spectrum, which is produced by an excited low-density gas radiating at a specific wavelength, and (iii) absorption spectrum that results from a light comprising a continuous spectrum while passing through a cool, low-density gas. The gas absorbs some of the wavelengths of light depending on the composition of the gas and the temperature of the light source. The emission spectra, used to study nebulae, are produced when a glowing gas emits energy at specific wavelengths, characteristic of the element composing the gas.

4. Calculus Revisited

4.1. Differentiation on Intervals

This chapter is a review of what one might call the intellectual skeleton of calculus. It is not intended to be a comprehensive review of the subject because it does not deal extensively with the techniques or applications of calculus. The focus is on the basic concepts and theorems, some of which we will need to extend beyond the level of generality customarily found in a calculus course.

Definition. *Let* I *be an interval on the real line, and let* F *be a function from* I *into* R^m. *If* x *is a point of* I, *we say that* F *is* **differentiable at** x *if the limit*

$$\lim_{t \to x} \frac{F(t) - F(x)}{t - x} \tag{4.1}$$

exists. If F *is differentiable at* x, *the limit* (4.1) *is called the* **derivative of** F **at** x *and is denoted by* $F'(x)$ *or* $(DF)(x)$. *The function* F *is called* **differentiable** *if* F *is differentiable at each point of* I.

If F is any function from I to R^m and if we fix a point $x \in I$, the difference quotient

$$\frac{F(t) - F(x)}{t - x}$$

is a function defined at all points $t \in I$ such that $t \neq x$. Thus, it makes sense to ask whether the limit (4.1) exists. Suppose it does, and let G be another function from I to R^m which is differentiable at x. From the corresponding properties of limits, we see that $F + G$ is differentiable at x

and

$$(F + G)'(x) = F'(x) + G'(x). \tag{4.2}$$

If F and G are (complex) matrix-valued functions, then FG is differentiable at x and

$$(FG)'(x) = F(x)G'(x) + F'(x)G(x). \tag{4.3}$$

The product rule (4.3) is derived by adding and then subtracting a term to the difference quotient for FG:

$$\begin{aligned}\frac{(FG)(t) - (FG)(x)}{t - x} &= \frac{F(t)G(t) - F(x)G(x)}{t - x} \\ &= F(t)\frac{G(t) - G(x)}{t - x} + \frac{F(t) - F(x)}{t - x}G(x).\end{aligned}$$

As t approaches x, $F(t)$ approaches $F(x)$ and the difference quotients approach $G'(x)$ and $F'(x)$, respectively. The result follows from the rules for limits of sums and products.

In the last paragraph we used the fact that, if F is differentiable at x, then

$$\lim_{t \to x} [F(t) - F(x)] = 0.$$

This is apparent, since in (4.1) the denominator of the difference quotient is tending to 0 and the quotient could not approach a limit unless the numerator were tending to 0 as well. What this says is that *differentiability at x implies continuity at x*. The reader should be aware that the converse is false, as the example $f(x) = |x|$ at the point $x = 0$ shows.

If F is differentiable at each point of I, then $DF = F'$ is a function on I, called the **derivative** of F, and it makes sense to ask whether DF is differentiable. If it is, we denote its derivative by D^2F or F''. The successive derivatives (if they exist) are denoted by $F^{(n)} = D^nF$. We say that the function F is **of class C^k** provided the kth derivative D^kF exists and is continuous. If F has derivatives of all orders, then F is **of class C^∞**.

If I is a semi-closed interval, then, at the closed end, the derivative is only a one-sided derivative; e.g., from within $I = [a, b)$ approach to a is possible only from the right. At times, it is useful to have left- and right-hand derivatives at interior points of the interval. Let us discuss this briefly.

Suppose F is defined on a neighborhood of x. We consider the difference quotient

$$\frac{F(x) - F(t)}{x - t}, \qquad x < t < x + \delta.$$

If that quotient has a limit at x, it is the **right-hand derivative** of F at x:

$$(D^+F)(x) = \lim_{t \to x^+} \frac{F(x) - F(t)}{x - t}. \tag{4.4}$$

The **left-hand derivative** of F at x (if it exists) is defined similarly

$$(D^{-}F)(x) = \lim_{t \to x^{-}} \frac{F(x) - F(t)}{x - t}. \tag{4.5}$$

Either of the one-sided derivatives may fail to exist. They may both exist and be different, as the example $f(x) = |x|$ at $x = 0$ shows. Evidently, *$(DF)(x)$ exists if and only if $(D^{+}F)(x)$ exists, $(D^{-}F)(x)$ exists, and $(D^{+}F)(x) = (D^{-}F)(x)$.*

Any map

$$I \xrightarrow{F} R^{m}$$

is described by an m-tuple of real-valued functions, $F = (f_1, \ldots, f_m)$. From the corresponding property of limits, it is immediate that F is differentiable at x precisely when every f_j is differentiable at x. In this case $F'(x) = (f'_1(x), \ldots, f'_m(x))$. Therefore, the entire discussion of differentiation could be carried out using only real-valued functions; however, this is not an advisable way to proceed. It is much better to learn to handle differentiation of vector-valued functions directly, without using coordinates.

This seems an appropriate time at which to discuss the special features of differentiation of real-valued functions. If f is a differentiable function, then $f'(x)$ is the slope of the tangent line to the graph of f at the point $(x, f(x))$. It measures the rate at which f is increasing at x. Thus, the tangent line to the graph is horizontal at points where f has a maximum or minimum. This simple observation has a number of important consequences.

Theorem 1. *Let* f *be a real-valued function on an interval* (a, b). *Let* x ∈ (a, b) *and suppose that*

(i) f *has a local maximum* (*or local minimum*) *at* x;
(ii) f *is differentiable at* x.

Then $f'(x) = 0$.

Proof. To say that f has a local maximum at x means that there exists $\delta > 0$ such that

$$f(t) \leq f(x), \qquad |x - t| < \delta. \tag{4.6}$$

From (4.6), it is clear that $(D^{+}f)(x) \leq 0$, if $(D^{+}f)(x)$ exists. Similarly $(D^{-}f)(x) \geq 0$ if $(D^{-}f)(x)$ exists. Hence, if they both exist and are equal, their common value must be 0.

Corollary (***Mean Value Theorem***). *If* f *is continuous on* [a, b] *and differentiable on* (a, b), *there exists an* x ∈ (a, b) *such that*

$$f'(x) = \frac{f(b) - f(a)}{b - a}. \tag{4.7}$$

Proof. Let

$$g(x) = f(b) - f(x) + \frac{f(b) - f(a)}{b - a}(x - b).$$

Then g satisfies the same conditions as f and $g(a) = g(b) = 0$. The continuous function g attains its maximum and minimum on $[a, b]$. One of those must occur at a point x in the open interval (a, b). Then $g'(x) = 0$, which gives us (4.7).

Corollary. *Suppose* f *is differentiable on* (a, b). *Then* f *is an increasing function if and only if* $f' \geq 0$; f *is constant if and only if* $f' = 0$.

Proof. The mean value theorem for derivatives.

Corollary (Chain Rule). *Let* F, g *be differentiable functions such that the image of* g *is contained in the domain of* F*:*

$$(a, b) \xrightarrow{g} (c, d) \xrightarrow{F} R^m.$$

Then the composition $F \circ g$ *is differentiable and* $(F \circ g)' = g'(F' \circ g)$, *i.e.*, $(F \circ g)'(x) = g'(x)F'(g(x))$.

Proof. Fix $x \in (a, b)$. From the definition of derivative

$$F(y) - F(g(x)) = [y - g(x)]F'(g(x)) + (y - g(x))R(y, g(x))$$

where

$$\lim_{y \to g(x)} R(y, g(x)) = 0.$$

Thus,

$$\left|\frac{F(g(t)) - F(g(x))}{t - x} - \frac{g(t) - g(x)}{t - x}F'(g(x))\right| \leq \left|\frac{g(t) - g(x)}{t - x}\right| |R(g(t), g(x))|.$$

Corollary. *If* g *is a differentiable real-valued function on the interval* (a, b) *such that* $g'(x) \neq 0$ *for each* $x \in (a, b)$, *then* g *is* 1 : 1, *the inverse function* g^{-1} *is differentiable, and*

$$(Dg^{-1})(g(x)) = \frac{1}{g'(x)}$$

Proof. If we had $g(x) = g(t)$ with $x \neq t$, the mean value theorem would provide a point c between x and t with $g'(c) = 0$. Hence g is 1 : 1, that is, g is either strictly increasing or strictly decreasing. As we observed in Chapter 3 (Theorem 9) this means that the image of (a, b) is an open interval and g^{-1} is continuous. Thus,

$$(Dg^{-1})(g(x)) = \lim_{u \to g(x)} \frac{g^{-1}(u) - g^{-1}(g(x))}{u - g(x)} = \lim_{t \to x} \frac{t - x}{g(t) - g(x)} = \frac{1}{g'(x)}.$$

EXAMPLE 1. Let A be a fixed $k \times k$ matrix with complex entries. Let

$$F(t) = e^{tA}, \qquad t \in R.$$

Then F is a differentiable function. We have

$$\frac{F(t)-F(x)}{t-x}=\frac{e^{tA}-e^{xA}}{t-x}$$
$$=\frac{e^{(t-x)A}-I}{t-x}\cdot e^{xA}$$

What we must investigate is

$$\lim_{t\to 0}\frac{e^{tA}-I}{t}.$$

Now

$$e^{tA}-I=\sum_{n=1}^{\infty}\frac{1}{n!}t^nA^n$$

so that

$$t^{-1}(e^{tA}-I)-A=\sum_{n=2}^{\infty}\frac{1}{n!}t^{n-1}A^n$$
$$|t^{-1}(e^{tA}-I)-A|\leq\sum_{n=2}^{\infty}\frac{1}{n!}|t|^{n-1}|A|^n$$
$$\leq\frac{|A|}{2}\cdot\frac{|t||A|}{1-|t||A|}.$$

Now it is clear that F is differentiable and

$$F'(x)=Ae^{xA}=AF(x). \tag{4.8}$$

Since $F'=AF$, it follows that F is a function of class C^∞.

We remark that the differential equation in (4.8) determines the exponential function. If G is a differentiable function from R into $C^{k\times k}$ and if

$$G'(x)=AG(x)$$

where A is some fixed matrix, then $e^{-xA}G(x)$ has derivative 0. Thus,

$$G(x)=e^{xA}B$$

where $B=G(0)$. Notice that, if $G(x)=Be^{xA}$, then in order that $G'=AG$ be satisfied, B must commute with A, i.e., $AB=BA$.

The most important special case is, of course, the real-valued function

$$f(t)=e^t,\qquad t\in R$$

which satisfies $f'=f$. Since $f'(t)\neq 0$, the last corollary tells us that the inverse function f^{-1}, which we defined to be the log function, satisfies

$$(D\log)(e^t)=e^{-t}\quad\text{or}\quad(D\log)(x)=\frac{1}{x}.$$

EXAMPLE 2. Let F be the complex-valued function on the real line: $F(x)=e^{ix}$. According to Example 1, this is a function of class C^∞ and $F^{(n)}(x)=i^nF(x)$. Notice that, if we did not know about sines and cosines, We could define the sine and cosine functions by:

$$\begin{aligned}\sin x &= \operatorname{Im}(F(x))\\ &= \operatorname{Im}\sum_0^\infty \frac{1}{n!}(ix)^n\\ &= x - \frac{x^3}{3!} + \frac{x^5}{5!} - \cdots\\ &= \sum_{n=0}^\infty \frac{(-1)^n}{(2n+1)!}x^{2n+1};\\ \cos x &= \operatorname{Re}(F(x))\\ &= \operatorname{Re}\sum_{n=0}^\infty \frac{1}{n!}(ix)^n\\ &= 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \cdots\\ &= \sum_{n=0}^\infty \frac{(-1)^n}{(2n)!}x^{2n}.\end{aligned}$$

These functions are of class C^∞ and

$$\begin{aligned}D(\cos) &= -\sin\\ D(\sin) &= \cos.\end{aligned}$$

Each of these functions satisfies the differential equation

$$f'' + f = 0. \tag{4.9}$$

Furthermore, any f which satisfies (4.9) on an interval is a linear combination of sin and cos. The proof of this should be very familiar to every serious student of mathematics. For convenience, suppose f is real-valued and (4.9) holds on a neighborhood of 0. Let

$$g(x) = f(x) - f(0)\cos x - f'(0)\sin x.$$

Then $g'' + g = 0$ and $g(0) = g'(0) = 0$. Thus,

$$\begin{aligned}g'g'' + gg' &= 0\\ D((g')^2 + g^2) &= 0\\ (g')^2 + g^2 &= \text{constant}.\end{aligned}$$

Since $g(0) = g'(0) = 0$, the constant is 0; so,

$$\begin{aligned}(g')^2 + g^2 &= 0\\ g' = g &= 0 \qquad \text{(since } g \text{ is real-valued)}\\ f(x) &= f(0)\cos x + f'(0)\sin x.\end{aligned}$$

EXAMPLE 3. Let f be a real-valued function on an interval. We call f a **convex function** if

$$f[cx + (1-c)u] \leq cf(x) + (1-c)f(u) \tag{4.10}$$

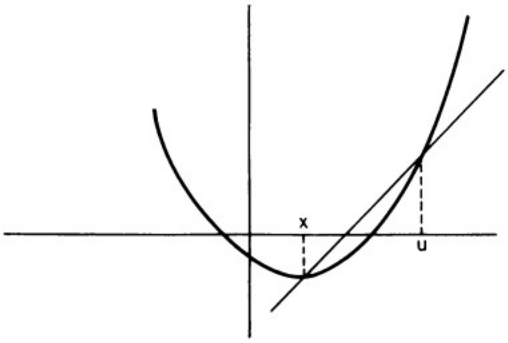

FIGURE 16

for all x, u in the domain and all c such that $0 \leq c \leq 1$. This says that, between x and u, the graph of f lies below the line joining the point $(x, f(x))$ to the point $(u, f(u))$. (See Figure 16.) Thus $f(x) = x^2$ and $f(x) = e^x$ define convex functions on the real line, while $f(x) = \sin x$ is a convex function on the interval $[-\pi, 0]$.

The defining property (4.1) can be rewritten in another useful way by observing that if $x < t < u$, then $t = cx + (1 - c)u$ where

$$c = \frac{u - t}{u - x}.$$

The condition (4.10) then says that

$$f(t) \leq \frac{u - t}{u - x} f(x) + \frac{t - x}{u - x} f(u)$$

which is more conveniently expressed as

$$\frac{f(t) - f(x)}{t - x} \leq \frac{f(u) - f(x)}{u - x}.$$

In other words, if $x < t < u$, the chord joining $(x, f(x))$ to $(u, f(u))$ has slope at least as great as the chord from $(x, f(x))$ to $(t, f(t))$. This suggests that for smooth functions convexity amounts to the fact that the derivative f' is an increasing (non-decreasing) function. This is the case, and we have left the proof to the Exercises.

As a matter of fact, the convexity property alone implies that f has a derivative at most points and that (where defined) f' is an increasing function. We sketch a proof. We know that if $x < t < u$, then

$$\frac{f(u) - f(x)}{u - x} \geq \frac{f(t) - f(x)}{t - x}.$$

Thus, unless x is the right end point of the interval of definition, the right-hand derivative $(D^+f)(x)$ exists and it is given by

$$(D^+f)(x) = \inf_{>x} \frac{f(t) - f(x)}{t - x}.$$

Similarly, unless x is the left end point, the left-hand derivative exists and

$$(D^-f)(x) = \sup_{t<x} \frac{f(t) - f(x)}{t - x}.$$

Since both $(D^+f)(x)$ and $(D^-f)(x)$ exist where they make sense, f is continuous at each such point x. More than that can be said. A little thought shows that

$$(D^+f)(t) \geq (D^-f)(t) \geq (D^+f)(x) \geq (D^-f)(x), \qquad t > x.$$

So, the left derivative D^-f is (as is D^+f) an increasing function. At any point where f fails to be differentiable, $(D^+f)(x) > (D^-f)(x)$ and so D^-f has a jump. The sum of all those jumps cannot exceed $(D^-f)(b) - (D^+f)(a)$, on the interval $[a, b]$. Therefore, there can be only a countable number of jumps. *Conclusion:* A convex function f on an open interval is continuous; it is differentiable except at a countable number of points; and the derivative Df (where defined) is an increasing function.

Exercises

1. Suppose that F is differentiable at a point x. Near x we approximate $F(t)$ by the affine function

$$A(t) = F(x) + (t - x)F'(x).$$

Show that the approximation satisfies

$$\lim_{t \to x} \frac{F(t) - A(t)}{t - x} = 0.$$

2. Let F be defined on an open interval about x. Prove that, if $(D^+F)(x)$ and $(D^-F)(x)$ both exist, then F is continuous at x.

3. Let

$$f_n(x) = \begin{cases} x^n \sin \dfrac{1}{x}, & x \neq 0 \\ 0, & x = 0. \end{cases}$$

Prove that f_1 is continuous but not differentiable at 0. Prove that f_2 is differentiable but not of class C^1. What is the corresponding fact about f_n?

4. Let $f_n(x) = x^n |x|$, $n = 0, 1, 2, \ldots$. Compute f_n' and find the largest integer k such that f_n is of class C^k.

5. Let F be a differentiable function from an interval I into R^m and suppose that $F' = 0$. Prove that F is constant.

6. Let f be the real-valued function on the real line

$$f(x) = \exp(-x^{-2}), \qquad x \neq 0$$
$$f(0) = 0.$$

Prove that f is a function of class C^∞ and that $f^{(n)}(0) = 0$ for every n.

7. Let f be a complex-valued function on an interval such that $f + f'' = 0$. Find the form of f by using the fact that $g = f - if'$ and $h = f + if'$ satisfy $g' = ig$, $h' = -ih$.

8. Let f, g be differentiable functions on R such that

$$\begin{aligned} f^2 + g^2 &= 1 \\ Df &= g \\ Dg &= -f \\ f(0) &= 0 \\ g(0) &= 1. \end{aligned}$$

Prove that f, g are what you think they are.

9. Let f be the Cantor function on $[0, 1]$, which was defined in Example 24 of Chapter 3. Prove that the derivative of f exists and is 0 at each point not in the Cantor set. Prove that f is not differentiable at any point of the Cantor set.

10. Show that the exponential function on the real line is a convex function and hence that

$$e^x \geq e^t(1 + x - t)$$

for all real numbers x and t.

11. Let f be a continuous real-valued function on an interval I which is differentiable at each interior point of I. Show that f is convex if and only if the derivative f' is an increasing (non-decreasing) function. (It is the "if" half of the result which we left unproved in the text.) What does this result tell you about the form of convex functions of class C^2?

12. If f and g are convex functions, is $\max(f, g)$ a convex function? What about $\min(f, g)$?

13. Let f be a real-valued function on an interval. The following are equivalent.

(a) f is convex.

(b) For each x, there is a line through the point $(x, f(x))$ such that the graph of f lies above that line.

(c) The set of all points in R^2 which lie above the graph of f is a convex set.

(d) f is continuous and

$$f\left(\frac{x + t}{2}\right) \leq \frac{1}{2}[f(x) + f(t)].$$

14. Let f be a continuous complex-valued function on the real line, which satisfies the functional equation

$$f(x + t) = f(x)f(t).$$

If $f \neq 0$, show that there is a complex number α such that $f(t) = e^{\alpha t}$. (You might ask first what kind of a function $\log|f|$ is.)

15. What about Exercise 14 for matrix-valued functions?

16. Let F be a differentiable function on the real line such that $|F'| \leq |F|$ and $F(0) = 0$. Prove that $F = 0$.

17. We know how to solve the differential equation $f'(x) = ax$. Suppose we have a system of differential equations

$$\begin{aligned} f_1' &= a_{11}f_1 + \cdots a_{1k}f_k \\ &\vdots \\ f_k' &= a_{k1}f_1 + \cdots + a_{kk}f_k \end{aligned}$$

involving k unknown functions f_i and k^2 known constants a_{ij}. Rewrite the system in the form

$$F' = AF$$

where A is the matrix of constants and

$$F = \begin{bmatrix} f_1 \\ \cdot \\ \cdot \\ \cdot \\ f_k \end{bmatrix}.$$

Prove that every solution for F has the form $F(t) = e^{tA}X_0$, where X_0 is some constant column matrix.

4.2. Integration on Intervals

Let F be a continuous function on a closed interval $I = [a, b]$. We want to define and discuss the integral of F over I:

$$\int_I F = \int_a^b F(x)\,dx.$$

In case F is a non-negative (and continuous) real-valued function, this integral is a *number* which measures the area under the graph of F and it is defined by a *process* known as integration, which gives a systematic method for approximating the area.

Since these ideas were first exploited systematically by Newton and Leibnitz 300 years ago, the range of applications of integration has been broadened enormously. This has been made possible in part by the modern definitions of the integral, in which the integration process is described in precise analytic terms, without appeal to any of its particular applications. In this chapter, we shall use a modified version of the formulation of integration given by Riemann. In Chapter 7 we will discuss the concept of integral given by Lebesgue, which is more general than Riemann's because it allows one to integrate many more functions. But we have no need of such generality at this point because our primary goal is to understand the basic theorems of calculus. Furthermore, it is important for every student of analysis to know that Riemann's process of integration converges for continuous functions.

In order to present the Riemann integral it is convenient to introduce two terms. A **partition** of the interval $[a, b]$ is any $(n + 1)$-tuple of the form

$$\begin{aligned} P &= (x_0, \dots, x_n) \\ a = x_0 &< x_1 < \cdots < x_n = b. \end{aligned} \tag{4.11}$$

Such a partition divides the interval into n subintervals, and the greatest of the lengths of these subintervals is called the **mesh** of the partition

$$\|P\| = \max_k (x_k - x_{k-1}) \qquad (1 \leq k \leq n). \tag{4.12}$$

Suppose F is a function from the interval $I = [a, b]$ into R^m. The integral of F over I, if it exists, will be a limit of sums

$$S(F, P, T) = \sum_{k=1}^{n} (x_k - x_{k-1})F(t_k) \tag{4.13}$$

where

$$P = (x_0, \dots, x_n)$$

is a partition of $[a, b]$ and

$$T = (t_1, \dots, t_n), \qquad t_k \in [x_{k-1}, x_k]$$

is a choice of points t_k, one from each subinterval defined by the partition. Such sums are frequently referred to as "Riemann sums", although we shall not use this terminology. The "limit" of these sums is to be taken as the mesh of the partition goes to 0; loosely speaking

$$\int_I F = \lim_{\|P\| \to 0} S(F, P, T).$$

There are so many (uncountably many) different partitions and different choices of points at which to evaluate the function that we will need to be careful how we describe the "limit" involved.

For any function which is integrable by the process we shall describe, it will always be possible (theoretically) to calculate the integral using any particular sequence of partitions $\{P_n\}$ for which the meshes tend to zero and any corresponding sequence of choices T_n. Any two such sequences will provide a sequence of vectors (approximating sums)

$$S_n = S(F, P_n, T_n)$$

which converges to the integral of F. For example, if

$$S_n = \sum_{k=1}^{n} \frac{b - a}{n} F\left(\frac{k(b - a)}{n}\right) \tag{4.14}$$

then for each integrable function F we shall have

$$\lim_n S_n = \int_a^b F(x)\, dx.$$

One might ask, therefore, why we do not use the sequence in (4.14) to define the integral, since it seems so much simpler than involving all sorts of partitions P and choices T, as in (4.13). There are two reasons, one practical and one theoretical.

(i) Even for very smooth functions F the particular sequence (4.14) may not provide the most convenient way of calculating the integral. We want to be able to use any sequence of partitions with meshes tending to 0 and know that the sums converge to the same limit. In other words, we want to be able to choose the sequence most convenient for each particular function F.

(ii) We need to deal with integrals of some functions which are not smooth and, therefore, we must be precise about the class of functions to which the integration process applies. Simple examples show that, were we to have the definition of this class of functions depend upon the values of the function at a particular sequence of points such as $(k/n)(b - a)$, we would generate chaos.

EXAMPLE 4. Let f be the real-valued function defined by

$$f(x) = \begin{cases} 0, & \text{if } x \text{ is rational} \\ 1, & \text{if } x \text{ is irrational.} \end{cases}$$

Suppose $a < b$ and let $P = (x_0, x_1, \ldots, x_n)$ be any partition of $[a, b]$. Each interval $[x_{k-1}, x_k]$ has positive length and, accordingly, it contains both rational and irrational points. For each k, choose a rational point $t_k \in [x_{k-1}, x_k]$ and an irrational point $t'_k \in [x_{k-1}, x_k]$. From the definition of f we have $f(t_k) = 0$ and $f(t'_k) = 1$ for each k. Accordingly,

$$S(F, P, T) = 0$$

$$S(F, P, T') = b - a.$$

Thus we can choose sequences (P_n, T_n) with $\|P_n\| \to 0$ for which $S(F, P_n, T_n) = 0$ and we can choose other sequences of this type for which $S(F, P_n, T_n) = b - a$. This leaves us a bit perplexed as to what the integral of f ought to be. In order to avoid this confusion, we shall define the class of functions which are "integrable" in such a way as to exclude this function f.

Definition. *Let* F *be a function from the interval* [a, b] *into* R^m. *We say that* F *is* **Riemann-integrable** *if there exists a vector* S *in* R^m *with this property: For each* $\epsilon > 0$ *there exists* $\delta > 0$ *such that if* P *is any partition of* [a, b] *with* $\|P\| \leq \delta$ *and if* T *is any choice of points in the subintervals defined by* P, *then*

$$|S - S(F, P, T)| < \epsilon.$$

Although this definition sounds somewhat complicated, it expresses a rather simple idea: The function F will be called Riemann-integrable if there exists a vector S (which will be the integral of F) to which the approximating sums $S(F, P, T)$ converge as $\|P\| \to 0$. Converge in which sense? In the sense that $S(F, P, T)$ will be close to S provided only that $\|P\|$ is small, and with no condition on T, the choice of points in the subintervals of P.

It should be clear that this basic definition can be reformulated as follows. The function F is Riemann-integrable if (and only if) there exists a vector S in R^m such that

$$\lim_n S(F, P_n, T_n) = S$$

for every sequence of partitions P_n with $\|P_n\| \longrightarrow 0$ and any corresponding choice(s) T_n of points in the subintervals defined by P_n. Thus the point of Example 4 can be described by saying that the function f which occurs there is not Riemann-integrable.

If F is Riemann-integrable, the vector S which occurs in the definition is obviously unique. It is called the **integral of F over the interval $I = [a, b]$** and is denoted by $\int_I F$ or $\int_a^b F(x)\,dx$.

A word about this notation. Part of the power of calculus as a tool derives from the very useful notation which Leibnitz invented for derivatives and integrals. For real-valued functions on an interval $[a, b]$ the integral was denoted by

$$\int_a^b f(x)\,dx$$

as a reminder of the process of integration

$$\begin{aligned}\int_a^b f(x)\,dx &= \lim_{\|P\|\to 0} \sum_{k=1}^n f(x_k)(x_k - x_{k-1})\\ &= \lim_{\max \Delta x_k \to 0} \sum_k f(x_k)\,\Delta x_k\\ &= \lim_{\Delta x \to 0} \sum f(x)\,\Delta x.\end{aligned}$$

We have not used the $\Delta x_k = x_k - x_{k-1}$ notation, in part because for vector-valued functions it would then be natural to write

$$\lim_{\|P\|\to 0} \sum_{k=1}^n \Delta x_k F(x_k) = \int_a^b dx\, F(x)$$

which is potentially confusing.

We want to direct our efforts immediately to proving that various well-behaved functions (e.g., continuous functions) are Riemann-integrable. In other words, we want to show that the process of integration "converges" for various well-behaved functions. We need a criterion for convergence analogous to the Cauchy criterion for sequences, i.e., a criterion which does not explicitly involve the limit vector.

If F is any function from $[a, b]$ into R^m, then, for each $\delta > 0$, we define the set $\Sigma_\delta = \Sigma_\delta(F)$ as follows. We consider all partitions $P = (x_0, \ldots, x_n)$ of the interval $[a, b]$ such that $\|P\| \leq \delta$ and all possible corresponding choices T of points $t_k \in [x_{k-1}, x_k]$. Each such pair (P, T) determines a sum

$$S(F, P, T) = \sum_{k=1}^n (x_k - x_{k-1})F(t_k)$$

and $\mathbf{\Sigma}_\delta(F)$ is defined to be the set of all such sums:

$$\sum_{\delta}(F) = \{S(F, P, T); \|P\| \leq \delta, t_k \in [x_{k-1}, x_k]\}. \tag{4.15}$$

If F is Riemann-integrable then, for small δ, all the sums $S(F, P, T)$ with $\|P\| \leq \delta$, i.e., all the vectors in $\mathbf{\Sigma}_\delta(F)$, will be close to the integral of F. Thus, when δ is small, $\mathbf{\Sigma}_\delta$ must be a set of small diameter clustered near the integral of F. And the integral is approximable by vectors in $\mathbf{\Sigma}_\delta$, that is, the integral lies in the closure $\bar{\mathbf{\Sigma}}_\delta$. What happens to the set $\mathbf{\Sigma}_\delta$ as we decrease δ? If $0 < \eta < \delta$, then it is immediate from the definition (4.15) that $\mathbf{\Sigma}_\eta \subset \mathbf{\Sigma}_\delta$. This is true for any F. For any integrable F it must be that, as δ tends to 0, the closed sets $\bar{\mathbf{\Sigma}}_\delta$ close down on the single vector $\int_I F$. In other words, the diameters of the sets $\mathbf{\Sigma}_\delta$ converge to 0 and $\int_I F$ is the single vector contained in the intersection

$$\bigcap_{\delta>0} \bar{\mathbf{\Sigma}}_\delta.$$

Theorem 2. *Let* F *be a function from the interval* [a, b] *into* R^m, *and define the set* $\mathbf{\Sigma}_\delta(\mathrm{F})$ *by* (4.15). *Then* F *is Riemann-integrable if and only if*

$$\lim_{\delta\to 0} \operatorname{diam} \mathbf{\Sigma}_\delta = 0. \tag{4.16}$$

Proof. It is the "if" statement which remains to be proved. Assume (4.16) and consider the intersection of the closures of the sets $\mathbf{\Sigma}_\delta$:

$$\bigcap_{\delta>0} \bar{\mathbf{\Sigma}}_\delta.$$

By the condition on the diameters, there cannot be more than one vector in this intersection. Furthermore, the intersection is nonempty for this reason. We know that $\mathbf{\Sigma}_\eta \subset \mathbf{\Sigma}_\delta$ if $\eta < \delta$. Hence the closed sets $\bar{\mathbf{\Sigma}}_\delta$ are nested:

$$\bar{\mathbf{\Sigma}}_\eta \subset \bar{\mathbf{\Sigma}}_\delta, \qquad \eta < \delta.$$

Furthermore, since the diameters of these sets tend to 0, they are bounded (sets) for all sufficiently small δ. Thus their intersection is non-empty. (See Theorem 9 of Chapter 2.) Let S be the single vector in the intersection. If $\epsilon > 0$, choose $\delta > 0$ such that $\operatorname{diam} \mathbf{\Sigma}_\delta(F) < \epsilon$. If P is any partition of $[a, b]$ with $\|P\| \leq \delta$ and if T is any choice of points in the subintervals defined by P, then the sum $S(F, P, T)$ is in the set $\mathbf{\Sigma}_\delta(F)$ and the vector S is in $\bar{\mathbf{\Sigma}}_\delta(F)$. Since $\operatorname{diam} \mathbf{\Sigma}_\delta(F) < \epsilon$,

$$|S - S(F, P, T)| < \epsilon.$$

Thus F is Riemann-integrable (and $S = \int_I F$).

In order to use the diameter criterion (4.16) to show that a given function F is Riemann-integrable, one needs to estimate, for a given δ, what the maximum distance is between any two approximating sums, formed by partitions of mesh at most δ. To carry out such estimates, we need to see what happens when we pass from a given partition to a more refined one.

Let $P = (x_0, \ldots, x_n)$ and $Q = (y_0, \ldots, y_p)$ be partitions of the interval $[a, b]$. We say that Q is a **refinement** of P if $\{x_0, \ldots, x_n\}$ is a subset of $\{y_0, \ldots, y_p\}$. In other words Q is a refinement of P if Q can be obtained by starting with the points $x_0 < x_1 < \cdots < x_n$ and interposing some $p - n$ points between them to form a finer subdivision. The fact that Q is a refinement of P guarantees among other things that $\|Q\| \leq \|P\|$, but note that it is a much stronger condition than the (mere) fact that Q has a smaller mesh than does P.

Lemma. *Let* F *be a function from* $[\mathrm{a}, \mathrm{b}]$ *into* R^{m}. *Let* $\mathrm{P} = (\mathrm{x}_0, \ldots, \mathrm{x}_{\mathrm{n}})$ *and* $\mathrm{Q} = (\mathrm{y}_0, \ldots, \mathrm{y}_{\mathrm{p}})$ *be partitions of* $[\mathrm{a}, \mathrm{b}]$ *such that* Q *is a refinement of* P. *If* T *is any choice of points* $\mathrm{t}_{\mathrm{k}} \in [\mathrm{x}_{\mathrm{k}-1}, \mathrm{x}_{\mathrm{k}}]$, $\mathrm{k} = 1, \ldots, \mathrm{n}$, *there exists points* $\mathrm{u}_1, \ldots, \mathrm{u}_{\mathrm{p}}$ *in* $[\mathrm{a}, \mathrm{b}]$ *such that*

(i) $\mathrm{y}_{\mathrm{j}-1} - \|\mathrm{P}\| \leq \mathrm{u}_{\mathrm{j}} \leq \mathrm{y}_{\mathrm{j}} + \|\mathrm{P}\|, \qquad \mathrm{j} = 1, \ldots, \mathrm{p};$

(ii) $\sum_{\mathrm{k}=1}^{\mathrm{n}} (\mathrm{x}_{\mathrm{k}} - \mathrm{x}_{\mathrm{k}-1})\mathrm{F}(\mathrm{t}_{\mathrm{k}}) = \sum_{\mathrm{j}=1}^{\mathrm{p}} (\mathrm{y}_{\mathrm{j}} - \mathrm{y}_{\mathrm{j}-1})\mathrm{F}(\mathrm{u}_{\mathrm{j}}).$

Proof. Let j be an index, $1 \leq j \leq p$. We shall define the corresponding point u_j. Since Q is a refinement of P, none of the points x_i lies in the open interval (y_{j-1}, y_j). Therefore the closed interval $[y_{j-1}, y_j]$ must lie wholly within one of the intervals $[x_{i-1}, x_i]$. In fact, since the interiors of the different intervals $[x_{i-1}, x_i]$ do not overlap, there is precisely one index i, $1 \leq i \leq n$, such that $[y_{j-1}, y_j] \subset [x_{i-1}, x_i]$. Call this index $i(j)$ and define $u_j = t_{i(j)}$.

Now observe that

$$\sum_{j=1}^{p} (y_j - y_{j-1})F(u_j) = \sum_{k=1}^{n} \sum_{i(j)=k} (y_j - y_{j-1})F(u_j)$$
$$= \sum_{k=1}^{n} \sum_{i(j)=k} (y_j - y_{j-1})F(t_k).$$

For a particular k, the indices j such that $i(j) = k$ are those for which $[y_{j-1}, y_j] \subset [x_{k-1}, x_k]$. Since Q is a refinement of P, these intervals form a partition of $[x_{k-1}, x_k]$, that is,

$$\sum_{i(j)=k} (y_j - y_{j-1}) = x_k - x_{k-1}.$$

This proves the lemma.

Theorem 3. *If* F *is a continuous function from the closed interval* $[\mathrm{a}, \mathrm{b}]$ *into* R^{m}, *then* F *is Riemann-integrable.*

Proof. The idea of the proof is to use the uniform continuity of F to estimate the diameters of the sets $\Sigma_\delta(F)$. Let $\delta > 0$. Let P, P' be partitions of $[a, b]$ of mesh at most δ and let $T = (t_1, \ldots, t_n)$, $T' = (t'_1, \ldots, t'_{n'})$

be choices of points in the subintervals determined by P and P', respectively. We want to estimate the distance from $S(F, P, T)$ to $S(F, P', T')$. To do this, we need to rewrite them as sums over the same partition. Accordingly, let $Q = (y_0, \dots, y_p)$ be the partition which is made up of the *distinct* points in the sequence $x_0, \dots, x_n, x'_0, \dots, x'_n$, arranged in increasing order. Then Q is a refinement of P and also a refinement of P'. By the preceding lemma, there exist points $u_1, \dots, u_p$ and $u'_1, \dots, u'_p$ in $[a, b]$ such that

$$S(F, P, T) = S(F, Q, U)$$
$$S(F, P', T') = S(F, Q, U').$$

We do not know that u_j and u'_j lie in the interval $[y_{j-1}, y_j]$. But, from the lemma, we do know that both u_j and u'_j lie in the interval $[y_{j-1} - \delta, y_j + \delta]$. Thus,

$$S(F, P, T) - S(F, P', T') = \sum_{j=1}^{p} (y_j - y_{j-1})[F(u_j) - F(u'_j)]$$

and $|u_j - u'_j| \leq 2\delta$, $j = 1, \dots, p$. Let

$$M = \max_j |F(u_j) - F(u'_j)|$$

and we have

$$\begin{aligned} |S(F, P, T) - S(F, P', T')| &\leq M \sum_{j=1}^{p} (y_j - y_{j-1}) \\ &= M(b - a). \end{aligned} \tag{4.17}$$

The idea now is to show that M is small whenever $\|P\|$ and $\|P'\|$ are small. The critical observation is that F is continuous on the closed interval $[a, b]$, and is therefore uniformly continuous, (Theorem 12 of Chapter 3). This guarantees that, when δ is small, each of the numbers $|F(u_j) - F(u'_j)|$ will be small, because u_j, u'_j are not more than 2δ apart. To be precise, if ω is the modulus of continuity of F (see (3.17)):

$$\omega(F, \eta) = \sup_{|x-t| \leq \eta} |F(x) - F(t)|$$

then (4.17) tells us that

$$|S(F, P, T) - S(F, P', T')| \leq (b - a)\omega(F, 2\delta).$$

Thus,

$$\operatorname{diam} \Sigma_\delta(F) \leq (b - a)\omega(F, 2\delta).$$

Now

$$\lim_{\eta \to 0} \omega(F, \eta) = 0$$

because this is what it means to say that F is uniformly continuous. We conclude that F is Riemann-integrable.

Corollary. *If* F *is a continuous function on the interval* [a, b], *if* $\mathrm{P} = (\mathrm{x}_0, \dots, \mathrm{x}_n)$ *is a partition of* [a, b] *and* $\mathrm{T} = (\mathrm{t}_1, \dots, \mathrm{t}_n)$ *any choice of points* $\mathrm{t}_k \in [\mathrm{x}_{k-1}, \mathrm{x}_k]$ *then*

$$\left|\int_a^b F(x)\,dx - \sum_{k=1}^{n} (x_k - x_{k-1})F(t_k)\right| \leq (b - a)\omega(F, 2\,||\,P\,||)$$

where ω *is the modulus of continuity of* F.

Proof. Let $\delta = ||\,P\,||$. In the proof of the theorem we verified that

$$\operatorname{diam} \Sigma_\delta(F) \leq (b, a)\omega(F, 2\delta).$$

Since the integral of F is in the closure of $\Sigma_\delta(F)$, its distance from the sum $S(F, P, T)$ cannot exceed $(b - a)\omega(F, 2\delta)$.

Exercises

1. Let F be a Riemann-integrable function on the closed interval I. Show that, if c is any real number, then cF is Riemann-integrable and

$$\int_I cF = c\int_I F.$$

(Work directly with $c\int F - S(cF, P, T)$ rather than $\Sigma_\delta(cF)$.)

2. In Exercise 1, if F is a complex-valued function and c is a complex number, is the same assertion valid? (Of course, we regard a complex-valued function as a map into R^2.)

3. Let F and G be functions from the closed interval I into R^m. Show that, if F and G are Riemann-integrable, then $F + G$ is and

$$\int_I (F + G) = \int_I F + \int_I G.$$

4. If f and g are real-valued Riemann-integrable functions on the closed interval I such that $f \geq g$, then

$$\int_I f \geq \int_I g.$$

5. If f is a non-negative continuous function on $[a, b]$ and

$$\int_a^b f(x)\,dx = 0$$

then $f = 0$.

6. Use the result of Exercise 5 to prove the following. If f is a continuous real-valued function on $[a, b]$ and

$$\int_a^b f(x)\,dx = 0$$

then there exists a point c, $a \leq c \leq b$, such that $f(c) = 0$.

7. Use the result of Exercise 6 to prove the *first mean value theorem of integral calculus*: If f is a continuous real-valued function on the interval $[a, b]$, there exists a point c, $a \leq c \leq b$, such that

$$\int_a^b f(x)\,dx = (b - a)f(c).$$

5 2 ((#1 7 ! = / 0 5!
' #; 6 & 2 / ! . D

is the correct formula, one has only to show that the covariant derivative of the induced metric is zero and that the torsion vanishes. This follows because

$$h_{ab\|c} = (g_{ef} \mp \bar{n}_e \bar{n}_f)_{;g} h^e{}_a h^f{}_b h^g{}_c = 0,$$

and

$$f_{\|ab} = h^e{}_a h^g{}_b f_{;eg} = h^e{}_a h^g{}_b f_{;ge} = f_{\|ba}.$$

The curvature tensor $R'^a{}_{bcd}$ of the induced metric **h** can be related to the curvature tensor $R^a{}_{bcd}$ on $\theta(\mathscr{S})$ and the second fundamental form $\boldsymbol{\chi}$ as follows. If $\mathbf{Y} \in H$ is a vector field on $\theta(\mathscr{S})$, then

$$R'^a{}_{bcd} Y^b = Y^a{}_{\|dc} - Y^a{}_{\|cd}.$$

Now

$$\begin{aligned} Y^a{}_{\|dc} &= (Y^a{}_{\|d})_{\|c} = (\bar{Y}^e{}_{;f} h^g{}_e h^f{}_i)_{;k} h^a{}_g h^i{}_d h^k{}_c \\ &= \bar{Y}^e{}_{;fk} h^a{}_e h^f{}_d h^k{}_c \mp \bar{Y}^e{}_{;f} \bar{n}_e \bar{n}^g{}_{;k} h^f{}_d h^a{}_g h^k{}_c \mp \bar{Y}^e{}_{;f} \bar{n}^f \bar{n}_{i;k} h^a{}_e h^i{}_d h^k{}_c \end{aligned}$$

and

$$\bar{Y}^e{}_{;f} \bar{n}_e h^f{}_d = (\bar{Y}^e \bar{n}_e)_{;f} h^f{}_d - \bar{Y}^e \bar{n}_{e;f} h^f{}_d = -\bar{Y}^e \bar{n}_{e;f} h^f{}_d,$$

since $\bar{Y}^e \bar{n}_e = 0$ on $\theta(\mathscr{S})$, therefore

$$R'^a{}_{bcd} Y^b = (R^e{}_{bkf} h^a{}_e h^k{}_c h^f{}_d \pm \chi_{bd} \chi^a{}_c \mp \chi_{bc} \chi^a{}_d) Y^b.$$

Since this holds for all $\mathbf{Y} \in H$,

$$R'^a{}_{bcd} = R^e{}_{fgh} h^a{}_e h^f{}_b h^g{}_c h^h{}_d \pm \chi^a{}_c \chi_{bd} \mp \chi^a{}_d \chi_{bc}. \tag{2.34}$$

This is known as Gauss' equation.

Contracting this equation on a and c and multiplying by h^{bd}, one obtains the curvature scalar R' of the induced metric:

$$R' = R \mp 2R_{ab} n^a n^b \pm (\chi^a{}_a)^2 \mp \chi^{ab} \chi_{ab}. \tag{2.35}$$

One can derive another relation between the second fundamental form and the curvature tensor $R^a{}_{bcd}$ on $\theta(\mathscr{S})$ by subtracting the expressions

$$(\chi^a{}_a)_{\|b} = (\bar{n}^a{}_{;d} h^d{}_a)_{;e} h^e{}_b$$

and

$$(\chi^a{}_b)_{\|a} = (\bar{n}^c{}_{;d} h^a{}_c h^d{}_e)_{;f} h^f{}_a h^e{}_b,$$

finding

$$\chi^a{}_{b\|a} - \chi^a{}_{a\|b} = R_{ef} n^f h^e{}_b. \tag{2.36}$$

This is known as Codacci's equation.

2.8 The volume element and Gauss' theorem

If $\{\mathbf{E}^a\}$ is a basis of one-forms, one can form from it the n-form

$$\boldsymbol{\epsilon} = n!\mathbf{E}^1 \wedge \mathbf{E}^2 \wedge \ldots \wedge \mathbf{E}^n.$$

If $\{\mathbf{E}^{a'}\}$, related to $\{\mathbf{E}^{a}\}$ by $\mathbf{E}^{a'} = \Phi^{a'}{}_{a}\mathbf{E}^{a}$, is another basis, the n-form $\boldsymbol{\epsilon}'$ defined by this basis will be related to $\boldsymbol{\epsilon}$ by

$$\boldsymbol{\epsilon}' = \det(\Phi^{a'}{}_{a})\,\boldsymbol{\epsilon},$$

so this form is not unique. However, one can use the existence of the metric to define (in a given basis) the form

$$\boldsymbol{\eta} = |g|^{\frac{1}{2}}\,\boldsymbol{\epsilon}$$

where $g \equiv \det(g_{ab})$. This form has components

$$\eta_{ab\ldots d} = n!\,|g|^{\frac{1}{2}}\,\delta^{1}{}_{[a}\delta^{2}{}_{b}\ldots\delta^{n}{}_{d]}.$$

The transformation law for g will just cancel the determinant, $\det(\Phi^{a'}{}_{a})$, provided that $\det(\Phi^{a'}{}_{a}) > 0$. Therefore if $\mathscr{M}$ is orientable the n-forms $\boldsymbol{\eta}$ defined by coordinate bases of an oriented atlas will be identical, i.e. given an orientation of $\mathscr{M}$, one can define a unique n-form field $\boldsymbol{\eta}$, the *canonical n-form*, on $\mathscr{M}$.

The contravariant antisymmetric tensor

$$\eta^{ab\ldots d} = g^{ae}g^{bf}\ldots g^{dh}\eta_{ef\ldots h}$$

has components

$$\eta^{ab\ldots d} = (-)^{\frac{1}{2}(n-s)}n!\,|g|^{\frac{1}{2}}\,\delta^{[a}{}_{1}\delta^{b}{}_{2}\ldots\delta^{d]}{}_{n},$$

where s is the signature of $\mathbf{g}$ (so $\frac{1}{2}(n-s)$ is the number of negative eigenvalues of the matrix of metric components (g_{ab})). Therefore these tensors satisfy the relations

$$\eta^{ab\ldots d}\eta_{ef\ldots h} = (-)^{\frac{1}{2}(n-s)}n!\,\delta^{a}{}_{[e}\delta^{b}{}_{f}\ldots\delta^{d}{}_{h]}. \tag{2.37}$$

The Christoffel relations imply that the covariant derivatives of $\eta_{ab\ldots d}$ and $\eta^{ab\ldots d}$ with respect to the connection defined by the metric vanish, i.e.

$$\eta^{ab\ldots d}{}_{;e} = 0 = \eta_{ab\ldots d;e}.$$

Using the canonical n-form, one can define the volume (with respect to the metric $\mathbf{g}$) of an n-dimensional submanifold $\mathscr{U}$ as $\dfrac{1}{n!}\displaystyle\int_{\mathscr{U}}\boldsymbol{\eta}$. Thus $\boldsymbol{\eta}$ can be regarded as a positive definite volume measure on $\mathscr{M}$. We shall often use it in this sense, and shall denote it by $\mathrm{d}v$. Note that d is not meant to represent the exterior differential operator here; $\mathrm{d}v$ is simply a measure on $\mathscr{M}$. If f is a function on $\mathscr{M}$, one can define its integral over $\mathscr{U}$ with respect to this volume measure as

$$\int_{\mathscr{U}} f\,\mathrm{d}v = \frac{1}{n!}\int_{\mathscr{U}} f\,\boldsymbol{\eta}.$$

With respect to local oriented coordinates $\{x^a\}$, this can be expressed as the multiple integral

$$\int_{\mathscr{U}} f|g|^{\frac{1}{2}}\,\mathrm{d}x^1\,\mathrm{d}x^2\ldots\mathrm{d}x^n,$$

which is invariant under a change of coordinates.

If $\mathbf{X}$ is a vector field on $\mathscr{M}$, its contraction with $\boldsymbol{\eta}$ will be an $(n-1)$-form field $\mathbf{X}\,.\,\boldsymbol{\eta}$, where

$$(\mathbf{X}\,.\,\boldsymbol{\eta})_{b\ldots d} = X^a\eta_{ab\ldots d}.$$

This $(n-1)$-form may be integrated over any $(n-1)$-dimensional compact orientable submanifold $\mathscr{V}$. We write this integral as

$$\int_{\mathscr{V}} X^a\mathrm{d}\sigma_a = \frac{1}{(n-1)!}\int_{\mathscr{V}}\mathbf{X}\,.\,\boldsymbol{\eta},$$

where the canonical form $\boldsymbol{\eta}$ is regarded as defining a measure-valued form $\mathrm{d}\sigma_a$ on the submanifold $\mathscr{V}$. If the orientation of $\mathscr{V}$ is given by the direction of the normal form n_a, then $\mathrm{d}\sigma_a$ can be expressed as $n_a\mathrm{d}\sigma$ where $\mathrm{d}\sigma$ is a positive definite volume measure on the submanifold $\mathscr{V}$. The volume measure $\mathrm{d}\sigma$ is not unique unless the normal n_a is normalized. If n_a is normalized to unit magnitude in a metric $\mathbf{g}$ on $\mathscr{M}$, i.e. $n_a n_b g^{ab} = \pm 1$, then $\mathrm{d}\sigma$ is equal to the volume measure on $\mathscr{V}$ defined by the induced metric on $\mathscr{V}$ (to see this, simply choose an orthonormal basis with $n_a g^{ab}$ as one of the basis vectors).

Using the canonical form, one can derive Gauss' formula from Stokes' theorem: for any compact n-dimensional submanifold $\mathscr{U}$ of $\mathscr{M}$,

$$\int_{\partial\mathscr{U}} X^a\mathrm{d}\sigma_a = \frac{1}{(n-1)!}\int_{\partial\mathscr{U}}\mathbf{X}\,.\,\boldsymbol{\eta} = \frac{1}{(n-1)!}\int_{\mathscr{U}}\mathrm{d}(\mathbf{X}\,.\,\boldsymbol{\eta}).$$

But

$$\begin{aligned}(\mathrm{d}(\mathbf{X}\,.\,\boldsymbol{\eta}))_{a\ldots de} &= (-)^{n-1}(X^g\eta_{g[a\ldots d})_{;e]}\\ &= (-)^{n-1}\delta^s{}_{[a}\ldots\delta^t{}_d\delta^u{}_{e]}\eta_{gs\ldots t}X^g{}_{;u}\\ &= (-)^{(n-1)-\frac{1}{2}(n-s)}\frac{1}{n!}\eta^{s\ldots tu}\eta_{a\ldots de}\eta_{gs\ldots t}X^g{}_{;u}\\ &= \eta_{a\ldots de}\delta^s{}_{[s}\ldots\delta^t{}_t\delta^u{}_{g]}X^g{}_{;u}\\ &= n^{-1}\eta_{a\ldots de}X^g{}_{;g},\end{aligned}$$

on using relation (2.37) twice. Therefore

$$\int_{\partial\mathscr{U}} X^a\,\mathrm{d}\sigma_a = \int_{\mathscr{U}} X^g{}_{;g}\,\mathrm{d}v$$

holds for any vector field $\mathbf{X}$; this is Gauss' theorem. Note that the orientation on $\mathscr{U}$ for which this theorem is valid is that given by the normal form $\boldsymbol{\eta}$ such that $\langle \mathbf{n}, \mathbf{X} \rangle$ is positive if $\mathbf{X}$ is a vector which points out of $\mathscr{U}$. If the metric $\mathbf{g}$ is such that $g^{ab}n_a n_b$ is negative, the vector $g^{ab}n_b$ will point into $\mathscr{U}$.

2.9 Fibre bundles

Some of the geometrical properties of a manifold $\mathscr{M}$ can be most easily examined by constructing a manifold called a fibre bundle, which is locally a direct product of $\mathscr{M}$ and a suitable space. In this section we shall give the definition of a fibre bundle and shall consider four examples that will be used later: the tangent bundle $T(\mathscr{M})$, the tensor bundle $T^r_s(\mathscr{M})$, the bundle of linear frames or bases $L(\mathscr{M})$, and the bundle of orthonormal frames $O(\mathscr{M})$.

A C^k *bundle* over a C^s ($s \geqslant k$) manifold $\mathscr{M}$ is a C^k manifold $\mathscr{E}$ and a C^k surjective map $\pi: \mathscr{E} \rightarrow \mathscr{M}$. The manifold $\mathscr{E}$ is called the total space, $\mathscr{M}$ is called the base space and π the projection. Where no confusion can arise, we will denote the bundle simply by $\mathscr{E}$. In general, the inverse image $\pi^{-1}(p)$ of a point $p \in \mathscr{M}$ need not be homeomorphic to $\pi^{-1}(q)$ for another point $q \in \mathscr{M}$. The simplest example of a bundle is a *product bundle* $(\mathscr{M} \times \mathscr{A}, \mathscr{M}, \pi)$ where $\mathscr{A}$ is some manifold and the projection π is defined by $\pi(p, v) = p$ for all $p \in \mathscr{M}, v \in \mathscr{A}$. For example, if one chooses $\mathscr{M}$ as the circle S^1 and $\mathscr{A}$ as the real line R^1, one constructs the cylinder C^2 as a product bundle over S^1.

A bundle which is locally a product bundle is called a fibre bundle. Thus a bundle is a *fibre bundle* with fibre $\mathscr{F}$ if there exists a neighbourhood $\mathscr{U}$ of each point q of $\mathscr{M}$ such that $\pi^{-1}(\mathscr{U})$ is isomorphic with $\mathscr{U} \times \mathscr{F}$, in the sense that for each point $p \in \mathscr{U}$ there is a diffeomorphism ϕ_p of $\pi^{-1}(p)$ onto $\mathscr{F}$ such that the map ψ defined by $\psi(u) = (\pi(u), \phi_{\pi(u)})$ is a diffeomorphism $\psi: \pi^{-1}(\mathscr{U}) \rightarrow \mathscr{U} \times \mathscr{F}$. Since $\mathscr{M}$ is paracompact, we can choose a locally finite covering of $\mathscr{M}$ by such open sets $\mathscr{U}_\alpha$. If $\mathscr{U}_\alpha$ and $\mathscr{U}_\beta$ are two members of such a covering, the map

$$(\phi_{\alpha, p}) \circ (\phi_{\beta, p}{}^{-1})$$

is a diffeomorphism of $\mathscr{F}$ onto itself for each $p \in (\mathscr{U}_\alpha \cap \mathscr{U}_\beta)$. The inverse images $\pi^{-1}(p)$ of points $p \in \mathscr{M}$ are therefore necessarily all diffeomorphic to $\mathscr{F}$ (and so to each other). For example, the Möbius strip is a fibre bundle over S^1 with fibre R^1; we need two open sets $\mathscr{U}_1$, $\mathscr{U}_2$

Analysis of PN Guided Missile Systems in the Frequency Domain

4.1 Introduction

The difficulty in the analysis of differential equations with time-varying coefficients describing linearized models of guidance systems does not allow researchers to obtain analytical expressions for miss distance that can be effectively utilized in practice. As mentioned in [7], "the disadvantage of the single time constant representation of a missile guidance system is that the miss distance can be seriously underestimated." The same remark can also be applied to the binomial representation.

The method of adjoints used in the previous section can be presented in the integral form as the impulse response of the adjoint system, i.e., its reaction to a unit impulse function. In the case of a single time constant guidance system, the transfer function between the target acceleration and the guidance system miss distance can be obtained from (3.21). In control theory, the method of transfer functions, as input–output characteristics of linear systems, is a foundation of frequency methods, i.e., analysis of systems in the frequency domain. Analogous to the unit step signal in the time domain, the unit sinusoidal input signal is the standard test signal in the frequency domain. The response of the system to a changing frequency is considered. The frequency response is defined as the steady-state response of the system to a sinusoidal input signal. The frequency approach is very popular among engineers because the design of a system in the frequency domain provides the designer with the control of the bandwidth of a system. It is very physical and enables researchers and designers to build realistic models and make justifiable simplifications.

The below analysis of the linearized PN guidance system models is based on the frequency response of the linearized guidance system, which corresponds to the miss distance due to a weaving target, i.e., due to a sinusoidal acceleration. As shown later, the miss due to a step target maneuver, i.e., the miss step response, can also be obtained from the frequency characteristics of the system under consideration.

The block diagram of an interceptor's main subsystems is given in Figure 4.1.

The seeker provides a guidance system with target information, which, together with the information from onboard sensors, is necessary to generate a guidance law. The guidance system generates acceleration commands for the autopilot channels to control the motion of the missile. The warhead subsystem receives a burst-hit command from the guidance system. The performance of the guided missile systems is assessed by their terminal effect. The generation and intelligent control of this "terminal effect" is one of the key requirements to missile systems.

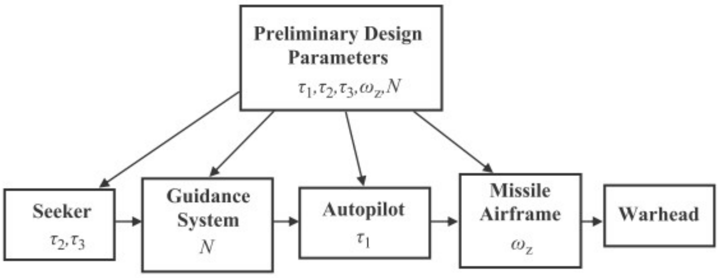

FIGURE 4.1
Block diagram of an interceptor's main subsystems.

The abovementioned subsystems are interconnected. The performance of a separate subsystem dictates requirements to the interconnected ones; e.g., the missile airframe parameters determine the airframe poles ω_z that influence significantly missile dynamics and, as a result, influence autopilot system τ_1 characteristic requirements. Higher accuracy guidance and autopilot systems can employ smaller warheads. The seeker dynamic parameters τ_2 and τ_3 influence the accuracy of the guidance system. The traditional approach to designing missile guidance and autopilot systems usually neglects the interaction between these systems and treats individual missile subsystems separately. The subsystems are designed separately and then integrated before verifying their performance. The quantification of the impact of missile parameters on the miss distance is the first important step toward integrated design of missile guidance and autopilot systems. The main factors that influence the miss distance in homing missiles are the seeker errors, aero frame characteristics, autopilot lag τ_1 and target maneuvers. An appropriate choice of the estimation system parameters (in Figure 4.1, it is combined with a seeker and presented by τ_2 and τ_3) can reduce requirements to a seeker's accuracy and a guidance law effective navigation ratio *N*. The abovementioned shows the importance of establishing an analytical relationship between the miss distance and the main parameters of the missile guidance system.

The analytical expressions for the miss distance (frequency response) and the related expressions for the missile system performance are obtained for the proportional navigation law and the guidance control system that reflects the most important characteristics of the flight control system that combines airframe and autopilot dynamics (damping, natural frequency, time constant, and airframe zero frequency). The obtained analytical expressions need to employ significantly simpler computational programs than by using the method of adjoints to analyze the influence of the basic guidance system parameters on the miss distance for step and weave maneuvers.

4.2 Adjoint Method: Generalized Model

As shown earlier, the method of adjoints is a useful tool to simulate the impulse response of the system, i.e., its response of an impulse function. The analysis in the time domain was bounded by the consideration of a step target acceleration signal. Because the frequency domain analysis utilizes a different test signal, it is convenient to consider a more general model of the adjoint system commonly used in modern control theory.

38 GEOMETRIC INTERSECTION

David M. Mount

INTRODUCTION

Detecting whether two geometric objects intersect and computing the region of intersection are fundamental problems in computational geometry. Geometric intersection problems arise naturally in a number of applications. Examples include geometric packing and covering, wire and component layout in VLSI, map overlay in geographic information systems, motion planning, and collision detection. In solid modeling, computing the volume of intersection of two shapes is an important step in defining complex solids. In computer graphics, detecting the objects that overlap a viewing window is an example of an intersection problem, as is computing the first intersection of a ray and a collection of geometric solids.

Intersection problems are fundamental to many aspects of geometric computing. It is beyond the scope of this chapter to completely survey this area. Instead we illustrate a number of the principal techniques used in efficient intersection algorithms. This chapter is organized as follows. Section 38.1 discusses intersection primitives, the low-level issues of computing intersections that are common to high-level algorithms. Section 38.2 discusses detecting the existence of intersections. Section 38.3 focuses on issues related to counting the number of intersections and reporting intersections. Section 38.4 deals with problems related to constructing the actual region of intersection. Section 38.5 considers methods for geometric intersections based on spatial subdivisions.

38.1 INTERSECTION PREDICATES

GLOSSARY

Geometric predicate: A function that computes a discrete relationship between basic geometric objects.

Boundary elements: The vertices, edges, and faces of various dimensions that make up the boundary of an object.

Complex geometric objects are typically constructed from a number of primitive objects. Intersection algorithms that operate on complex objects often work by breaking the problem into a series of primitive geometric predicates acting on basic elements, such as points, lines and curves, that form the boundary of the objects involved. Examples of geometric predicates include determining whether two line segments intersect each other or whether a point lies above, below, or on a given line.

© 2004 by Chapman & Hall/CRC

Computing these predicates can be reduced to computing the sign of a polynomial, ideally of low degree. In many instances the polynomial arises as the determinant of a symbolic matrix.

Computing geometric predicates in a manner that is efficient, accurate, and robust can be quite challenging. Floating-point computations are fast but suffer from round-off errors, which can result in erroneous decisions. These errors in turn can lead to topological inconsistencies in object representations, and these inconsistencies can cause the run-time failures. Some of the approaches used to address robustness in geometric predicates include approximation algorithm that are robust to floating-point errors [SI94], computing geometric predicates exactly using adaptive floating-point arithmetic [Cla92, ABD$^+$97], exact arithmetic combined with fast floating-point filters [BKM$^+$[95, FV96], and designing algorithms that are based on a restricted set of geometric predicates [BS00].

We will concentrate on geometric intersections involving flat objects (line segments, polygons, polyhedra), but there is considerable interest in computing intersections of curves and surfaces. Predicates for curve and surface intersections are particularly challenging, because the intersection of surfaces of a given algebraic degree generally results in a curve of a significantly higher degree. Computing intersection primitives typically involves solving an algebraic system equations, which can be performed either exactly by algebraic and symbolic methods [Yap93] or approximately by numerical methods [Hof89, MC91]. See Chapter 41.

38.2 INTERSECTION DETECTION

GLOSSARY

Polygonal chain: A sequence of line segments joined end-to-end.

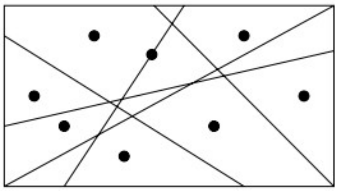
Self-intersecting: Said of a polygonal chain if any pair of nonadjacent edges intersects one another.

Bounding box: A rectangular box surrounding an object, usually axis-aligned (***isothetic***).

Intersection detection, the easiest of all intersection tasks, requires merely determining the existence of an intersection. Nonetheless, detecting intersections efficiently in the absence of simplifying geometric structure can be challenging. As an example, consider the following fundamental intersection problem, posed by John Hopcroft in the early 1980's. Given a set of n points and n lines in the plane, does any point lie on any line? See Figure 38.2.1. A series of efforts to solve *Hopcroft's problem* culminated in the best algorithm known for this problem to date, due to Matoušek [Mat93], which runs in $O(n^{4/3})2^{O(\log^* n)}$. There is reason to believe that this may be close to optimal; Erickson [Eri96] has shown that, in certain models of computation, $\Omega(n^{4/3})$ is a lower bound. Agarwal and Sharir [AS90] have shown that, given two sets of line segments denoted red and blue, it is possible to determine whether there is any red-blue intersection in $O(n^{4/3+\epsilon})$ time, for any positive constant ϵ.

© 2004 by Chapman & Hall/CRC

FIGURE 38.2.1
Hopcroft's Problem.



The types of objects considered in this section are polygons, polyhedra, and line segments. Let P and Q denote the two objects to be tested for intersection. Throughout, n_p and n_q denote the combinatorial complexity of P and Q, respectively, that is, the number of vertices, edges, and faces (for polyhedra). Let $n = n_p + n_q$ denote the total complexity.

Table 38.2.1 summarizes a number of results on intersection detection, which will be discussed further in this section. In the table, the terms *convex* and *simple* refer to convex and simple polygons, respectively. The notation $(s(n), q(n))$ in the "Time" column means that the solution involves preprocessing, where a data structure of size $O(s(n))$ is constructed so that intersection detection queries can be answered in $O(q(n))$ time.

TABLE 38.2.1 Intersection detection.

DIM	OBJECTS	TIME	SOURCE
2	convex-convex	$\log n$	[DK83]
	simple-simple	n	[Cha91]
	simple-simple	$(n, s\log^2 n)$	[Mou92]
	line segments	$n \log n$	[SH76]
	Hopcroft's problem	$n^{4/3}2^{O(\log^* n)}$	[Mat93]
3	convex-convex	n	[DK85]
	convex-convex	$(n, \log n_p \log n_q)$	[DK90]

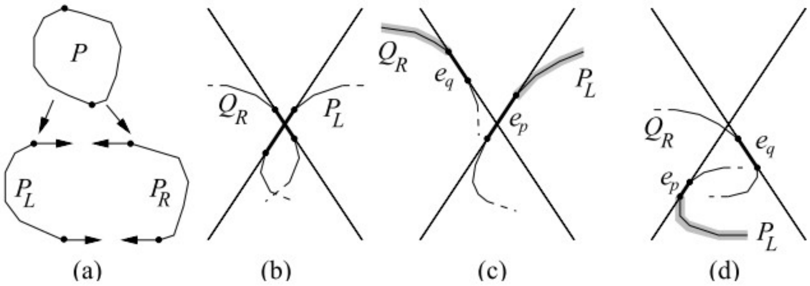
INTERSECTION DETECTION OF CONVEX POLYGONS

Perhaps the most easily understood example of how the structure of geometric objects can be exploited to yield an efficient intersection test is that of detecting the intersection of two convex polygons. There are a number of solutions to this problem that run in $O(\log n)$ time. We present one due to Dobkin and Kirkpatrick [DK83].

Assume that each polygon is given by an array of vertex coordinates, sorted in counterclockwise order. The first step of the algorithm is to find the vertices of each of P and Q with the highest and lowest y-coordinates. This can be done in $O(\log n)$ time by an appropriate modification of binary search and consideration of the direction of the edges incident to each vertex [O'R98, Section 7.6]. After these vertices are located, the boundary of each polygon is split into two semi-infinite convex chains, denoted P_L, P_R and Q_L, Q_R (see Figure 38.2.2(a)). P and Q intersect if and only if P_L and Q_R intersect, and P_R and Q_L intersect.

© 2004 by Chapman & Hall/CRC

FIGURE 38.2.2
Intersection detection for two convex polygons.



Consider the case of P_L and Q_R. The algorithm applies a variant of binary search. Consider the median edge e_p of P_L and the median edge e_q of Q_R (shown as heavy lines in the figure). By a simple analysis of the relative positions of these edges and the intersection point of the two lines on which they lie, it is possible to determine in constant time either that the polygons intersect, or that half of at least one of the two boundary chains can be eliminated from further consideration. The cases that arise are illustrated in Figure 38.2.2(b)-(d). The shaded regions indicate the portion of the boundary that can be eliminated from consideration.

SIMPLE POLYGONS

Without convexity, it is generally not possible to detect intersections in sublinear time without preprocessing; but efficient tests do exist.

One of the important intersection questions is whether a closed polygonal chain defines the edges of a simple polygon. The problem reduces to detecting whether the chain is self-intersecting. This problem can be solved efficiently by supposing that the polygonal chain is a simple polygon, attempting to triangulate the polygon, and seeing whether anything goes wrong in the process. Some triangulation algorithms can be modified to detect self intersections. In particular, the problem can be solved in $O(n)$ time by modifying Chazelle's linear-time triangulation algorithm [Cha91]. See Section 25.2.

Another variation is that of determining the intersection of two simple polygons. Chazelle observed that this can also be reduced to testing self intersections in $O(n)$ time by joining the polygons into a single closed chain by a narrow channel as shown in Figure 38.2.3.

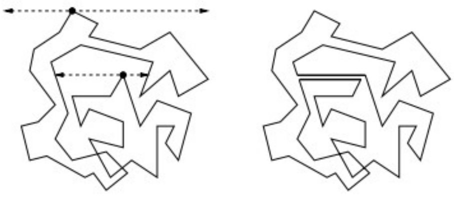


FIGURE 38.2.3
Intersection detection for two simple polygons.

© 2004 by Chapman & Hall/CRC

bounded by a given closed path C in item 2 with the law of conservation of charge, we obtain for any closed surface S,

$$\frac{d}{dt}\left(\oint_S \mathbf{D}\cdot d\mathbf{S} - \int_V \rho\, dv\right) = 0 \tag{1.25}$$

where V is the volume bounded by S. Once again, one can then argue that the quantity inside the parentheses is zero, since at an instant of time when no sources are present, it vanishes. Thus, Gauss' law for the electric field is not independent of Ampere's circuital law in view of the law of conservation of charge.

10. The cut view in Fig. 1.8 indicates that magnetic field lines are continuous, having no beginnings or endings, whereas the cut view in Fig. 1.7 indicates that electric field lines are discontinuous wherever there are charges, diverging from positive charges and converging on negative charges.

1.2.2 Maxwell's Equations in Differential Form and the Continuity Equation

From the integral forms of Maxwell's equations, one can obtain the corresponding differential forms through the use of Stoke's and divergence theorems in vector calculus, given, respectively, by

$$\oint_C \mathbf{A}\cdot d\mathbf{l} = \int_S (\nabla\times\mathbf{A})\cdot d\mathbf{S} \tag{1.26a}$$

$$\oint_S \mathbf{A}\cdot d\mathbf{S} = \int_V (\nabla\cdot\mathbf{A})\, dv \tag{1.26b}$$

where in Eq. (1.26a), S is any surface bounded by C and in Eq. (1.26b), V is the volume bounded by S. Thus, Maxwell's equations in differential form are given by

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{1.27}$$

$$\nabla\times\mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \tag{1.28}$$

$$\nabla\cdot\mathbf{D} = \rho \tag{1.29}$$

$$\nabla\cdot\mathbf{B} = 0 \tag{1.30}$$

corresponding to the integral forms Eqs. (1.18)–(1.21), respectively. These differential equations state that at any point in a given medium, the curl of the electric field intensity is equal to the time rate of decrease of the magnetic flux density, and the curl of the magnetic field intensity is equal to the sum of the current density due to flow of charges and the displacement current density (time derivative of the displacement flux density); whereas the divergence of the displacement flux density is equal to the volume charge density, and the divergence of the magnetic flux density is equal to zero.

Auxiliary to the Maxwell's equations in differential form is the differential equation following from the law of conservation of charge Eq. (1.22) through the use of Eq. (1.26b). Familiarly known as the *continuity equation*, this is given by

$$\nabla \cdot \mathbf{J} + \frac{\partial \rho}{\partial t} = 0 \tag{1.31}$$

It states that at any point in a given medium, the divergence of the current density due to flow of charges plus the time rate of increase of the volume charge density is equal to zero.

From the interdependence of the integral laws discussed in the previous section, it follows that Eq. (1.30) is not independent of Eq. (1.27), and Eq. (1.29) is not independent of Eq. (1.28) in view of Eq. (1.31).

Maxwell's equations in differential form lend themselves well for a qualitative discussion of the interdependence of time-varying electric and magnetic fields giving rise to the phenomenon of electromagnetic wave propagation. Recognizing that the operations of curl and divergence involve partial derivatives with respect to space coordinates, we observe that time-varying electric and magnetic fields coexist in space, with the spatial variation of the electric field governed by the temporal variation of the magnetic field in accordance with Eq. (1.27), and the spatial variation of the magnetic field governed by the temporal variation of the electric field in addition to the current density in accordance with Eq. (1.28). Thus, if in Eq. (1.28) we begin with a time-varying current source represented by $\mathbf{J}$, or a time-varying electric field represented by $\partial\mathbf{D}/dt$, or a combination of the two, then one can visualize that a magnetic field is generated in accordance with Eq. (1.28), which in turn generates an electric field in accordance with Eq. (1.27), which in turn contributes to the generation of the magnetic field in accordance with Eq. (1.28), and so on, as depicted in Fig. 1.11. Note that $\mathbf{J}$ and ρ are coupled, since they must satisfy Eq. (1.31). Also, the magnetic field automatically satisfies Eq. (1.30), since Eq. (1.30) is not independent of Eq. (1.27).

The process depicted in Fig. 1.11 is exactly the phenomenon of electromagnetic waves propagating with a velocity (and other characteristics) determined by the parameters of the medium. In free space, the waves propagate unattenuated with the velocity $1/\sqrt{\mu_0\varepsilon_0}$, familiarly represented by the symbol c. If either the term $\partial\mathbf{B}/\partial t$ in Eq. (1.27) or the term $\partial\mathbf{D}/\partial t$ in Eq. (1.28) is not present, then wave propagation would not occur. As already stated in the previous section, it was through the addition of the term

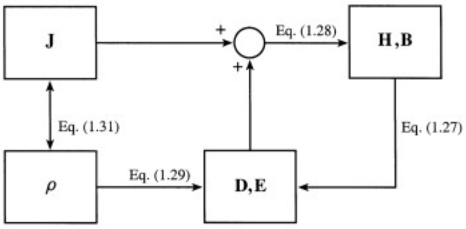

Figure 1.11 Generation of interdependent electric and magnetic fields, beginning with sources $\mathbf{J}$ and ρ.

$\partial \mathbf{D}/\partial t$ in Eq. (1.28) that Maxwell predicted electromagnetic wave propagation before it was confirmed experimentally.

Of particular importance is the case of time variations of the fields in the sinusoidal steady state, that is, the frequency domain case. In this connection, the frequency domain forms of Maxwell's equations are of interest. Using the phasor notation based on

$$A\ \cos(\omega t + \phi) = \mathrm{Re}\left[Ae^{j\phi}e^{j\omega t}\right] = \mathrm{Re}\left[\bar{A}e^{j\omega t}\right] \tag{1.32}$$

where $\bar{A} = Ae^{j\phi}$ is the phasor corresponding to the time function, we obtain these equations by replacing all field quantities in the time domain form of the equations by the corresponding phasor quantities and $\partial/\partial t$ by $j\omega$. Thus with the understanding that all phasor field quantities are functions of space coordinates, that is, $\bar{\mathbf{E}} = \bar{\mathbf{E}}(\mathbf{r})$, etc., we write the Maxwell's equations in frequency domain as

$$\nabla \times \bar{\mathbf{E}} = -j\omega\bar{\mathbf{B}} \tag{1.33}$$

$$\nabla \times \bar{\mathbf{H}} = \bar{\mathbf{J}} + j\omega\bar{\mathbf{D}} \tag{1.34}$$

$$\nabla \cdot \bar{\mathbf{D}} = \bar{\rho} \tag{1.35}$$

$$\nabla \cdot \bar{\mathbf{B}} = 0 \tag{1.36}$$

Also, the continuity equation, Eq. (1.31), transforms to the frequency domain form

$$\nabla \cdot \bar{\mathbf{J}} + j\omega\bar{\rho} = 0 \tag{1.37}$$

Note that since $\nabla \cdot \nabla \times \bar{\mathbf{E}} = 0$, Eq. (1.36) follows from Eq. (1.33), and since $\nabla \cdot \nabla \times \bar{\mathbf{H}} = 0$, Eq. (1.35) follows from Eq. (1.34) with the aid of Eq. (1.37).

Now the constitutive relations in phasor form are

$$\bar{\mathbf{D}} = \varepsilon\bar{\mathbf{E}} \tag{1.38a}$$

$$\bar{\mathbf{H}} = \frac{\bar{\mathbf{B}}}{\mu} \tag{1.38b}$$

$$\bar{\mathbf{J}}_c = \sigma\bar{\mathbf{E}} \tag{1.38c}$$

Substituting these into Eqs. (1.33)–(1.36), we obtain for a material medium characterized by the parameters ε, μ, and σ,

$$\nabla \times \bar{\mathbf{E}} = -j\omega\mu\bar{\mathbf{H}} \tag{1.39}$$

$$\nabla \times \bar{\mathbf{H}} = (\sigma + j\omega\varepsilon)\bar{\mathbf{E}} \tag{1.40}$$

$$\nabla \cdot \bar{\mathbf{H}} = 0 \tag{1.41}$$

$$\nabla \cdot \bar{\mathbf{E}} = \frac{\bar{\rho}}{\varepsilon} \tag{1.42}$$

Note however that if the medium is homogeneous, that is, if the material parameters are independent of the space coordinates, Eq. (1.40) gives

$$\nabla \cdot \bar{\mathbf{E}} = \frac{1}{\sigma + j\omega\varepsilon} \nabla \cdot \nabla \times \bar{\mathbf{H}} = 0 \tag{1.43}$$

so that $\bar{\rho} = 0$ in such a medium.

A point of importance in connection with the frequency domain form of Maxwell's equations is that in these equations, the parameters ε, μ, and σ can be allowed to be functions of ω. In fact, for many dielectrics, the conductivity increases with frequency in such a manner that the quantity $\sigma/\omega\varepsilon$ is more constant than is the conductivity. This quantity is the ratio of the magnitudes of the two terms on the right side of Eq. (1.40), that is, the conduction current density term $\sigma\bar{\mathbf{E}}$ and the displacement current density term $j\omega\varepsilon\bar{\mathbf{E}}$.

1.2.3. Boundary Conditions

Maxwell's equations in differential form govern the interrelationships between the field vectors and the associated source densities at points in a given medium. For a problem involving two or more different media, the differential equations pertaining to each medium provide solutions for the fields that satisfy the characteristics of that medium. These solutions need to be matched at the boundaries between the media by employing "boundary conditions," which relate the field components at points adjacent to and on one side of a boundary to the field components at points adjacent to and on the other side of that boundary. The boundary conditions arise from the fact that the integral equations involve closed paths and surfaces and they must be satisfied for all possible closed paths and surfaces whether they lie entirely in one medium or encompass a portion of the boundary.

The boundary conditions are obtained by considering one integral equation at a time and applying it to a closed path or a closed surface encompassing the boundary, as shown in Fig. 1.12 for a plane boundary, and in the limit that the area enclosed by the closed path, or the volume bounded by the closed surface, goes to zero. Let the quantities pertinent to medium 1 be denoted by subscript 1 and the quantities pertinent to medium 2 be denoted by subscript 2, and $\mathbf{a}_n$ be the unit normal vector to the surface and directed into medium 1. Let all normal components at the boundary in both media be directed along $\mathbf{a}_n$ and denoted by an additional subscript n and all tangential components at the boundary in both media be denoted by an additional subscript t. Let the surface charge density (C/m^2) and the surface current density (A/m) on the boundary be ρ_S and $\mathbf{J}_S$, respectively. Then, the boundary conditions corresponding to the Maxwell's equations in integral form can be summarized as

$$\mathbf{a}_n \times (\mathbf{E}_1 - \mathbf{E}_2) = \mathbf{0} \tag{1.44a}$$

$$\mathbf{a}_n \times (\mathbf{H}_1 - \mathbf{H}_2) = \mathbf{J}_S \tag{1.44b}$$

$$\mathbf{a}_n \cdot (\mathbf{D}_1 - \mathbf{D}_2) = \rho_S \tag{1.44c}$$

$$\mathbf{a}_n \cdot (\mathbf{B}_1 - \mathbf{B}_2) = 0 \tag{1.44d}$$

' &# 6 &

Remarks.

(1) Serendipity interpolations are obviously incomplete polynomials in ξ and η, hence have poorer local approximation compared to the local approximations based on Pascal rectangle.

(2) There is no particular theoretical basis for deriving them.

(3) In view of p-version hierarchical elements presented in the previous sections, serendipity elements are precluded and are of no practical significance.

8.11 Interpolation functions for 3D elements

For BVPs in $\mathbb{R}^3$ the domain of definition of the BVP is a subspace of $\mathbb{R}^3$, i.e. a volume. Discretizations of such domain naturally leads to 3D subdomains, i.e. 3D elements. In this section we consider hexahedron and tetrahedral families of subdomains (i.e. elements).

8.11.1 Hexahedron elements

Figure 8.50 shows hexahedron elements with distorted faces and edges and their maps in the natural coordinate space ξ, η, ζ in a two unit cube with the origin of the coordinate system located at the center of the element.

8.11.1.1 Mapping of points

In the abstract sense, the mapping of points between ξ, η, ζ and x, y, z-spaces is defined by

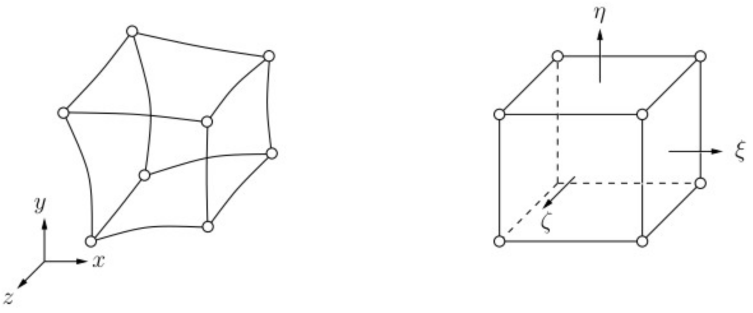
$$\begin{aligned} x &= x(\xi, \eta, \zeta) \\ y &= y(\xi, \eta, \zeta) \\ z &= z(\xi, \eta, \zeta) \end{aligned} \tag{8.216}$$

The inverse of the mapping is given by

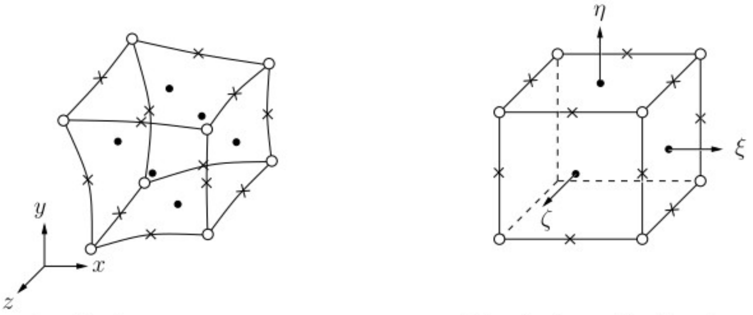
$$\begin{aligned} \xi &= \xi(x, y, z) \\ \eta &= \eta(x, y, z) \\ \zeta &= \zeta(x, y, z) \end{aligned} \tag{8.217}$$

As in the case of 2D elements, (8.216) is preferable over (8.217). The explicit form of the mapping defined by (8.216) can be established. Let $\bar{N}_i(\xi, \eta, \zeta)$ be basis functions in the natural coordinate space such that $\forall \xi, \eta, \zeta \in \bar{\Omega}^{\xi\eta\zeta}$ or $\bar{\Omega}^m$ we have

$$\bar{N}_i(\xi_j, \eta_j, \zeta_j) = \begin{cases} 1, & j = i \\ 0, & j \neq i \end{cases} \tag{8.218}$$



Eight-node element in x, y, z space   Eight-node element in ξ, η, ζ space



27-node element in x, y, z space   27-node element in ξ, η, ζ space

Figure 8.50: Hexahedral 3D elements

$$\sum_{i=1}^{\bar{n}} \bar{N}_i(\xi, \eta, \zeta) = 1 \tag{8.219}$$

in which $\bar{\Omega}^m$ is the map of $\bar{\Omega}^e$ in ξ, η, ζ space, i.e. mapping (8.216) is such that $\bar{\Omega}^m \to \bar{\Omega}^e$ or by (8.217), $\bar{\Omega}^e \to \bar{\Omega}^m$. Using $\bar{N}_i(\xi, \eta, \zeta)$ we can write,

$$\begin{aligned} x = x(\xi, \eta, \zeta) &= \sum_{i=1}^{\bar{n}} \bar{N}_i(\xi, \eta, \zeta)\, x_i \\ y = y(\xi, \eta, \zeta) &= \sum_{i=1}^{\bar{n}} \bar{N}_i(\xi, \eta, \zeta)\, y_i \\ z = z(\xi, \eta, \zeta) &= \sum_{i=1}^{\bar{n}} \bar{N}_i(\xi, \eta, \zeta)\, z_i \end{aligned} \tag{8.220}$$

in which (x_i, y_i, z_i) are coordinates of node i in x, y, z space. Equation (8.220) map a point (ξ^*, η^*, ζ^*) into (x^*, y^*, z^*).

8.11.1.2 Mapping of lengths

In this section we establish a relationship between length dx, dy, dz in x, y, z space and $d\xi, d\eta, d\zeta$ in ξ, η, ζ space. Based on (8.216), we can write

$$\begin{aligned} dx =& \frac{\partial x}{\partial \xi}\, d\xi + \frac{\partial x}{\partial \eta}\, d\eta + \frac{\partial x}{\partial \zeta}\, d\zeta \\ dy =& \frac{\partial y}{\partial \xi}\, d\xi + \frac{\partial y}{\partial \eta}\, d\eta + \frac{\partial y}{\partial \zeta}\, d\zeta \\ dz =& \frac{\partial z}{\partial \xi}\, d\xi + \frac{\partial z}{\partial \eta}\, d\eta + \frac{\partial z}{\partial \zeta}\, d\zeta \end{aligned} \tag{8.221}$$

or

$$\begin{Bmatrix} dx \\ dy \\ dz \end{Bmatrix} [J] \begin{Bmatrix} d\xi \\ d\eta \\ d\zeta \end{Bmatrix} \tag{8.222}$$

where

$$[J] = \begin{bmatrix} \frac{\partial x}{\partial \xi} & \frac{\partial x}{\partial \eta} & \frac{\partial x}{\partial \zeta} \\ \frac{\partial y}{\partial \xi} & \frac{\partial y}{\partial \eta} & \frac{\partial y}{\partial \zeta} \\ \frac{\partial z}{\partial \xi} & \frac{\partial z}{\partial \eta} & \frac{\partial z}{\partial \zeta} \end{bmatrix} \tag{8.223}$$

is called the Jacobian of transformation. For the mapping to be unique, i.e. one-to-one and onto,

$$det\,[J] > 0 \quad \forall (\xi, \eta, \zeta) \in \bar{\Omega}^m \tag{8.224}$$

must hold. Equations (8.222) is the desired relationship for mapping of lengths. The elements of $[J]$ can easily be obtained using (8.220) in which $\bar{N}_i(\xi, \eta, \zeta)$ and (x_i, y_i, z_i) are known.

8.11.1.3 Mapping of volumes

In this section we derive a relationship that relates elemental volume $dx\, dy\, dz$ in x, y, z space to the elemental volume $d\xi\, d\eta\, d\zeta$ in $\xi\, \eta\, \zeta$ space. Let $\vec{i}, \vec{j}, \vec{k}$ be the unit vectors in x, y, z space and let $\vec{e}_\xi, \vec{e}_\eta, \vec{e}_\zeta$ be unit vectors in ξ, η, ζ space, then we can write

$$\begin{aligned} dx\, \vec{i} &= \frac{\partial x}{\partial \xi}\, d\xi\, \vec{e}_\xi + \frac{\partial x}{\partial \eta}\, d\eta\, \vec{e}_\eta + \frac{\partial x}{\partial \zeta}\, d\zeta\, \vec{e}_\zeta \\ dy\, \vec{j} &= \frac{\partial y}{\partial \xi}\, d\xi\, \vec{e}_\xi + \frac{\partial y}{\partial \eta}\, d\eta\, \vec{e}_\eta + \frac{\partial y}{\partial \zeta}\, d\zeta\, \vec{e}_\zeta \\ dz\, \vec{k} &= \frac{\partial z}{\partial \xi}\, d\xi\, \vec{e}_\xi + \frac{\partial z}{\partial \eta}\, d\eta\, \vec{e}_\eta + \frac{\partial z}{\partial \zeta}\, d\zeta\, \vec{e}_\zeta \end{aligned} \tag{8.225}$$

We note that

$$dx\, \vec{i} \cdot (dy\, \vec{j} \times dz\, \vec{k}) = dx\, \vec{i} \cdot dy\, dz\, \vec{i} = dx\, dy\, dz \tag{8.226}$$

Substituting for $dx\,\vec{i}, dy\,\vec{j}, dz\,\vec{k}$ from (8.225) into (8.226) and using properties of the dot product and cross products of the unit vectors in x, y, z and ξ, η, ζ spaces, we obtain

$$dx\,dy\,dz = det[J]\,d\xi\,d\eta\,d\zeta \tag{8.227}$$

Based on (8.227), $det[J] > 0$ must hold otherwise the volume in xyz space could be negative or zero if $det[J] = 0$.

8.11.1.4 Obtaining derivatives of $\phi_h^e(\xi,\eta,\zeta)$ with respect to x, y, z

With the local approximation $\phi_h^e(\xi,\eta,\zeta)$ of ϕ defined by (8.232), and assuming that $N_i(\xi,\eta,\zeta)$ are known functions, obtaining derivatives of $\phi_h^e(\xi,\eta,\zeta)$ with respect to x, y, z needed in the integral form is not directly possible due to the fact that $N_i(\cdot)$ are functions of ξ, η and ζ. First, we note that when $\phi_h^e(\xi,\eta,\zeta)$ is defined by (8.232) we have

$$\begin{aligned}\frac{\partial \phi_h^e}{\partial x} &= \sum_{i=1}^{n} \frac{\partial N_i}{\partial x}\,\delta_i^e \\ \frac{\partial \phi_h^e}{\partial y} &= \sum_{i=1}^{n} \frac{\partial N_i}{\partial y}\,\delta_i^e \\ \frac{\partial \phi_h^e}{\partial z} &= \sum_{i=1}^{n} \frac{\partial N_i}{\partial z}\,\delta_i^e\end{aligned} \tag{8.228}$$

Thus, obtaining $\frac{\partial \phi_h^e}{\partial x}$, $\frac{\partial \phi_h^e}{\partial y}$ and $\frac{\partial \phi_h^e}{\partial z}$ implies establishing $\frac{\partial N_i}{\partial x}$, $\frac{\partial N_i}{\partial y}$ and $\frac{\partial N_i}{\partial z}$; $i = 1,\dots,n$. Since $N_i = N_i(\xi,\eta,\zeta)$ and $x = x(\xi,\eta,\zeta)$, $y = y(\xi,\eta,\zeta)$ and $z = z(\xi,\eta,\zeta)$, we proceed as follows.

$$\left.\begin{aligned}\frac{\partial N_i}{\partial \xi} &= \frac{\partial N_i}{\partial x}\frac{\partial x}{\partial \xi} + \frac{\partial N_i}{\partial y}\frac{\partial y}{\partial \xi} + \frac{\partial N_i}{\partial z}\frac{\partial z}{\partial \xi} \\ \frac{\partial N_i}{\partial \eta} &= \frac{\partial N_i}{\partial x}\frac{\partial x}{\partial \eta} + \frac{\partial N_i}{\partial y}\frac{\partial y}{\partial \eta} + \frac{\partial N_i}{\partial z}\frac{\partial z}{\partial \eta} \\ \frac{\partial N_i}{\partial \zeta} &= \frac{\partial N_i}{\partial x}\frac{\partial x}{\partial \zeta} + \frac{\partial N_i}{\partial y}\frac{\partial y}{\partial \zeta} + \frac{\partial N_i}{\partial z}\frac{\partial z}{\partial \zeta}\end{aligned}\right\}, \quad i = 1,\dots,n \tag{8.229}$$

or

$$\begin{Bmatrix} \frac{\partial N_i}{\partial \xi} \\ \frac{\partial N_i}{\partial \eta} \\ \frac{\partial N_i}{\partial \zeta} \end{Bmatrix} = [J]^T \begin{Bmatrix} \frac{\partial N_i}{\partial x} \\ \frac{\partial N_i}{\partial y} \\ \frac{\partial N_i}{\partial z} \end{Bmatrix}, \quad i = 1,\dots,n \tag{8.230}$$

Therefore

$$\begin{Bmatrix} \frac{\partial N_i}{\partial x} \\ \frac{\partial N_i}{\partial y} \\ \frac{\partial N_i}{\partial z} \end{Bmatrix} = \Big[[J]^T\Big]^{-1} \begin{Bmatrix} \frac{\partial N_i}{\partial \xi} \\ \frac{\partial N_i}{\partial \eta} \\ \frac{\partial N_i}{\partial \zeta} \end{Bmatrix}, \quad i = 1,\dots,n \tag{8.231}$$

Using (8.231) derivatives of $N_i(\xi,\eta,\zeta)$ with respect to ξ, η and ζ can be transformed into the derivatives of $N_i(\xi,\eta,\zeta)$ with respect to x, y, z and, hence, the derivatives of $\phi_h^e(\xi,\eta,\zeta)$ with respect to x, y, z in (8.228) are defined.

8.11.2 Local approximation for a dependent variable ϕ over $\bar{\Omega}^m$

8.11.2.1 Hexahedron elements

Let $\phi_h^e(\xi,\eta,\zeta)$ be the local approximation of ϕ over $\bar{\Omega}^m$. Then symbolically we can write

$$\phi_h^e(\xi,\eta,\zeta) = \sum_{i=1}^{n} N_i(\xi,\eta,\zeta)\,\delta_i^e = [N]\{\delta^e\} \tag{8.232}$$

where $N_i(\xi,\eta,\zeta)$ are the local approximation functions or interpolation functions corresponding to the nodes of the element and δ_i^e are the nodal degrees of freedom. Functions $N_i(\xi,\eta,\zeta)$ are also referred to as basis functions. Explicit forms of $N_i(\xi,\eta,\zeta)$ depend upon many considerations (similar to these for 2D elements).

(1) The first important issue is the choice of nodal configuration for the element. That is, how many nodes and their locations.

(2) Means of constructing $N_i(\xi,\eta,\zeta)$ for

   (a) C^{000} local approximations of higher degree
   (b) C^{000} p-version hierarchical local approximations
   (c) C^{ijk}, $i,j,k \geq 1$ local approximations for prism family
   (d) C^{ijk}, $i,j,k \geq 1$ local approximations for distorted geometries in $\mathbb{R}^3$

(3) In the developments in (2), the choices of δ_i^e, nodal dofs are crucial and require careful considerations.

(4) The developments in (2) and (3) could be based on (i) Lagrange interpolation functions (ii) Legendre polynomials or (iii) Chebyshev polynomials. The specific details presented in the following are based on Lagrange polynomials. The extensions to the other two types are straight forward. We consider details in the following

$C^{000}(\bar{\Omega}^e)$ polynomial approximations: linear approximation

We consider local approximations of type $C^{000}(\bar{\Omega}^e)$, i.e. across the inter-element boundaries ϕ is continuous but the derivative of ϕ normal to the inter-element boundaries may be discontinuous in the physical domain. For with sides parallel to xyz axes and pointing in the same direction as xyz axes. We consider map of this element in xyz space, a prism where sides are also parallel to xyz axes and pointing in the same direction. By using tensor products of C^i, C^j and C^k one-dimensional interpolations in xyz directions, the local approximation functions and nodal variable operators for the 27 node prism family of hexahedron can be derived in a straight forward manner. These elements have same limitations and restrictions as discussed in section 8.5 for similar local approximations for 2D case in xy space. We remark that these interpolation functions can be of Lagrange, Legendre or Chebyshev type by choosing 1D interpolations based on these.

8.11.2.6 3D $C^{ijk}(\bar{\Omega}^e)$ *p*-version interpolations for distorted hexahedron elements: 27 node element

In deriving the local approximations for this family of hexahedron elements we can follow the procedure similar to that used for 2D elements (section 8.6). The decision of the choice of dofs at the corner is straight forward due to the fact that these must constitute a transformable set between $\xi\eta\zeta$ and xyz space. However, from which nodes to borrow the needed degrees of freedom is not as straight forward but can be facilitated by examining Pascal prism and ensuring that lower order admissible terms are chosen first. These interpolations can also be of Lagrange, Legendre, or Chebyshev type depending upon the choice of 1D interpolations.

8.11.2.7 Interpolation theory for 3D tetrahedron elements: basis functions of class $C^{000}(\bar{\Omega}^e)$ based on Lagrange interpolations

Parallel to Pascal prism, in case of tetrahedron elements we have Pascal pyramid (see Fig. 8.62). The locations of the terms are the locations of the nodes and the terms themselves are to be used in the linear combination for the local approximations. For example a linear tetrahedron will contain four vertex nodes with the local approximation (for a dependent variable ϕ)

$$\phi_h^e(x,y,z) = c_1 + c_2x + c_3y + c_4z \tag{8.251}$$

Using Cartesian coordinates of the vertex nodes (x_i, y_i, z_i) are the function values $\phi(x_i, y_i, z_i) = \phi_i^e$ $(i = 1, 2, \dots, 4)$. In (8.251), it is straight forward to establish

$$\phi_h^e(x,y,z) = \sum_{i=1}^{4} N_i(x,y,z)\,\phi_i^e \tag{8.252}$$

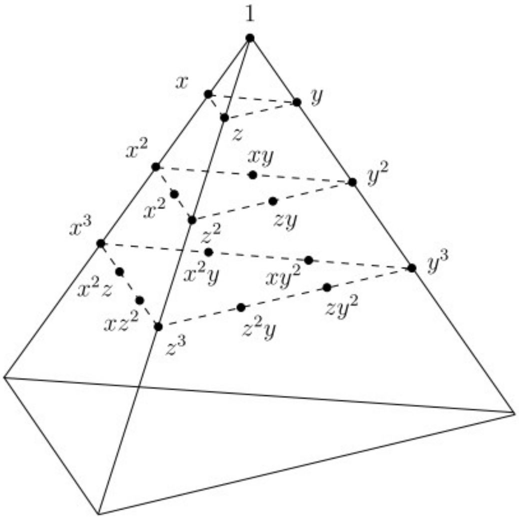


Figure 8.62: Pascal pyramid

in which $N_i(x, y, z)$ are the interpolation functions with the properties

$$
\begin{gathered}
N_i(x_j, y_j, z_j) = \begin{cases} 1, & \text{if } j = i \\ 0, & \text{if } j \neq i \end{cases} \\
\sum_{i=1}^{4} N_i(x, y, z) = 1
\end{gathered}
\tag{8.253}
$$

Using this procedure higher degree local approximations of class $C^{000}(\bar{\Omega}^e)$ can be constructed for the tetrahedron elements. As in case of hexahedron elements based on Pascal prism, here also with increasing degree of local approximations the number of nodes for an element increase and we require inverse of progressively increasing size coefficient matrices to determine $N_i(x, y, z)$.

8.11.2.8 Lagrange family C^{000} interpolations based on volume coordinates

Parallel to the area coordinates for 2D triangular elements, in case of tetrahedron elements we introduce the concept of volume coordinates. Consider a four-node tetrahedron element shown in Fig. 8.63. Consider a point P in the interior of the element. Connect point P with the vertices of the tetrahedron by straight lines. By doing so we divide the volume V into four volumes V_1, V_2, V_3 and V_4. Let the side opposite to node i be side i with volume V_i.

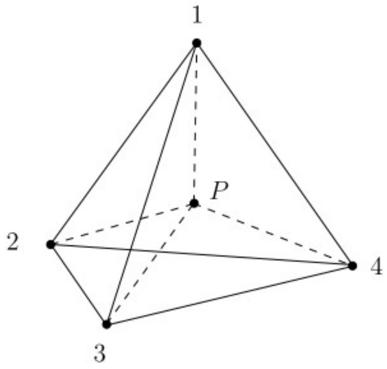

Figure 8.63: Tetrahedron element with volume coordinates

Let

$$\begin{aligned} &L_1 = \frac{V_i}{V}, \quad i = 1, 2, \dots, 4 \\ &\text{with} \quad \sum_{i=1}^{4} L_i = 1 \end{aligned} \tag{8.254}$$

be the volume coordinates. Clearly L_i is equal to 1 at node i but zero on side i. The volume coordinates can be used to define the Cartesian coordinates of any point on the element. If (x_i, y_i, z_i) are the Cartesian coordinates of the nodes of the element, then

$$\begin{aligned} x &= L_1x_1 + L_2x_2 + L_3x_3 + L_4x_4 \\ y &= L_1y_1 + L_2y_2 + L_3y_3 + L_4y_4 \\ z &= L_1z_1 + L_2z_2 + L_3z_3 + L_4z_4 \end{aligned} \tag{8.255}$$

Using (8.255) and the second equation of (8.254), we can write

$$\begin{Bmatrix} 1 \\ x \\ y \\ z \end{Bmatrix} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ x_1 & x_2 & x_3 & x_4 \\ y_1 & y_2 & y_3 & y_4 \\ z_1 & z_2 & z_3 & z_4 \end{bmatrix} = \begin{Bmatrix} L_1 \\ L_2 \\ L_3 \\ L_4 \end{Bmatrix} = [C] \begin{Bmatrix} L_1 \\ L_2 \\ L_3 \\ L_4 \end{Bmatrix} \tag{8.256}$$

Therefore

$$\begin{Bmatrix} L_1 \\ L_2 \\ L_3 \\ L_4 \end{Bmatrix} = [C]^{-1} \begin{Bmatrix} 1 \\ x \\ y \\ z \end{Bmatrix} = \begin{Bmatrix} N_1(x,y,z) \\ N_2(x,y,z) \\ N_3(x,y,z) \\ N_4(x,y,z) \end{Bmatrix} \tag{8.257}$$

We can show that $N_i(x, y, z)$ here in (8.257) are same as these using Pascal pyramid. We note that $\det[C]$ is related to the volume of tetrahedron hence

$\det[C] > 0$ holds implying that $N_i(x,y,z)$ in (8.257) are unique. Thus for the four-node tetrahedron we can use L_1, L_2, L_3, L_4 as interpolation functions instead of $N_i(x,y,z)$; $i = 1, 2, \dots, 4$.

8.11.2.9 Higher degree C^{000} basis functions using volume coordinates

Consider the four-node tetrahedron element shown in Fig. 8.63 with vertex nodes 1, 2, 3 and 4. We draw m equally spaced planes parallel to side 1 labelled $0, 1, \dots, p \dots, m$, 0 being label for side 1. Similarly, we also draw m equally spaced planes parallel to sides 2, 3 and 4, sides 2, 3 and 4 being marked '0' and q, r, s being intermediate locations of the planes parallel to sides 2, 3, and 4. If we consider typical planes p, q, r and s (parallel to sides 1, 2, 3 and 4) then their intersection $pqrs$ defines a point within the tetrahedron element. The intersection of these planes with sides 1, 2, 3 and 4 and amongst themselves define the location of the nodes in agreement with the Pascal pyramid. Consider side 1 and planes parallel to it. We note that L_1 is one at node 1 and zero on side 1, hence we can setup Lagrange type interpolations to define functions $N_0(L_1), N_1(L_1), \dots, N_m(L_1)$ corresponding to $(m+1)$ parallel planes. We can define $N_i(L_1)$ by

$$\begin{aligned} N_i(L_1) &= \prod_{j=1}^{i} \Big(\frac{mL_1 - j + 1}{j} \Big), \quad \text{for } j \geq 1;\ i = 1, 2, \dots, m \\ &= 0 \quad \text{for } i = 0 \end{aligned} \tag{8.258}$$

Similarly in the other three directions, we setup $N_i(L_2$, $N_i(L_3)$ and $N_i(L_4)$

$$\begin{aligned} N_i(L_2) &= \prod_{j=1}^{i} \Big(\frac{mL_2 - j + 1}{j} \Big), \quad \text{for } j \geq 1;\ i = 1, 2, \dots, m \\ &= 0 \quad \text{for } i = 0 \end{aligned} \tag{8.259}$$

$$\begin{aligned} N_i(L_3) &= \prod_{j=1}^{i} \Big(\frac{mL_3 - j + 1}{j} \Big), \quad \text{for } j \geq 1;\ i = 1, 2, \dots, m \\ &= 0 \quad \text{for } i = 0 \end{aligned} \tag{8.260}$$

$$\begin{aligned} N_i(L_4) &= \prod_{j=1}^{i} \Big(\frac{mL_4 - j + 1}{j} \Big), \quad \text{for } j \geq 1;\ i = 1, 2, \dots, m \\ &= 0 \quad \text{for } i = 0 \end{aligned} \tag{8.261}$$

The 3D interpolations or basis functions for a node located at p, q, r, s i.e. $N_{pqrs}(L_1, L_2, L_3, L_4)$ can now be defined using

$$N_{pqrs}(L_1, L_2, L_3, L_4) = N_p(L_1)\, N_q(L_2)\, N_r(L_3)\, N_s(L_4) \tag{8.262}$$

' & $ $:

For the second Householder reflection ($j = 2$), the linear system becomes

$$\begin{bmatrix} -95.39 & -2.20 \\ 0 & -1.47 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} -54.51 \\ -51.10 \\ 11.91 \\ 13.64 \\ 5.36 \\ -17.91 \\ 3.81 \end{bmatrix}.$$

We can now solve the system with back substitution, starting with the first nonzero row, and the solution is

$$\begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} -0.23 \\ 34.82 \end{bmatrix}.$$

Excluding numerical round-off, this is the same solution found using the normal equations in Example 12.13.

◆

13.2 Vector Norms

Finding the magnitude or length of a 3D vector is fundamental to many geometric operations. It is also fundamental for n-dimensional vectors, even though such vectors might no longer have geometric meaning. For example, in Section 13.6, we examine iterative methods for solving linear systems, and vector length is key for monitoring improvements in the solution.

The magnitude or length of an $n-$dimensional vector $\mathbf{v}$ is typically measured by

$$\|\mathbf{v}\|_2 = \sqrt{v_1^2 + \ldots + v_n^2}. \qquad (13.2)$$

The (nonnegative) scalar $\|\mathbf{v}\|_2$ is also referred to as the *Euclidean norm* because in $\mathbb{R}^3$ it is Euclidean length. Since this is the "usual" way to measure length, the subscript 2 often is omitted.

More generally, (13.2) is a *vector norm*. Other vector norms are conceivable, for instance the 1-norm

$$\|\mathbf{v}\|_1 = |v_1| + |v_2| + \ldots + |v_n| \qquad (13.3)$$

or the ∞-norm

$$\|\mathbf{v}\|_\infty = \max_i |v_i|. \qquad (13.4)$$

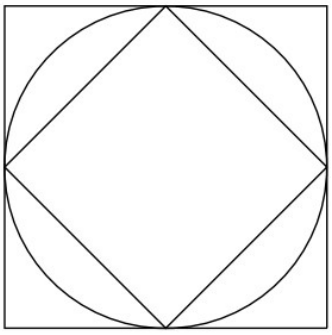

Figure 13.2.

Vector norms: outline of the unit vectors for the 2-norm is a circle, ∞-norm is a square, 1-norm is a diamond.

We can gain an understanding of these norms by studying the familiar case $n = 2$. Recall that a *unit vector* is one whose norm equals one. For the 2-norm $\|\mathbf{v}\|_2$, all unit vectors form a circle of radius one. With a bit of thinking, we can see that for the 1-norm all unit vectors form a diamond, while in the ∞-norm, all unit vectors form a square of edge length two. This geometric interpretation is shown in Figure 13.2.

All three of these norms may be viewed as members of a whole family of norms, referred to as p-norms. The p-norm of $\mathbf{v}$ is given by

$$\|\mathbf{v}\|_p = (v_1^p + v_2^p + \ldots + v_n^p)^{1/p}.$$

It is easy to see that the 1- and 2-norm fit this mold. That $p \to \infty$ gives the ∞-norm requires a little more thought; give it a try!

Example 13.4

Let

$$\mathbf{v} = \begin{bmatrix} 1 \\ 0 \\ -2 \end{bmatrix}.$$

Then

$$\|\mathbf{v}\|_1 = 3, \qquad \|\mathbf{v}\|_2 = \sqrt{5} \approx 2.24, \qquad \|\mathbf{v}\|_\infty = 2.$$

This example and Figure 13.2 demonstrate that

$$\|\mathbf{v}\|_1 \geq \|\mathbf{v}\|_2 \geq \|\mathbf{v}\|_\infty; \tag{13.5}$$

this is also true in n dimensions.

All vector norms share some basic properties:

$$\|\mathbf{v}\| \geq 0, \tag{13.6}$$

$$\|\mathbf{v}\| = 0 \quad \text{if and only if} \quad \mathbf{v} = \mathbf{0}, \tag{13.7}$$

$$\|c\mathbf{v}\| = |c|\|\mathbf{v}| \quad \text{for} \quad c \in \mathbb{R}, \tag{13.8}$$

$$\|\mathbf{v} + \mathbf{w}\| \leq \|\mathbf{v}\| + \|\mathbf{w}\|. \tag{13.9}$$

The last of these is the familiar *triangle inequality.*

By this time, we have developed a familiarity with the 2-norm, and these properties are easily verified. Recall the steps for the triangle inequality were demonstrated in (2.24).

Let's show that the vector norm properties hold for the ∞-norm. Examining (13.4), for each $\mathbf{v}$ in $\mathbb{R}^n$, by definition, $\max_i |v_i| \geq 0$. If $\max_i |v_i| = 0$ then $v_i = 0$ for each $i = 1, \ldots, n$ and $\mathbf{v} = \mathbf{0}$. Conversely, if $\mathbf{v} = \mathbf{0}$ then $\max_i |v_i| = 0$. Thus we have established that the first two properties hold. The third property is easily shown by the properties of the absolute value function:

$$\|c\mathbf{v}\|_\infty = \max_i |cv_i| = |c| \max_i |v_i| = |c|\|\mathbf{v}\|_\infty.$$

For the triangle inequality:

$$\begin{aligned}
\|\mathbf{v} + \mathbf{w}\|_\infty &= \max_i |v_i + w_i| \\
&\leq \max_i \{|v_i| + |w_i|\} \\
&\leq \max_i |v_i| + \max_i |w_i| \\
&= \|\mathbf{v}\|_\infty + \|\mathbf{w}\|_\infty.
\end{aligned}$$

From a 2D geometric perspective, consider the 1-norm: starting at the origin, move v_1 units along the $\mathbf{e}_1$-axis and then move v_2 units along the $\mathbf{e}_2$-axis. The sum of these travels determines $\mathbf{v}$'s length. This is analogous to driving in a city with rectilinear streets, and thus this norm is also called the Manhattan or taxicab norm.

The ∞-norm is also called the max-norm. Our standard measure of length, the 2-norm, can take more computing power than we might be willing to spend on a proximity problem, where we want to determine whether two points are closer than a given tolerance. Problems of this sort are often repeated many times and against many points. Instead, the max norm might be more suitable from a computing point of view and sufficient given the relationship in (13.5). This method of using an inexpensive measure to exclude many possibilities is called *trivial reject* in some disciplines such as computer graphics.

13.3 Matrix Norms

A vector norm measures the magnitude of a vector; does it also make sense to talk about the magnitude of a matrix?

Instead of exploring the general case right away, we will first give some 2D insight. Let A be a 2×2 matrix. It maps the unit circle to an ellipse—the action ellipse. In Figure 13.3 we see points on the unit circle at the end of unit vectors $\mathbf{v}_i$ and their images $A\mathbf{v}_i$, forming this action ellipse. We can learn more about this ellipse by looking at $A^{\mathrm{T}}A$. It is *symmetric* and *positive definite*, and thus has real and positive eigenvalues, which are λ'_1 and λ'_2, in decreasing value. We then define

$$\sigma_i = \sqrt{\lambda'_i}, \tag{13.10}$$

to be the *singular values* of A. (In Chapter 16, we will explore singular values in more detail.)

The singular value σ_1 is the length of the action ellipse's semi-major axis and σ_2 is the length of the action ellipse's semi-minor axis. If A

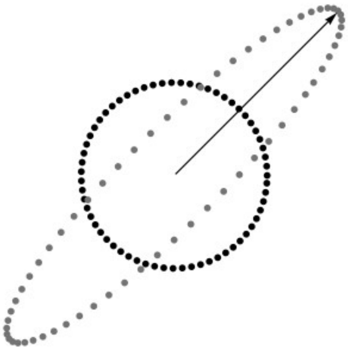

Figure 13.3.

Action of a 2×2 matrix: points on the unit circle (black) are mapped to points on an ellipse (gray) This is the *action ellipse*. The vector is the semi-major axis of the ellipse, which has length σ_1.

12

Gauss for Linear Systems

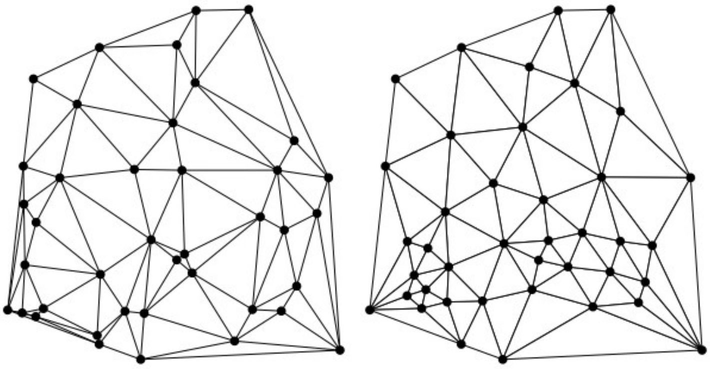

Figure 12.1.

Linear systems: the triangulation on the right was obtained from the left one by solving a linear system.

In Chapter 5, we studied linear systems of two equations in two unknowns. A whole chapter for such a humble task seems like a bit of overkill—its main purpose was really to lay the groundwork for this chapter.

Linear systems arise in virtually every area of science and engineering—some are as big as 1,000,000 equations in as many unknowns. Such huge systems require more sophisticated treatment than the methods introduced here. They *will* allow you to solve systems with several thousand equations without a problem.

Figure 12.1 illustrates the use of linear systems in the field of data smoothing. The left triangulation looks somewhat "rough"; after setting up an appropriate linear system, we compute the "smoother" triangulation on the right, in which the triangles are closer to being equilateral.

This chapter explains the basic ideas underlying linear systems. Readers eager for hands-on experience should get access to software such as Mathematica or MATLAB. Readers with advanced programming knowledge can download linear system solvers from the web. The most prominent collection of routines is LAPACK.

12.1 The Problem

A linear system is a set of equations like this:

$$\begin{aligned} 3u_1 - 2u_2 - 10u_3 + u_4 &= 0 \\ u_1 - u_3 &= 4 \\ u_1 + u_2 - 2u_3 + 3u_4 &= 1 \\ u_2 + 2u_4 &= -4. \end{aligned}$$

The unknowns are the numbers u_1, u_2, u_3, u_4. There are as many equations as there are unknowns, four in this example. We rewrite this 4×4 linear system in matrix form:

$$\begin{bmatrix} 3 & -2 & -10 & 1 \\ 1 & 0 & -1 & 0 \\ 1 & 1 & -2 & 3 \\ 0 & 1 & 0 & 2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{bmatrix} = \begin{bmatrix} 0 \\ 4 \\ 1 \\ -4 \end{bmatrix}.$$

A general $n \times n$ linear system looks like this:

$$\begin{aligned} a_{1,1}u_1 + a_{1,2}u_2 + \ldots + a_{1,n}u_n &= b_1 \\ a_{2,1}u_1 + a_{2,2}u_2 + \ldots + a_{2,n}u_n &= b_2 \\ &\vdots \\ a_{n,1}u_1 + a_{n,2}u_2 + \ldots + a_{n,n}u_n &= b_n. \end{aligned}$$

In matrix form, it becomes

$$\begin{bmatrix} a_{1,1} & a_{1,2} & \ldots & a_{1,n} \\ a_{2,1} & a_{2,2} & \ldots & a_{2,n} \\ & & \vdots & \\ a_{n,1} & a_{n,2} & \ldots & a_{n,n} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_n \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_n \end{bmatrix}, \tag{12.1}$$

$$\begin{bmatrix}\mathbf{a}_1 & \mathbf{a}_2 & \dots & \mathbf{a}_n\end{bmatrix}\mathbf{u} = \mathbf{b},$$

or even shorter

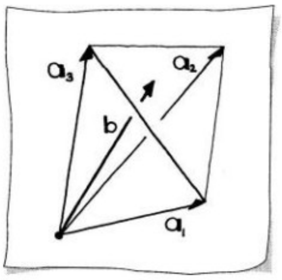
$$A\mathbf{u} = \mathbf{b}.$$

The *coefficient matrix* A has n rows and n columns. For example, the first row is

$$a_{1,1}, a_{1,2}, \dots, a_{1,n},$$

and the second column is

$$\begin{matrix} a_{1,2} \\ a_{2,2} \\ \vdots \\ a_{n,2}. \end{matrix}$$



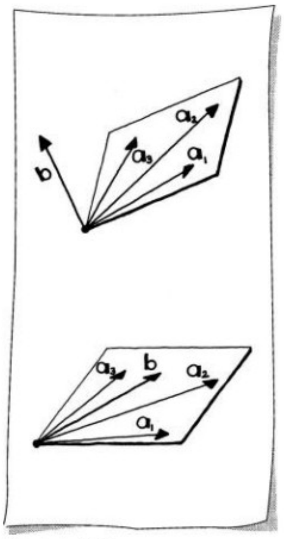
Sketch 12.1.
A solvable 3×3 system.

Equation (12.1) is a compact way of writing n equations for the n unknowns $u_1, \dots, u_n$. In the 2×2 case, such systems had nice geometric interpretations; in the general case, that interpretation needs n-dimensional linear spaces, and is not very intuitive. Still, the methods that we developed for the 2×2 case can be gainfully employed here!

Some underlying principles with a geometric interpretation are best explained for the example $n = 3$. We are given a vector $\mathbf{b}$ and we try to write it as a linear combination of vectors $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3$,

$$\begin{bmatrix}\mathbf{a}_1 & \mathbf{a}_2 & \mathbf{a}_3\end{bmatrix}\mathbf{u} = \mathbf{b}.$$

If the $\mathbf{a}_i$ are truly 3D, i.e., if they form a tetrahedron, then a *unique solution* may be found (see Sketch 12.1). But if the three $\mathbf{a}_i$ all lie in a plane (i.e., if the volume formed by them is zero), then you cannot write $\mathbf{b}$ as a linear combination of them, unless it is itself in that 2D plane. In this case, you cannot expect uniqueness for your answer. Sketch 12.2 covers these cases. In general, a linear system is uniquely solvable if the $\mathbf{a}_i$ have a nonzero n-dimensional volume. If they do not, they span a k-dimensional *subspace* (with $k < n$)—nonunique solutions exist only if $\mathbf{b}$ is itself in that subspace. A linear system is called *consistent* if at least one solution exists.



Sketch 12.2.
Top: no solution, bottom: nonunique solution.

For 2D and 3D, we encountered many problems that lent themselves to constructing the linear system in terms of a linear combination of column vectors, the $\mathbf{a}_i$. However, in Section 5.11 we looked at how a linear system can be interpreted as a problem using equations built row by row. In n-dimensions, this commonly occurs. An example follows.

Example 12.1

Suppose that at five time instances, say $t_i = 0, 0.25, 0.5, 0.75, 1$ seconds, we have associated observation data, $p(t_i) = 0, 1, 0.5, 0.5, 0$. We would like to fit a polynomial to these data so we can estimate values in between the observations. This is called *polynomial interpolation*. Five points require a degree four polynomial,

$$p(t) = c_0 + c_1 t + c_2 t^2 + c_3 t^3 + c_4 t^4,$$

which has five coefficients c_i. Immediately we see that we can write down five equations,

$$p(t_i) = c_0 + c_1 t_i + c_2 t_i^2 + c_3 t_i^3 + c_4 t_i^4, \qquad i = 0, \dots, 4,$$

or in matrix form,

$$\begin{bmatrix} 1 & t_0 & t_0^2 & t_0^3 & t_0^4 \\ 1 & t_1 & t_1^2 & t_1^3 & t_1^4 \\ & & \vdots & & \\ 1 & t_4 & t_4^2 & t_4^3 & t_4^4 \end{bmatrix} \begin{bmatrix} c_0 \\ c_1 \\ \vdots \\ c_4 \end{bmatrix} = \begin{bmatrix} p(t_0) \\ p(t_1) \\ \vdots \\ p(t_4) \end{bmatrix}.$$

Figure 12.2 illustrates the result, $p(t) = 12.667t - 50t^2 + 69.33t^3 - 32t^4$, for the given data.

◇□◆

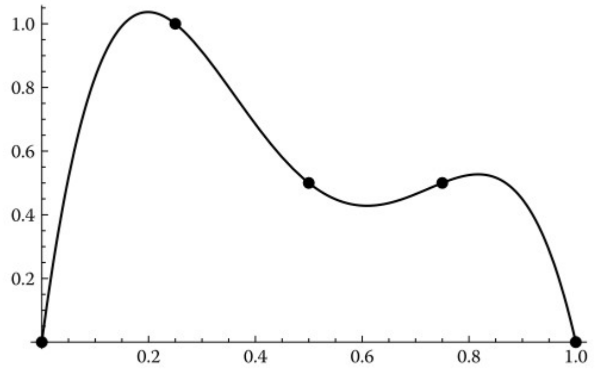


Figure 12.2.
Polynomial interpolation: a degree four polynomial fit to five data points.

12.2 The Solution via Gauss Elimination

The key to success in the 2×2 case was the application of a shear (forward elimination) so that the matrix A was transformed to *upper triangular*, meaning all entries below the diagonal are zero. Then it was possible to apply *back substitution* to solve for the unknowns. A shear was constructed to map the first column vector of the matrix onto the $\mathbf{e}_1$-axis. Revisiting an example from Chapter 5, we set

$$\begin{bmatrix} 2 & 4 \\ 1 & 6 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} 4 \\ 4 \end{bmatrix}. \tag{12.2}$$

The shear used was

$$S_1 = \begin{bmatrix} 1 & 0 \\ -1/2 & 1 \end{bmatrix},$$

which when applied to the system as

$$S_1 A\mathbf{u} = S_1 \mathbf{b}$$

produced the system

$$\begin{bmatrix} 2 & 4 \\ 0 & 4 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} 4 \\ 2 \end{bmatrix}.$$

Algebraically, what this shear did was to change the *rows* of the system in the following manner:

$$\mathrm{row}_1 \leftarrow \mathrm{row}_1 \quad \text{and} \quad \mathrm{row}_2 \leftarrow \mathrm{row}_2 - \frac{1}{2}\mathrm{row}_1.$$

Each of these constitutes an *elementary row operation.* Back substitution came next, with

$$u_2 = \frac{1}{4} \times 2 = \frac{1}{2}$$

and then

$$u_1 = \frac{1}{2}(4 - 4u_2) = 1.$$

The divisions in the back substitution equations are actually scalings, thus they could be rewritten in terms of a scale matrix:

$$S_2 = \begin{bmatrix} 1/2 & 0 \\ 0 & 1/4 \end{bmatrix},$$

and then the system would be transformed via

$$S_2 S_1 A\mathbf{u} = S_2 S_1 \mathbf{b}.$$

The corresponding upper triangular matrix and system is

$$\begin{bmatrix} 1 & 2 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} 2 \\ 1/2 \end{bmatrix}.$$

Check for yourself that we get the same result.

Thus, we see the geometric steps for solving a linear system have methodical algebraic interpretations. We will be following this algebraic approach for the rest of the chapter. For general linear systems, the matrices, such as S_1 and S_2 above, are not actually constructed due to speed and storage expense. Notice that the shear to zero one element in the matrix, changed the elements in only one row, thus it is unnecessary to manipulate the other rows. This is an important observation for large systems.

In the general case, just as in the 2×2 case, *pivoting* will be used. Recall for the 2×2 case this meant that the equations were reordered such that the (pivot) matrix element $a_{1,1}$ is the largest one in the first column. A row exchange can be represented in terms of a *permutation matrix*. Suppose the 2×2 system in (12.2) was instead,

$$\begin{bmatrix} 1 & 6 \\ 2 & 4 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} 4 \\ 4 \end{bmatrix},$$

requiring pivoting as the first step. The permutation matrix that will exchange the two rows is

$$P_1 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix},$$

which is the identity matrix with the rows (columns) exchanged. After this row exchange, the steps for solving $P_1 A\mathbf{u} = P_1\mathbf{b}$ are the same as for the system in (12.2): $S_2 S_1 P_1 A\mathbf{u} = S_2 S_1 P_1 \mathbf{b}$.

Example 12.2

Let's step through the necessary row exchanges and shears for a 3×3 linear system. The goal is to get it in upper triangular form so we may use back substitution to solve for the unknowns. The system is

$$\begin{bmatrix} 2 & -2 & 0 \\ 4 & 0 & -2 \\ 4 & 2 & -4 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} 4 \\ -2 \\ 0 \end{bmatrix}.$$

The matrix element $a_{1,1}$ is not the largest in the first column, so we choose the 4 in the second row to be the *pivot element* and we reorder the rows:

$$\begin{bmatrix} 4 & 0 & -2 \\ 2 & -2 & 0 \\ 4 & 2 & -4 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} -2 \\ 4 \\ 0 \end{bmatrix}.$$

The permutation matrix that achieves this row exchange is

$$P_1 = \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

(The subscript 1 indicates that this matrix is designed to achieve the appropriate exchange for the first column.)

To zero entries in the first column apply:

$$\begin{aligned} \text{row}_2 &\leftarrow \text{row}_2 - \frac{1}{2}\text{row}_1 \\ \text{row}_3 &\leftarrow \text{row}_3 - \text{row}_1, \end{aligned}$$

and the system becomes

$$\begin{bmatrix} 4 & 0 & -2 \\ 0 & -2 & 1 \\ 0 & 2 & -2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} -2 \\ 5 \\ 2 \end{bmatrix}.$$

The shear matrix that achieves this is

$$G_1 = \begin{bmatrix} 1 & 0 & 0 \\ -1/2 & 1 & 0 \\ -1 & 0 & 1 \end{bmatrix}.$$

Now the first column consists of only zeroes except for $a_{1,1}$, meaning that it is lined up with the $\mathbf{e}_1$-axis.

Now work on the second column vector. First, check if pivoting is necessary; this means checking that $a_{2,2}$ is the largest in absolute value of all values in the second column that are below the diagonal. No pivoting is necessary. (We could say that the permutation matrix $P_2 = I$.) To zero the last element in this vector apply

$$\text{row}_3 \leftarrow \text{row}_3 + \text{row}_2,$$

which produces

$$\begin{bmatrix} 4 & 0 & -2 \\ 0 & -2 & 1 \\ 0 & 0 & -1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} -2 \\ 5 \\ 7 \end{bmatrix}.$$

The shear matrix that achieves this is

$$G_2 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 1 \end{bmatrix}.$$

By chance, the second column is aligned with $\mathbf{e}_2$ because $a_{1,2} = 0$. If this extra zero had not appeared, then the last operation would have mapped this 3D vector into the $[\mathbf{e}_1, \mathbf{e}_2]$-plane.

Now that we have the matrix in upper triangular form, we are ready for back substitution:

$$u_3 = \frac{1}{-1}(7)$$

$$u_2 = \frac{1}{-2}(5 - u_3)$$

$$u_1 = \frac{1}{4}(-2 + 2u_3).$$

This implicitly incorporates a scaling matrix. We obtain the solution

$$\begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} -4 \\ -6 \\ -7 \end{bmatrix}.$$

It is usually a good idea to insert the solution into the original equations:

$$\begin{bmatrix} 2 & -2 & 0 \\ 4 & 0 & -2 \\ 4 & 2 & -4 \end{bmatrix} \begin{bmatrix} -4 \\ -6 \\ -7 \end{bmatrix} = \begin{bmatrix} 4 \\ -2 \\ 0 \end{bmatrix}.$$

It works!

◆

The example above illustrates each of the *elementary row operations* that take place during Gauss elimination:

- Pivoting results in the exchange of two rows.
- Shears result in adding a multiple of one row to another.
- Scaling results in multiplying a row by a scalar.

Gauss elimination for solving a linear system consists of two basic steps: forward elimination (pivoting and shears) and then back substitution (scaling). Here is the algorithm for solving a general $n \times n$ system of linear equations.

Gauss Elimination with Pivoting

Given: An $n \times n$ coefficient matrix A and a $n \times 1$ right-hand side $\mathbf{b}$ describing a linear system

$$A\mathbf{u} = \mathbf{b},$$

which is short for the more detailed (12.1).

Find: The unknowns $u_1, \ldots, u_n$.

Algorithm:

```
Initialize the $n \times n$ matrix $G = I$.
For $j = 1, \ldots, n-1$   ($j$ counts columns)

    Pivoting step:

    Find the element with the largest absolute value in column $j$
    from $a_{j,j}$ to $a_{n,j}$; this is element $a_{r,j}$.
        If $r > j$, exchange equations $r$ and $j$.

    If $a_{j,j} = 0$, the system is not solvable.

    Forward elimination step for column $j$:

    For $i = j+1, \ldots, n$  (elements below diagonal of column $j$)
        Construct the multiplier $g_{i,j} = a_{i,j}/a_{j,j}$
        $a_{i,j} = 0$
        For $k = j+1, \ldots, n$  (each element in row $i$ after
                                  column $j$)
            $a_{i,k} = a_{i,k} - g_{i,j}a_{j,k}$
        $b_i = b_i - g_{i,j}b_j$

At this point, all elements below the diagonal have been set to
zero. The matrix is now in upper triangular form.

    Back substitution:

    $u_n = b_n/a_{n,n}$
    For $j = n-1, \ldots, 1$
        $u_j = \frac{1}{a_{j,j}}[b_j - a_{j,j+1}u_{j+1} - \ldots - a_{j,n}u_n]$.
```

In a programming environment, it can be convenient to form an *augmented matrix*, which is the matrix A augmented with the vector $\mathbf{b}$. Here is the idea for a 3×3 linear system:

$$\begin{bmatrix} a_{1,1} & a_{1,2} & a_{1,3} & b_1 \\ a_{2,1} & a_{2,2} & a_{2,3} & b_2 \\ a_{3,1} & a_{3,2} & a_{3,3} & b_3 \end{bmatrix}.$$

Then the k steps would run to $n+1$, and there would be no need for the extra line for the b_i element.

As demonstrated in Example 12.2, the operations in the elimination step above may be written in matrix form. If A is the current matrix, then at step j, we first check if a row exchange is necessary. This may be achieved with a permutation matrix, P_j. If no pivoting is necessary, $P_j = I$. To produce zeroes under $a_{j,j}$ the matrix product $G_j A$ is formed, where

$$G_j = \begin{bmatrix} 1 & & & & & & \\ & \ddots & & & & & \\ & & 1 & & & & \\ & & & 1 & & & \\ & & & -g_{j+1,j} & 1 & & \\ & & & \vdots & & \ddots & \\ & & & -g_{n,j} & & & 1 \end{bmatrix}. \tag{12.3}$$

The elements $-g_{i,j}$ of G_j are the *multipliers*. The matrix G_j is called a *Gauss matrix*. All entries except for the diagonal and the entries $-g_{i,j}$ below the diagonal of the jth column are zero. We could store all P_j and G_j in one matrix

$$G = G_{n-1}P_{n-1} \cdot \ldots \cdot G_2 \cdot P_2 \cdot G_1 \cdot P_1. \tag{12.4}$$

If no pivoting is required, then it is possible to store the $g_{i,j}$ in the zero elements of A rather than explicitly setting the $a_{i,j}$ element equal to zero. Regardless, it is more efficient with regard to speed and storage not to multiply A and $\mathbf{b}$ by the permutation and Gauss matrices because this would result in many unnecessary calculations.

To summarize, Gauss elimination with pivoting transforms the linear system $A\mathbf{u} = \mathbf{b}$ into the system

$$GA\mathbf{u} = G\mathbf{b},$$

which has the same solution as the original system. The matrix GA is upper triangular, and it is referred to as U. The diagonal elements of U are the pivots.

does not vary in the horizontal direction for a fluid at rest and making use of the hydrostatic pressure equation at various points, the gauge pressure at A is calculated as

$$p_A = \gamma_2 y_2 - \gamma_1 y_1 \tag{10}$$

Figure 9 illustrates a differential manometer. The difference in pressure between A and B is calculated as

$$p_B - p_A = \gamma_1 y_1 - \gamma_2 y_2 - \gamma_3 (y_3 - y_2) \tag{11}$$

Another commonly used mechanical device for measuring both gauge pressure and absolute pressure is the Bourdon-type gauge (Fig. 10).

3.3 Fluid Forces on Plane Surfaces

The magnitude of the total fluid force exerted on a plane (flat) surface can be calculated with the equation (refer to Fig. 11)

$$F_R = p_c A \tag{12}$$

where p_c is the pressure at the centroid of the surface and A is the total area of the surface. Note that pressure always acts normal to the surface.

If the fluid is a liquid with a free surface open to the atmosphere,

$$p_c = \gamma h_c \tag{13}$$

where h_c is the distance the centroid lies below the free surface. Locations of centroids of variously shaped areas are shown in Table 5.

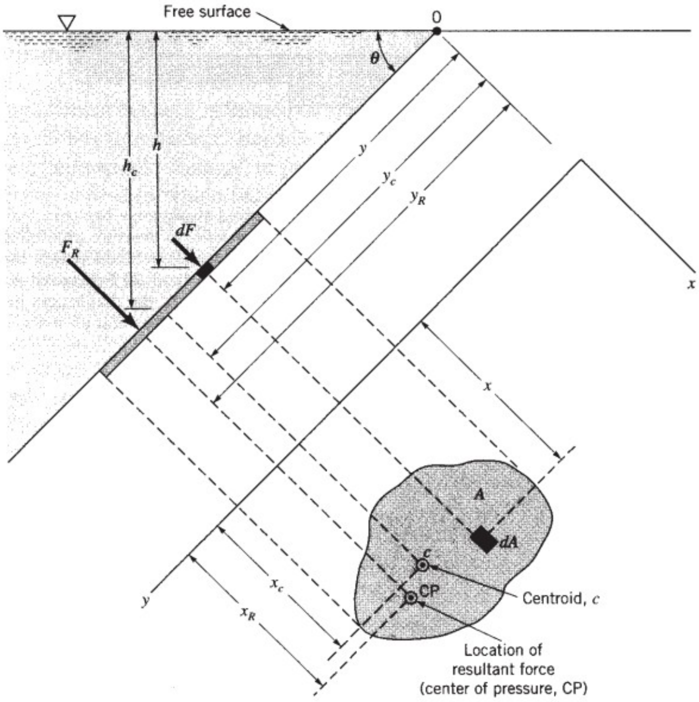

Figure 11 Notation for pressure force calculation on submerged plane of arbitrary shape. (From Ref. 2.)

The location of the resultant of the pressure forces acting on a plane area is known as the center of pressure. For a plane area lying below a liquid surface, the center-of-pressure location is computed with the equation

$$y_R - y_c = \frac{I_c}{y_c A} \tag{14}$$

where y_R is measured in the plane of the area (slant distance) from the free surface to the center of pressure, y_c is the distance (in the same plane) from the free surface to the centroid of the area, and I_c is the second moment of the area about a horizontal axis through the centroid and in the plane of the area. Values of I_c for common geometric shapes are given in Table 5.

Two special cases of this application are the horizontal-plane and the vertical-plane cases. For a horizontal plane ($\theta = 0°$ of inclination), the centroid of the surface and the center of pressure coincide since the pressure distribution over the entire surface area is uniform. For the vertical case ($\theta = 90°$ of inclination), the center of pressure will always be below the centroid of the surface since the pressure acting on the surface increases with depth. Note that for deeply submerged plane areas, the center of pressure approaches the centroid of the area regardless of the angle of inclination.

3.4 Fluid Forces on Curved Surfaces

Pressure forces exerted on curved surfaces vary in direction and must usually be divided into horizontal and vertical components to facilitate calculation. The resultants of the horizontal and

vertical components of the pressure forces are determined with assistance from the equations developed for plane surfaces. Figure 12 illustrates a common situation. The fluid mass *ABC* is in equilibrium under the action of pressure forces; hence the vertical component of the resultant of the pressure forces is equal to the weight of the fluid mass plus the force $\mathbf{F}_{AC}$ exerted on the upper surface of the fluid mass by the overlying fluid. The horizontal component of the resultant of the pressure forces is equal to the force on a vertical projection of the curved surface. The line of action and point of application (center of pressure) for the resultant force is determined by taking moments of the contributing forces about an axis of convenience. The force $\mathbf{F}_{BC}$ is located using the formula for plane surfaces. The weight W_{ABC} is concentrated at the centroid of the area *ABC* (see Table 5).

3.5 Buoyancy and Stability

An object floating or submerged in a fluid at rest experiences pressure forces from the surrounding fluid. Consider a square block of material that is submerged in a liquid; due to hydrostatic pressure variation with depth, the pressure on the bottom surface will be greater than on the top surface (pressure on the two sides is equal and opposite). The resultant of these pressure forces is known as the buoyant force, which acts in the upward direction, and is equal in magnitude to the weight of the displaced fluid. The line of action of the buoyant force is vertical through the centroid of the volume of displaced fluid (center of buoyancy). The magnitude of the buoyant force can be found from the following equation:

$$F_B = \gamma V \tag{15}$$

where V is the volume of the displaced fluid. If the object is totally submerged in the fluid, then the volume of the displaced fluid equals the volume of the object; otherwise, the displaced volume equals only the volume of the submerged portion of the object.

The overturning stability (Fig. 13) of a floating or submerged body is affected by the relative position of the center of gravity (CG) of the body and the center of buoyancy. When the

Surfaces

On the surface of the Earth, there are two degrees of freedom. Simply fix a direction to face; the line forward and backward relative to you is one degree of freedom, while the line left and right through you determines another. Ignoring the scenery, buildings, etc., there is no topological difference between the patch of Earth you are standing on and the one near me; the Earth's surface always looks the same locally (see Figure 5.1). In fact, if we did not realize the Earth is a sphere, we could mistake any particular patch of land or sea as part of a plane,[1] or a cylinder, or even a torus. This property of indistinguishability is key in defining what we mean by a surface. In this chapter we define surfaces; introduce methods for combining, dissecting, and analyzing surfaces; and then prove half of the important theorem that classifies all compact surfaces. Near the end of the chapter we explore vector fields on surfaces other than the familiar plane.

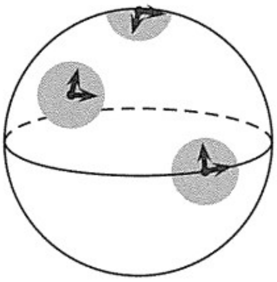

Figure 5.1: There are two degrees of freedom at any point on the surface of the Earth.

---

[1] As early as the sixth century BC, Pythagoras postulated that the Earth is a sphere, though his reasons were more philosophical than empirical. In the fourth century BC, Eratosthenes computed the circumference of the Earth using the observation that shadows were cast at different angles in two distant places at the same time. Eratosthenes's estimate was amazingly accurate.

5.1 Surfaces and Surfaces-with-Boundary

Let's begin with a formal definition of *surface*. We assume that our surfaces are connected and have no boundary edge.

Definition 5.1.1. A **surface** is a connected Hausdorff space S such that for each $x \in S$, there is an open set $U \subseteq S$ with $x \in U$, such that $U \approx B_1(\mathbf{0}) \subseteq \mathbb{R}^2$.

An open set $U \approx B_1(\mathbf{0})$ as in Definition 5.1.1 is called a **disk neighborhood** or **patch**, so we may think of a surface S as a patchwork of overlapping open disks. In this chapter we primarily work with *compact* surfaces. Recall from §4.4 that a compact space is one in which every open cover has a finite subcover. Thus, for a compact surface, it is always possible to fulfill Definition 5.1.1 with a *finite* collection of *patches*. Moreover, surfaces that have *punctures* or open edges, as illustrated in Figure 5.2, are not compact. On the other hand, there is no requirement for "smoothness" – a surface may have corners or sharp edges, as in the surface of a cube.

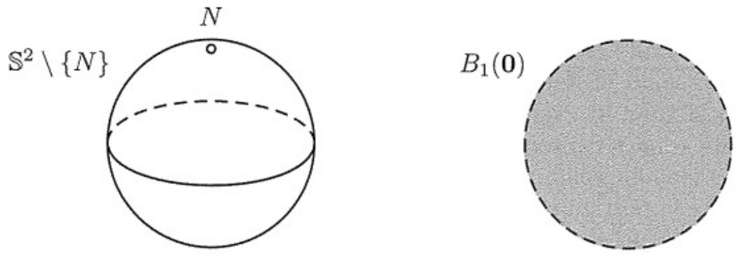

Figure 5.2: The punctured sphere, $\mathbb{S}^2 \setminus \{N\}$, and open disk are noncompact surfaces.

Example 85. Examples of compact surfaces include the sphere $\mathbb{S}^2$, the torus $\mathbb{T}$, and Klein bottle $\mathbb{K}$, among many others. Note that $\mathbb{K}$ cannot be realized in three-dimensional space without *self-intersections* (see, e.g., a typical representation of $\mathbb{K}$ in Figure 1.3). A noncompact surface may extend infinitely, such as the Euclidean plane $\mathbb{R}^2$, or the infinite cylinder, $\mathbb{S}^1 \times \mathbb{R}$, or such a surface may have a puncture and/or open boundary edge, as in the two spaces shown in Figure 5.2.

The following examples are *not* surfaces at all, according to the definition (see Figure 5.3).

- The circle $\mathbb{S}^1$. No open set of $\mathbb{S}^1$ homeomorphic to an open disk. Indeed, we may say $\mathbb{S}^1$ is one dimensional, whereas surfaces are, by definition, two dimensional. The higher-dimensional spheres $\mathbb{S}^3$, $\mathbb{S}^4$, etc., are also not surfaces.

- The closed unit disk $\mathbb{D}^2 = D_1(\mathbf{0}) \subseteq \mathbb{R}^2$. $\mathbb{D}^2$ is not a surface because there are *boundary points* in $\mathbb{D}^2$ that cannot be surrounded by an open set U homeomorphic to an open disk.
- A pair of intersecting planes. Suppose x is any point on the intersection line. Any open set U containing x must contain points that are on both planes, which implies that U is not homeomorphic to an open disk.

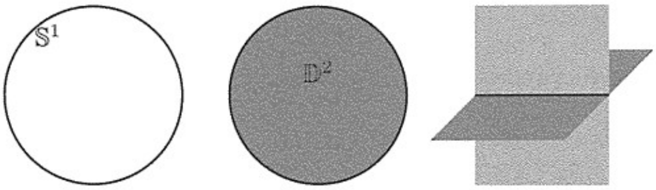

Figure 5.3: The circle, closed disk, and a pair of intersecting planes. None of these spaces is a surface according to Definition 5.1.1.

Consider two related spaces: the open unit disk, $U = B_1(\mathbf{0}) = \{x \in \mathbb{R}^2 \mid d(x, \mathbf{0}) < 1\}$, and the closed unit disk, $\mathbb{D}^2$. According to Definition 5.1.1, U is a noncompact surface, while $\mathbb{D}^2$ is a compact set that is technically *not* a surface. However, *most* points of $\mathbb{D}^2$ do fit the conditions of the definition. Only those points on the boundary edge fail to meet the requirement of belonging to an open set homeomorphic to the open disk; instead, a typical open set containing the boundary point is homeomorphic to the *half-disk* $V = \{(x, y) \in \mathbb{R}^2 \mid d((x, y), 0) < 1,\ y \geq 0\}$, as illustrated in Figure 5.4.

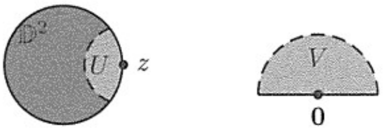

Figure 5.4: An open neighborhood $U \ni z$, for z on the boundary of the closed disk, is homeomorphic to a half-disk V.

Definition 5.1.2. A **surface-with-boundary** is a connected Hausdorff topological space S such that for each $x \in S$, there is an open set $U \subseteq S$ with $x \in U$, such that *either*:

- $U \approx B_1(\mathbf{0}) \subseteq \mathbb{R}^2$ *or*
- $U \approx V = \{(x, y) \in \mathbb{R}^2 \mid d((x, y), 0) < 1,\ y \geq 0\}$.

The terminology *surface-with-boundary* is an unfortunate misnomer, as these spaces are not actually *surfaces* according to the strict definition, unless the boundary is empty. In the literature, the term is usually *surface with boundary* (with no hyphens). While it is important to conform to the established terminology, I compromise in this textbook, erring on the side of clarity, by always writing *surface-with-boundary* (with hyphens).

Example 86. The following are examples of surfaces-with-boundary that are not surfaces.

- The closed cylinder, $\mathbb{S}^1 \times \mathbb{I}$. The boundary consists of two disjoint circles.
- The Möbius strip. The boundary consists of only one circle (see Figure 4.8).
- Suppose S is a surface and U is any open disk neighborhood of a point $x \in S$. Then $S \setminus U$ is a surface-with-boundary.

Throughout the remainder of the text, we use the notation $\mathcal{S}_c$ to denote the collection of all compact connected surfaces and surfaces-with-boundary.

Connected Sum Construction

Surfaces or surfaces-with-boundary may be combined by a process called *connected sum.* Intuitively, the construction is simple: remove an open disk from each of the two spaces, resulting in two surfaces with boundary; then glue the two pieces together along the boundary. A precise definition of this construction is tricky, as is the proof that the construction does not depend on any of the choices made along the way. (*Which open disks? In what way should the boundaries be identified?*) The fact that the connected sum construction is well defined for all compact surfaces is beyond the scope of this text,[2] and we shall take it for granted.

Definition 5.1.3. Suppose $A, B \in \mathcal{S}_c$. Choose $U_1 \subseteq A$ and $U_2 \subseteq B$ open sets, each homeomorphic to an open disk, and let C_1 and C_2 be the boundary circles of U_1 and U_2, respectively. Let $f : C_1 \to C_2$ be a homeomorphism. The **connected sum** of A and B (with respect to U_1, U_2 and f) is the quotient space,

$$A \# B = ((A \setminus U_1) \cup (B \setminus U_2)) \, / \sim,$$

where $x \sim y$ if and only if $x \in C_1$, $y \in C_2$, and $y = f(x)$.

---

[2] See Proposition 2.6.1 of Bloch [Blo97].

The connected sum operation is *commutative* and *associative*, in the sense that the resulting spaces are homeomorphic. That is:

- $A\#B \approx B\#A, \quad \forall A, B \in \mathcal{S}_c$.
- $(A\#B)\#C \approx A\#(B\#C), \quad \forall A, B, C \in \mathcal{S}_c$.

Example 87. Let's see what $\mathbb{T}\#\mathbb{T}$ looks like. As Figure 5.5 illustrates, the result is a *two-holed torus*, $2\mathbb{T}$.

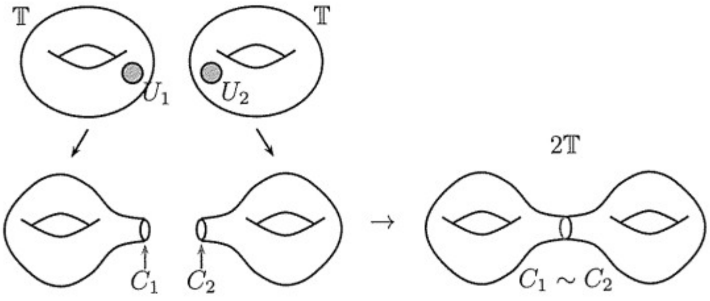

Figure 5.5: $\mathbb{T}\#\mathbb{T} = 2\mathbb{T}$.

Definition 5.1.4. The **n-holed torus**, $n\mathbb{T}$, is the connected sum of n tori. In general, if S is any surface, then nS is the connected sum of n copies of S.

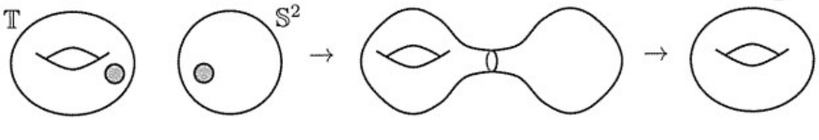
See Figure 5.6 for illustrations of the n-holed torus.

Example 88. Describe each of the following:

(a) $\mathbb{T}\#\mathbb{S}^2$ (b) $4\mathbb{S}^2$ (c) $3\mathbb{T}\#2\mathbb{T}$

Solution:

(a) $\mathbb{T}\#\mathbb{S}^2 \approx \mathbb{T}$, as illustrated below.



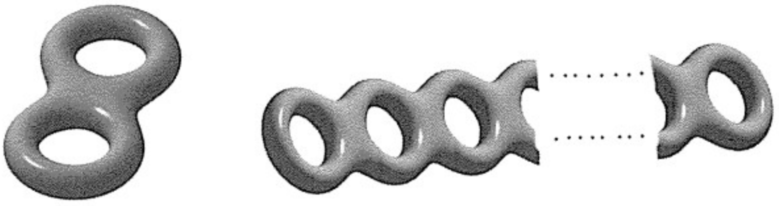


Figure 5.6: *Left*, the two-holed torus, $2\mathbb{T}$. *Right*, the n-holed torus, $n\mathbb{T}$. Images courtesy of Wikimedia Commons (modified).

(b) Just as in example (a), it should be clear that $\mathbb{S}^2\#\mathbb{S}^2 \approx \mathbb{S}^2$. Then $4\mathbb{S}^2 = \left(\left[\mathbb{S}^2\#\mathbb{S}^2\right]\#\mathbb{S}^2\right)\#\mathbb{S}^2 \approx \left(\mathbb{S}^2\#\mathbb{S}^2\right)\#\mathbb{S}^2 \approx \mathbb{S}^2\#\mathbb{S}^2 \approx \mathbb{S}^2$.

(c) $3\mathbb{T}\#2\mathbb{T} = (\mathbb{T}\#\mathbb{T}\#\mathbb{T})\#(\mathbb{T}\#\mathbb{T}) \approx 5\mathbb{T}$.

Example 89. Suppose P is a polyhedron in $\mathbb{R}^3$. Let P' be the union of the edges of P (think of this as a "wireframe"). Now suppose the edges in P' are thickened a bit, and let S be the surface of the "thickened wireframe." (That is, S is the boundary of a *tubular neighborhood* of P'; see §4.5, Exercise 8.) It can be shown that S is always homeomorphic to a connected sum of tori ($n\mathbb{T}$ for some $n \in \mathbb{N}$). Consider the tetrahedron T. Its thickened wireframe can be deformed to $3\mathbb{T}$, as illustrated in Figure 5.7. First flatten the wireframe and then arrange the holes. For what value of n is the surface in Figure 5.8 homeomorphic to $n\mathbb{T}$?

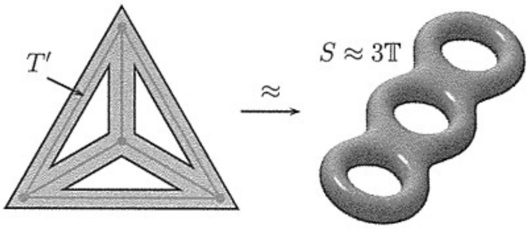

Figure 5.7: The thickened wireframe of a tetrahedron is homeomorphic to $3\mathbb{T}$.

In Example 88, we have shown that $3\mathbb{T}\#2\mathbb{T} \approx 5\mathbb{T}$. It's not too hard to see that $m\mathbb{T}\#n\mathbb{T} \approx (m+n)\mathbb{T}$ in general. It should also be clear that the sphere $\mathbb{S}^2$ acts as an *identity* for the connected sum operation. That is,

$$A\#\mathbb{S}^2 \approx \mathbb{S}^2\#A \approx A, \quad \forall A, B \in \mathcal{S}_c.$$

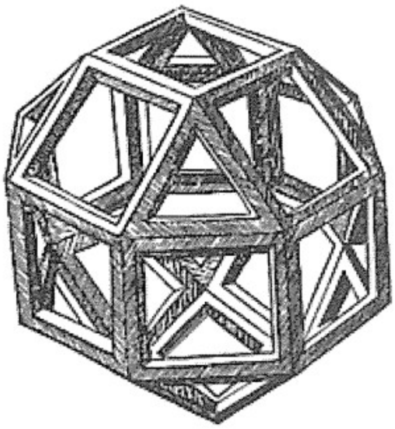

Figure 5.8: The thickened frame of a polyhedron (drawn by Leonardo da Vinci). The surface is homeomorphic to a connected sum of tori. Image courtesy of Wikimedia Commons.

Together with associativity, the existence of an identity makes $\mathcal{S}_c$ into a *monoid* under the connected sum operation. We shall have more to say about this in the next section.

Manifolds

Surfaces are essentially two-dimensional spaces, but Definition 5.1.1 can easily be extended to arbitrary dimensions. We call such spaces *manifolds.*[3]

Definition 5.1.5. Let $n \in \mathbb{N}$. A **manifold** is a connected Hausdorff space M such that for each $x \in M$, there is an open set $U \subseteq M$ with $x \in U$, such that $U \approx B_1(\mathbf{0}) \subseteq \mathbb{R}^n$. The manifold is said to be n-dimensional, or M is called an n-manifold.

There is an analogous definition of **manifold-with-boundary** (try to formulate a reasonable definition yourself, extending Definition 5.1.2).

Example 90. Because manifolds (by our definition) must be connected, the only zero-dimensional manifold is a single point. A one-dimensional manifold must be locally homeomorphic to an open interval. The whole real line $\mathbb{R}$ and the open interval (a, b) are examples of *noncompact* 1-manifolds. A closed interval

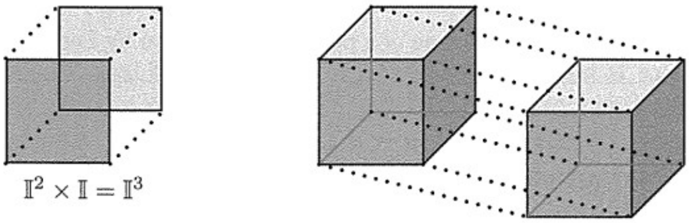
---

[3] Perhaps the better term here would be *topological* manifolds. In the literature, much more attention is paid to the more restrictive *smooth* or *differentiable* manifold theory, which falls outside the scope of this text.

$[a, b]$ is compact, but not a manifold; instead, $[a, b]$ is a manifold-with-boundary. The only compact 1-manifold (according to Definition 5.1.5) is the circle $\mathbb{S}^1$.

Example 91. Let's explore a few interesting manifolds and manifolds-with-boundary.

- Recall that $\mathbb{I}^n = \mathbb{I} \times \mathbb{I} \times \ldots \times \mathbb{I} \subseteq \mathbb{R}^n$ is the product of the unit interval with itself n times. This space is not a manifold because it has a boundary whose points cannot be surrounded by an open ball contained in $\mathbb{I}^n$. However, this space, which is called a **hypercube**, is a compact manifold-with-boundary. It is interesting to ponder what a 4-cube ($\mathbb{I}^4$) might look like. This object is called a **tesseract**,[4] and we might visualize it as a cube that has been extended through a fourth dimension (see Figure 5.9). What might $\mathbb{I}^5$ or $\mathbb{I}^6$ look like?



$\mathbb{I}^2 \times \mathbb{I} = \mathbb{I}^3$

$\mathbb{I}^3 \times \mathbb{I} = \mathbb{I}^4$

Figure 5.9: Just as a solid cube may be thought of as a square that has been extended through a third dimension, the tesseract is a cube extended through a fourth dimension.

- The open balls $B_\epsilon(x)$ for $x \in \mathbb{R}^n$ and $\epsilon \in \mathbb{R}^+$ are noncompact manifolds. Their closures $D_\epsilon(x) \approx \mathbb{D}^n$ are compact manifolds-with-boundary (but not manifolds). Note that $\mathbb{I}^n \approx \mathbb{D}^n$ via a deformation that "inflates" the hypercube until all points on the boundary are the same distance from the center (recall Exercise 2 from §4.5).

- The n-sphere $\mathbb{S}^n$, or **hypersphere**, was introduced in Chapter 2 by way of a particular representation of the space, as a *unit* sphere:

  $$\mathbb{S}^n = \{x \in \mathbb{R}^{n+1} \mid d(x, \mathbf{0}) = 1\} = \{(x_1, \ldots, x_{n+1}) \mid x_1^2 + \cdots x_{n+1}^2 = 1\}.$$

  There are many other useful representations of the n-sphere. It should not be hard to see that for any given $x \in \mathbb{R}^{n+1}$ and $\epsilon > 0$, we have $\partial B_\epsilon(x) = \partial \mathbb{D}^{n+1} \approx \mathbb{S}^n$; that is, the boundary of any open ball or closed disk in $\mathbb{R}^{n+1}$ is an n-sphere. Thus we also get $\mathbb{S}^n \approx \partial\mathbb{I}^{n+1}$ by way of the homeomorphism $\mathbb{I}^n \approx \mathbb{D}^n$.

---

[4] The tesseract has fascinated many science fiction authors, making an appearance in Robert Heinlein's short story "And He Built a Crooked House" [Hei41] and Madeleine L'Engle's popular children's novel *A Wrinkle in Time* [L'E62].

Now suppose H^+ and $H^- \subseteq \mathbb{S}^n$ are the "northern" and "southern" hemispheres of the unit n-sphere, respectively. That is,

$$\begin{aligned} H^+ &= \{(x_1, \ldots, x_{n+1}) \mid x_1^2 + \cdots x_{n+1}^2 = 1 \text{ and } x_{n+1} \geq 0\} \\ H^- &= \{(x_1, \ldots, x_{n+1}) \mid x_1^2 + \cdots x_{n+1}^2 = 1 \text{ and } x_{n+1} \leq 0\}. \end{aligned}$$

The quotient space H^+/H^- that collapses the entire southern hemisphere to a single point is also homeomorphic to $\mathbb{S}^n$ (and, by symmetry, $H^-/H^+ \approx \mathbb{S}^n$ as well). In fact, if we let $E = H^+ \cap H^-$, which is the equatorial sphere $\mathbb{S}^{n-1} \subseteq \mathbb{S}^n$, then we have

$$H^+/E \approx H^-/E \approx \mathbb{S}^n.$$

Example 22 (in Chapter 2) explains how $\mathbb{S}^n$ can also be regarded as $\mathbb{R}^n \cup \{\infty\}$, where ∞ is the *point at infinity.* Consider now a variation on this idea. Suppose $F : \mathbb{S}^n \setminus \{N\} \to \mathbb{R}^n$ is stereographic projection. The image $F[H^-]$ of the southern hemisphere is a closed disk $\mathbb{D}^n \subseteq \mathbb{R}^n$, as shown in Figure 5.10 (for the two-dimensional case). When all points on the boundary of that disk are identified to a single point, the resulting quotient space is again the n-sphere. That is,

$$\mathbb{D}^n/\partial\mathbb{D}^n \approx \mathbb{I}^n/\partial\mathbb{I}^n \approx \mathbb{S}^n.$$

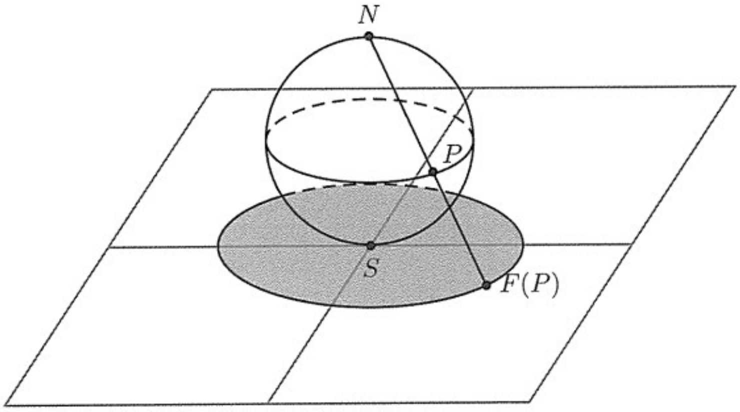


Figure 5.10: Stereographic projection to $\mathbb{R}^2$ sends the southern hemisphere of $\mathbb{S}^2$ to a disk in the plane.

- The n-**torus** $\mathbb{T}^n$ is an n-dimensional manifold defined by $\mathbb{T}^n = \mathbb{I}^n/\sim$, in which the equivalence relation is generated by identifying corresponding points on opposite facets of the hypercube. That is, $(x_1, \ldots, 0, \ldots, x_n) \sim$

$(x_1, \ldots, 1, \ldots, x_n)$, with the understanding that the 0 and 1 occur in the same position and all other entries agree. For $n = 1$, this reduces to the usual definition of $\mathbb{S}^1 = \mathbb{I}/\{0 \sim 1\}$, and for $n = 2$, this space is the familiar torus, $\mathbb{T}^2 = \mathbb{T}$.

The "n" in $\mathbb{T}^n$ is a little misleading. The n-torus is not the product of n copies of $\mathbb{T}$. In fact, the n-torus may be expressed better by $(\mathbb{S}^1)^n$, since $\mathbb{T}^n$ is actually the product of n copies of $\mathbb{S}^1$.

- **Projective space** $\mathbb{P}^n$ is defined as a certain quotient space of $\mathbb{R}^{n+1} \setminus \{\mathbf{0}\}$ as in §4.3, Example 76, and Exercise 11). In essence, every point on a line through the origin (except the origin itself) gets identified to a single point. But $\mathbb{P}^n$ can also be defined by identifying all pairs of **antipodal** points on $\mathbb{S}^n$; that is, points on the sphere that differ only by the scalar multiple -1. This means that $\mathbb{P}^n \approx \mathbb{S}^n/(x \sim -x)$, and so representatives for the equivalence classes may be taken just from the upper hemisphere, $H^+ \subseteq \mathbb{S}^n$. There are still antipodal identifications on the equator, leading to another useful way to write projective space:

$$\mathbb{P}^n \approx H^+/(x \sim -x) \approx \mathbb{D}^n/(x \sim -x, \forall x \in \partial\mathbb{D}^n). \tag{5.1}$$

Looking ahead to Figure 5.24, we can see how these identifications work in $\mathbb{P}^2 = \mathbb{P}$, the *projective plane*. Figure 5.11 shows a representation of $\mathbb{P}^3$.

The connected sum of manifolds may be defined in a manner similar to that of Definition 5.1.3, with $\mathbb{S}^n$ serving as an identity for the connected sums of n-manifolds. However, care must be taken for $n \geq 3$; the *orientation* of each manifold must be considered in order to have a well-defined operation. It would take us too far afield to explore manifolds further in this textbook. The interested reader may consult more advanced texts, such as *Introduction to Topological Manifolds* by John Marshall Lee [Lee00].

Exercises

1. Classify each of the following as surface, surface-with-boundary, or not a surface. If the space is a surface-with-boundary, describe the boundary. In each case, indicate whether the space is compact or not.
   (a) Closed square, $\mathbb{I}^2$.
   (b) Annulus, $\{(x, y) \in \mathbb{R}^2 \mid 1 \leq x^2 + y^2 \leq 2\}$.
   (c) $\mathbb{T} \setminus \{p\}$, where $p \in \mathbb{T}$ is any single point.
   (d) The union of the xy-plane, xz-plane, and yz-plane in $\mathbb{R}^3$.
   (e) Finite open cylinder $\mathbb{S}^1 \times (0, 1)$.

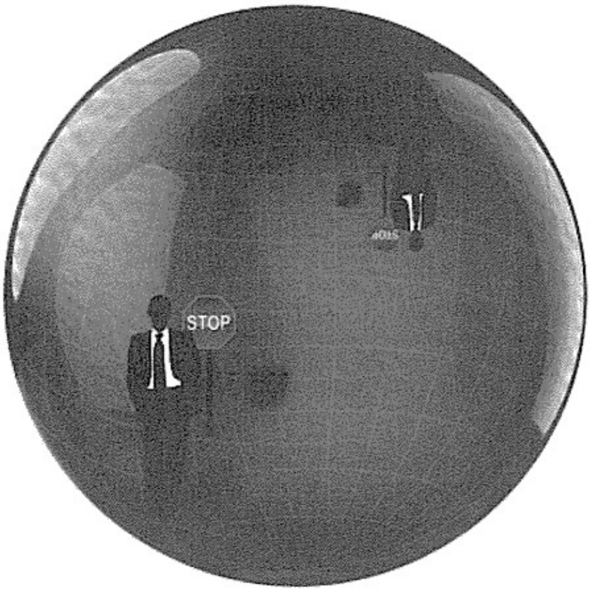

Figure 5.11: Three-dimensional projective space $\mathbb{P}^3$ may be defined as the solid sphere $\mathbb{D}^3$ with antipodal points on the surface identified. If you lived within a small model of $\mathbb{P}^3$, then you could look down the street and see yourself rotated by one half-turn. Image courtesy of Cyrus Rua – used by permission.

2. Consider the capital letters of the alphabet written in block form and thickened to three-dimensional objects (as in Exercise 1 in §1.1). For each letter, identify the value of n such that the letter is homeomorphic to $n\mathbb{T}$.

3. For each of the five Platonic solids (Figure 1.11) P, find the value n such that $P' \approx n\mathbb{T}$, where P' is the *thickened wireframe* of P (see Example 89). What about the object in Figure 5.8?

4. Recall that the Jordan Curve Theorem (Theorem 2.4.8) states that a simple closed curve C separates the plane $\mathbb{R}^2$ into two arc-connected components. Argue, with the help of stereographic projection, that the same happens on the surface of a sphere $\mathbb{S}^2$. Give an example of a simple closed curve on the torus $\mathbb{T}$ that does not separate it.

5. Write a reasonable definition for manifold-with-boundary, analogous to Definition 5.1.2.

6. Show that the connected sum of two connected surfaces is arc-connected (therefore also connected).

7. Show that the connected sum of two compact surfaces is compact. What if one or both of the surfaces are noncompact?

8. Write each connected sum below as $n\mathbb{T}$ for an appropriate value of n. In part (b), assume $k \in \mathbb{N}$.

   (a) $\mathbb{T}\#3\mathbb{S}^2\#2\mathbb{T}\#7\mathbb{S}^2$ (b) $\mathbb{T}\#2\mathbb{T}\#3\mathbb{T}\#\cdots\#k\mathbb{T}$

9. Let $S \in \mathcal{S}_c$ be arbitrary. Describe $S\#\mathbb{D}^2$.

5.2 Plane Models and Words

In this section we develop a powerful combinatorial tool that enables us to work with surfaces in an easier way, eventually allowing us to classify compact surfaces and to understand subtle structures in the surface. Let's revisit the torus, defined as a quotient space as in §4.3.

$$\mathbb{T} = \mathbb{I}^2/\{(0,y) \sim (1,y),\ (x,0) \sim (x,1)\}$$

We represent $\mathbb{T}$ as a square together with the appropriate identifications along the edges as shown in Figure 5.12, with the convention that edges labeled with the same letter should be identified in the direction indicated by the arrowheads.

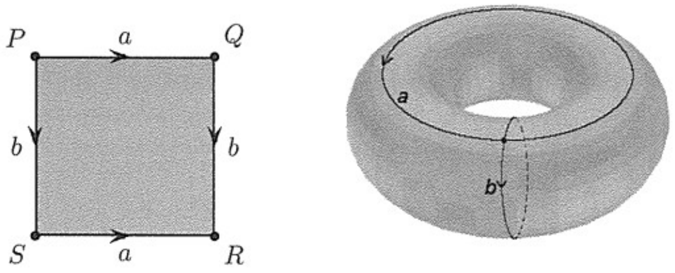

Figure 5.12: Plane model for the torus $\mathbb{T}$ and its realization. After the identifcation, all four vertices are identified to a single point, $P \sim Q \sim R \sim S$.

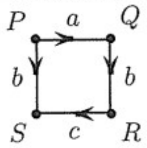
This type of diagram – a polygon showing certain pairs of edges identified – is called a **plane model** for the surface or surface-with-boundary, and it exhibits the space as a quotient space of a closed disk (recall $\mathbb{I}^2 \approx \mathbb{D}^2$). Any pair of edges marked with the same letter correspond to a single segment or loop in the space itself. Any segments without a label or with a unique label correspond to edges in the space, and in that case, the space may be a surface-with-boundary, but not a surface.

For each plane model, there is a way to describe the model using a sequence of letters, or a **word**. Simply pick a starting vertex; choose a direction, clockwise or counterclockwise; then list the letters in order, indicating the direction of the edge by placing an "exponent" -1 on the letter if the arrow is backward with respect to the direction you chose. There are many different words for the same plane model. For instance, there are eight equivalent words for the torus in Figure 5.12:

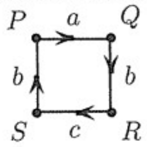
$$aba^{-1}b^{-1}, \qquad ba^{-1}b^{-1}a, \qquad a^{-1}b^{-1}ab, \qquad b^{-1}aba^{-1},$$
$$bab^{-1}a^{-1}, \qquad ab^{-1}a^{-1}b, \qquad b^{-1}a^{-1}ba, \qquad a^{-1}bab^{-1}.$$

Example 92. Describe the topological spaces represented by their plane models below, and find a word for the model. Of the vertices in the original diagram, indicate which ones are identified in the resulting space.

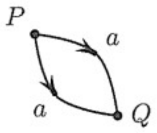
(a)



(b)



(c)



Solution:

(a) Only the left and right sides get glued together. The top and bottom remain as boundaries. This is a surface-with-boundary homeomorphic to the cylinder $\mathbb{S}^1 \times \mathbb{I}$. One word for the model is $abcb^{-1}$. The vertices are identified in pairs: $P \sim Q$ and $R \sim S$.

(b) Again the left and right sides are glued, but this time with a twist. The result is a Möbius strip, as shown in Figure 4.8. One word for the model is $abcb$. The vertices are again identified in pairs, but in the opposite sense: $P \sim R$ and $Q \sim S$.

(c) The opposite sides are identified much like the the two edges of a purse when they get zippered together. This plane model defines the sphere $\mathbb{S}^2$, with corresponding word aa^{-1}. Points P and Q are not identified and may be associated with the north and south pole of the sphere, respectively.

Plane Models and Connected Sum

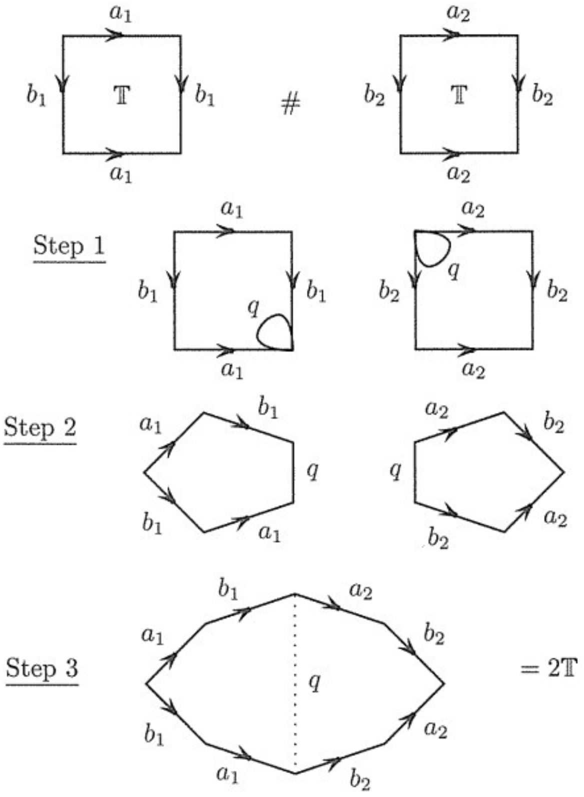
Suppose we have two plane models representing spaces $A, B \in \mathcal{S}_c$. A plane model for $A\#B$ can be found by the following procedure:

1. Choose a vertex in the plane model for A, and draw a loop at A within the model. Label the loop with a letter not already used in the models for A or B, let's say q. Do the same in the plane model for B, labeling the loop with the same letter, q.

2. Remove the region inside each loop. Then separate each loop at the vertex, thereby creating plane models for $A \setminus U_1$ and $B \setminus U_2$ (where U_1 and U_2 are as in Definition 5.1.3). Now q labels a new edge of each plane model.

3. Join together the two plane models along the edge q. This edge q is now interior to the plane model and so can be erased.

Example 93. Find a plane model and corresponding word for $2\mathbb{T}$.
Solution: The steps are illustrated below. **Caution:** It is important to give distinct labels to the edges of each space.



Beginning at the leftmost vertex and going clockwise, a word for $2\mathbb{T}$ is: $a_1b_1a_2b_2a_2^{-1}b_2^{-1}a_1^{-1}b_1^{-1}$ (there are many other equivalent words).

It is interesting to see how a given representation of a surface relates to the plane model for the surface. For example, how does Figure 5.6 correspond to the octagonal plane model for $2\mathbb{T}$ found in Example 93? The key idea is to find *nonseparating* loops – loops that do not divide the space into disconnected pieces. Some spaces like the sphere have no nonseparating loops, while on the torus $\mathbb{T}$, one can find two loops that can be cut simultaneously and not separate the space (e.g., the loops a and b in Figure 5.12). It turns out that the n-holed torus has a set of $2n$ simultaneously nonseparating loops.

Example 94. By cutting along nonseparating loops, a_1, a_2, b_1, and b_2, Figure 5.13 illustrates how the standard embedding of $2\mathbb{T}$ within $\mathbb{R}^3$ corresponds to its plane model. Keep in mind that the cuts are not actually changing the topology of the surface because we still keep track of the identifications.

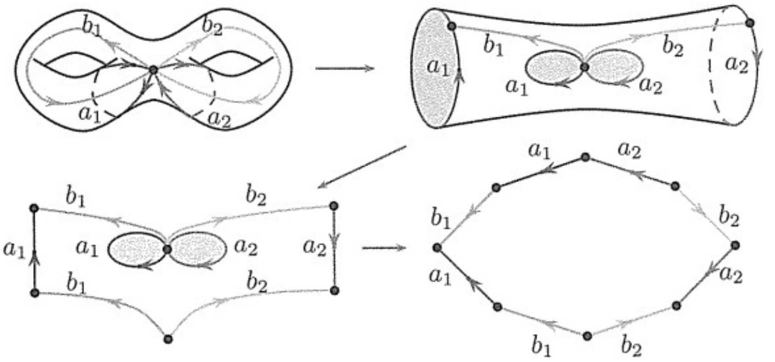


Figure 5.13: Cutting $2\mathbb{T}$ along nonseparating loops to obtain the plane model. First cut along a_1 and a_2 to create a tube with a pair of holes near the middle. Then cut lengthwise along b_1 and b_2 to unwrap the tube, finally opening up the figure into an octagon plane model for $2\mathbb{T}$.

Word Arithmetic

The construction given above for the connected sum of two plane models naturally suggests an operation on words themselves. If $abc\dots$ is a word for a space A and $zyx\dots$ is a word for B *having different letters than the word for* A, then the concatenation $abc\dots zyx\dots$ is a word for $A\#B$. Furthermore, there are certain rules for rearranging words to make equivalent words (i.e., representing the same space). We will use the notation $\equiv$ to indicate that two words are equivalent.

- For convenience, we often write aa as a^2 and $a^{-1}a^{-1}$ as a^{-2}.
- The letters in words do not **commute** ($abcd \neq bacd$); however, *cyclic permutations* are permissible. A **cyclic permutation** of a word is the result of moving one letter from the start of the word to the end, or vice versa. Thus

$$aba^{-1}b^{-1} \equiv ba^{-1}b^{-1}a \equiv a^{-1}b^{-1}ab \equiv b^{-1}aba^{-1}.$$

  This move is equivalent to picking a different starting vertex, or rotating the plane figure.

- If a letter and its inverse appear adjacent to one another, then they *cancel* each other out, *except* in the case of the sphere $\mathbb{S}^2$, whose smallest word has only two letters, aa^{-1}: canceling out these two would result in an *empty word*, which cannot be drawn as a plane model. For example,

$$abc^{-1}dd^{-1}ca^{-1}b^{-1} \equiv abc^{-1}ca^{-1}b^{-1} \equiv aba^{-1}b^{-1}.$$

- If X is a word, the inverse word X^{-1} is obtained by reversing the order and inverting each letter. For example,

$$(abc^{-1}d)^{-1} = d^{-1}cb^{-1}a^{-1}.$$

  This has the effect of choosing to read the labels in the opposite direction, or flipping over the plane model, so the resulting space is not affected: $X^{-1} \equiv X$.

- There is a *split-and-rejoin* operation, which is a useful tool in the classification of surfaces. Choose a location in the word in which to insert a new edge and its inverse, then split the word between the new letter and its inverse to obtain two words (which together still describe a single space). Any equivalence operation mentioned above may then be applied to each subword separately. Join the words again by concatenating at a letter-inverse pair.

$$\begin{array}{rll} XY \equiv Xqq^{-1}Y \equiv & Xq, & q^{-1}Y \\ & \equiv & \equiv \\ & Ua, & a^{-1}V \equiv Uaa^{-1}V \equiv UV \end{array}$$

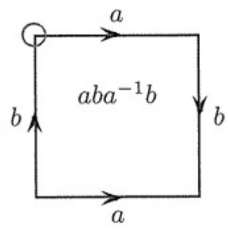
  This operation corresponds to a cut in the plane model represented by XY by a curve that separates all edges in X from those in Y.

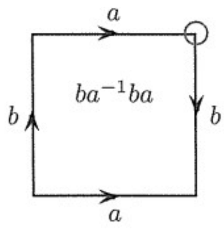
Example 95. The **Klein bottle** is defined as a quotient space by

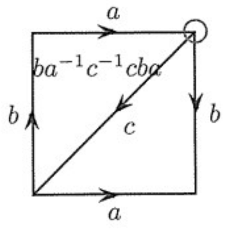
$$\mathbb{K} = \mathbb{I}^2/\{(x,0) \sim (x,1),\ (0,y) \sim (1,1-y)\}.$$

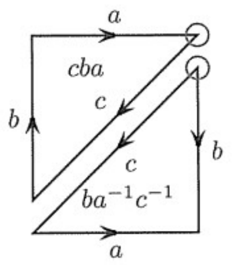
Draw a plane model representing $\mathbb{K}$, and then show that the Klein bottle has a plane model whose word has the form x^2y^2.

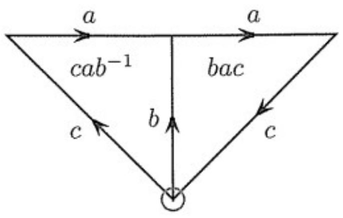
Solution: According to the definition of $\mathbb{K}$, the top and bottom edges are identified in the same direction; however, the sides are identified with a *twist.* A word corresponding to this plane model is $aba^{-1}b$. Consider the following sequence of moves, along with their depictions in the plane model. In each picture, we have circled the starting vertex to make it easier to identify the corresponding word. The direction of the word is clockwise in each diagram.











Note that in the fifth diagram above, the triangle $ba^{-1}c^{-1}$ has been flipped to create cab^{-1}, while the word cba has been cyclically permuted to bac, allowing the sides labeled b to be joined together with matching arrow directions. The result is $cab^{-1}bac \equiv caac \equiv aacc = a^2c^2$, having the desired form.

Correspondence between Plane Models and Surfaces

Not every plane model diagram corresponds to an element of $\mathcal{S}_c$. For example, if there are three or more edges labeled by the same letter, then no neighborhood of any point on the common edge would be homeomorphic to a disk. Figure 5.14 illustrates this issue in a space called the *dunce cap*. Any neighborhood of the point x fails to be homeomorphic to a disk; the neighborhood could be described as a "disk with flap."

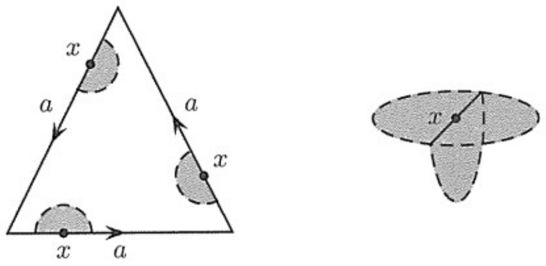


Figure 5.14: The dunce cap.

On the other hand, it can be shown that any plane model diagram in which no letter appears more than twice *does* correspond to a surface or a surface-with-boundary. For simplicity, we will prove the result when it applies to a surface;

the necessary modifications in the case of a surface-with-boundary should be clear.

Theorem 5.2.1. *Suppose X is a plane model diagram in which each letter appears exactly twice. Then X represents a compact surface.*

Proof. We must show that each point of the plane model has an open neighborhood U homeomorphic to an open disk. There are three cases to consider. It may be helpful to refer to Figures 5.15 and 5.16. In what follows, when we say *interior* to X, we mean interior to the plane model diagram before identifications are made along the boundary.

Case I. Suppose $x \in X$ is in the interior of the plane model. Then an open neighborhood U of x may be chosen small enough to lie entirely interior to X, and U is clearly homeomorphic to an open disk.

Case II. Suppose $x \in X$ is on a boundary edge of the plane model, but not at a vertex. Let the edge have label a. Then, by assumption, there is exactly one other edge labeled a. Since those two edges are identified in X, a disk neighborhood U surrounding x exists. In terms of the plane model, it is equivalent to cut and paste a small portion of the model to show how U connects across the edge a.

Case III. Suppose $x \in X$ is a vertex of the plane model. This is the trickiest case because x may be identified to many other vertices on the plane model, and we must build up the disk neighborhood from portions of the model surrounding all vertices equivalent to x. A priori, we do not know which other vertices belong to the equivalence class $[x]$, but the procedure below locates them all.

First suppose that the word for X contains no adjacent inverse pair (i.e., $\ldots aa^{-1} \ldots$ or $\ldots a^{-1}a \ldots$). If it does, then X can be simplified by zippering along the inverse pair. For each edge e, let e^- be a chosen point on that edge near its tail vertex, and let e^+ be on the edge near its head vertex. We shall take a

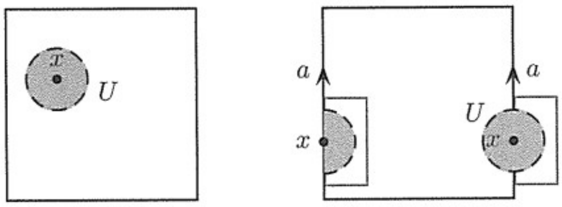

Figure 5.15: Open disk neighborhoods around an interior point and edge point of a plane model. The diagram on the right shows how a portion of the plane model can be cut and pasted to form a disk neighborhood around x.

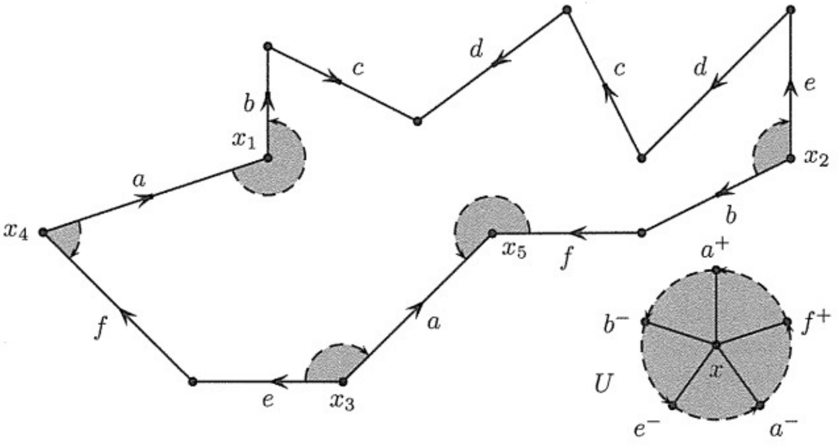

Figure 5.16: Open disk neighborhood U around a vertex x, assembled from regions surrounding all equivalent vertices. This example shows that x is enclosed by a curve containing (in order) $a^+b^-e^-a^-f^+a^+$.

tour of some (or all) of these points that eventually bounds a disk neighborhood of x.

For the purpose of this algorithm, let $x_1 = x$, and let a_1 and a_2 be the two edges meeting at x_1. If x is the tail of a_1, select a_1^-; if x is the head of a_1, select a_1^+. Do the same with respect to a_2. Then draw a small arc in X connecting the selected points. Since edge labels must come in pairs, there must be another edge labeled a_2. Let x_2 be the vertex near to the head (a_2^+) or tail (a_2^-) in the other edge, matching the sign of a_2 that was near x_1. We now know that $x_2 \sim x_1$. Now let a_3 be the label of the other edge meeting x_2. As before, select either a_3^- or a_3^+ depending on how x_2 meets a_3, and draw a small arc in X connecting the selected points. Continue this process until reaching an edge a_n that matches the first edge a_1 *and* meets x in the same way (as head or tail). This completes the tour around vertex x. By cutting and pasting all of these regions together according to the identifications in X, the union of all open regions within the arcs forms an open disk neighborhood of x. ☐

Unfortunately, what we haven't proven yet is that *every* space $X \in \mathcal{S}_c$ *has* a plane model. This depends on the existence of a *triangulation* for X, which is not a trivial thing to prove in general. We define triangulation in the next section.

Toward Triangulation

Does every surface and surface-with-boundary have a plane model? The answer is *yes*, because every space $X \in \mathcal{S}_c$ has a *triangulation*. Let's first define the term. Let $X \in \mathcal{S}_c$. A **triangulation** of X consists of:

- A finite set $V = \{v_1, v_2, \ldots, v_k\}$ of points $v_i \in X$, called the **vertices** of X.
- A finite set $E = \{e_1, e_2, \ldots, e_\ell\}$, called the **edges** of X, such that each $e_i \subseteq X$ is homeomorphic to $\mathbb{I}$, and the endpoints of each e_i are two distinct points from V. If $i \neq j$, then either $e_i \cap e_j = \emptyset$ or there is a unique $v \in V$ such that $e_i \cap e_j = v$. Each edge $e \in E$ may be described by its endpoints: $e = [v_0, v_1]$.
- A finite set $F = \{f_1, f_2, \ldots, f_m\}$, called the **faces** or **triangles** of X, such that each $f_i \subseteq X$ is homeomorphic to a closed disk, and the boundary of f_i consists of three distinct edges from E. Furthermore, if $f_i \cap f_j \neq \emptyset$ for some $i \neq j$, then $f_i \cap f_j$ is either a unique edge $e \in E$ or a unique vertex $v \in V$. Morever, the triangles *cover* X in the sense that $X = \bigcup F$. Each $f \in F$ may be described by its vertices: $f = [v_0, v_1, v_2]$.

Note that by Definition 5.1.2, every edge can belong to at most two triangles. If X is a surface (rather than surface-with-boundary), then every edge belongs to *exactly* two distinct triangles. Figure 5.17 illustrates a few ways of cutting up the torus that are not triangulations, while Figure 5.18 shows a triangulation of the torus. In fact, many different triangulations exist for a given $X \in \mathcal{S}_c$.

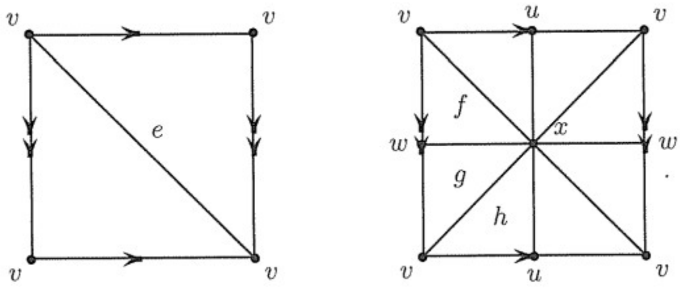

Figure 5.17: Nontriangulations of the torus. *Left*, every edge has both endpoints the same: $e = [v, v]$. *Right*, some pairs of triangles have intersections that are not a single edge or a single vertex. For example, $f \cap g = [w, x] \cup \{v\}$, and $f \cap h = \{x, v\}$.

Theorem 5.2.2. *Every $X \in \mathcal{S}_c$ has a triangulation.*

The proof of Theorem 5.2.2 is not easy. First proved rigorously in 1925 by Radó [Rad25],[5] the result relies on the Jordan Curve Theorem (Theorem 2.4.8), among other things. As a consequence of the theorem, every $S \in \mathcal{S}_c$ has a plane

---

[5] See also Ahlfors and Sario [AS60], Thomassen [Tho92], and Doyle and Moran [DM68].

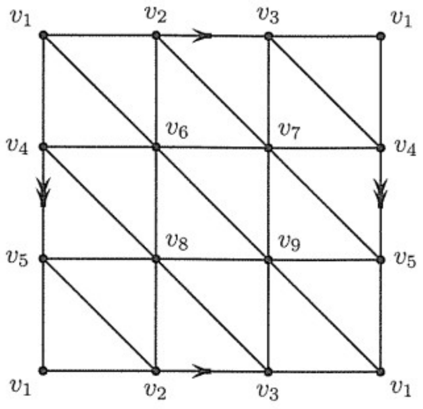

Figure 5.18: A triangulation of the torus using nine vertices. Can you find one that uses fewer vertices?

model. Given a triangulation T for S, with triangles $\{t_1, t_2, \ldots, t_n\}$, build the plane model as follows.

- For each triangle t_k, label its edges and indicate the orientation of each edge so that shared edges receive the same label and orientation.
- Start with $P_1 = t_1$.
- Choose a triangle t_2 that shares an edge with t_1 (which we may do since S is assumed to be a connected surface), and join these triangles at the common edge to form $P_2 = t_1 \cup t_2$. Label the unjoined edges.
- Having constructed $P_k = t_1 \cup t_2 \cup \cdots \cup t_k$, for $k < n$, there must be at least one such triangle t_{k+1} that shares an edge with an existing triangle in P_k. Join t_{k+1} to P_k along that edge, but do not join any other edge of t_{k+1} to P_k. This ensures that P_k remains homeomorphic to a disk.
- Repeat the procedure until all triangles are used. Labels on internal edges should be discarded.

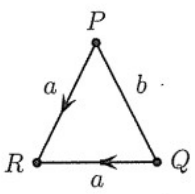
At each step k, the model P_k is a disk with edge labels. Since each edge belongs to at most two triangles, there are no more than two edges in P_k having the same label. Thus P_n is a plane model.

Because of the rather strict rules defining a triangulation, a compact surface can be described unambiguously by a finite set of *combinatorial* data, namely, the list of triangles given in terms of their vertices. In fact, we need only identify each vertex by a number, so a triangle $f = [v_1, v_2, v_3]$ could be represented as $[1, 2, 3]$. This makes it convenient to work with triangulations in computer code, for example.

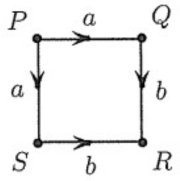
Exercises

1. Describe the surface or surface-with-boundary represented by each plane model and find a corresponding word, reducing as much as possible. Indicate which vertices are identified in the space.

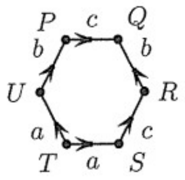
(a)



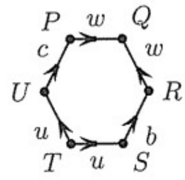
(b)



(c)



(d)



2. Find a plane model and corresponding word representing each of the following spaces.

   (a) $\mathbb{I}^2$ (b) $3\mathbb{T}$ (c) $\mathbb{T}\#\mathbb{K}$ (d) $2\mathbb{K}$

3. Redo Example 93, choosing a different vertex so that the resulting word for $2\mathbb{T}$ is $a_1b_1a_1^{-1}b_1^{-1}a_2b_2a_2^{-1}b_2^{-1}$.

4. Write a word for the n-holed torus, $n\mathbb{T}$.

5. Use words to show that there is no $Q \in \mathcal{S}_c$, such that $\mathbb{T}\#Q = \mathbb{S}^2$. This demonstrates that $\mathcal{S}_c$ is not a *group* with respect to connected sum.

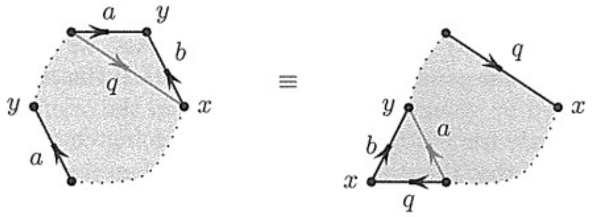
6. Describe the result when any surface S is joined to the square $\mathbb{I}^2$ by connected sum. How is the word of $S\#\mathbb{I}^2$ related to the word of S?

7. Illustrate the algebraic operations of cyclic permutation and cancellation in a series of plane model pictures.

8. Write a word for the plane model shown in Figure 5.16. Show that the vertices fall into two distinct equivalence classes, $[x]$ and $[y]$. It was shown that x is enclosed by a curve labeled $a^+b^-e^-a^-f^+a^+$. Determine a curve bounding a disk neighborhood of y in this figure.

9. Suppose a compact surface has a triangulation with v vertices, e edges, and f faces. Show that $3f = 2e$. Show by example that $3f < 2e$ in a compact surface-with-boundary.

10. Show that any given plane model of a compact surface is equivalent to one in which all of the vertices belong to the same equivalence class. (*Hint:* Suppose there is a vertex y not in the same equivalence class as another vertex x, and suppose y is the head vertex of edge a. Perform the split-and-rejoin operation suggested by the picture below. Why can we assume there is another edge labeled a? How does this procedure eventually eliminate all vertices in the equivalence class of y? What happens if there is only a single vertex in the class of y?)



5.3 Orientability

Suppose an ant walks around on the surface of the sphere $\mathbb{S}^2$. We're talking about a three-dimensional ant whose legs touch the outside surface of the sphere as it walks. No matter where the ant walks or for how long it walks, it will never appear on the "inside" of the sphere. To be a little more precise, suppose that the ant is trailing paint as it walks – that way, we can clearly track its path. No matter how long the ant walks, or what kind of meandering path it takes, at the end of the journey we observe that there is paint only on one "side" of the surface (what we call the outside). But now consider an ant walking around on a Möbius strip M. Do this experiment for yourself: Use your pencil or pen to mark your path as you "walk" around on M. If your path is long enough, and stays in roughly the same direction, you will find that you can eventually return to your starting position, but there are now markings on both "sides" of M. This means that M really has only *one* side. The two spaces differ in that $\mathbb{S}^2$ is *orientable* while M is not.

In order to define orientability more precisely, let's first talk about what an orientation is. On the real number line $\mathbb{R}^1$, there are of course only two directions of travel, in order of increasing real numbers (*right*), or decreasing real numbers (*left*). Similarly, there are only two directions of travel on the circle $\mathbb{S}^1$. Let's assume $\mathbb{S}^1$ is represented in the xy-plane as a unit circle. Then at any point of the circle, you may go in order of either increasing angle measure with respect to the x-axis (*counterclockwise*), or decreasing angle measure (*clockwise*). Notice that in each case, we may record the direction using only one bit of information, say, $+1$ for *right* in $\mathbb{R}^1$ and -1 for *left*, or, in the circle, $+1$ for *counterclockwise* and -1 for *clockwise*.

What about an orientation on $\mathbb{R}^2$? This time there are infinitely many distinct directions that a path could take from any given starting point. Suppose

topological protection cannot decay into the trivial solution, meaning that a topologically protected solution is not equivalent to the trivial one. There are many topological solitons in materials (Menzel 2011), such as screw dislocations in crystals, domain walls in ferromagnets, and other spin textures like vortices, merons, bubbles, and skyrmions. Manipulation of the topological solitons may lead to applications in magnetic storage and spintronics (Parkin et al. 2008; Pfleiderer and Rosch 2010; Jung et al. 2011; Zhang et al. 2015).

This chapter introduces different kinds of topological solitons existing in magnets and is organized as follows: Section 1.2 captures the essential features of topology, such as topological equivalence and invariants, surfaces and knots, winding numbers, and applications of homotopy theory in topological defects. Section 1.3 is devoted to the Gibbs free energy for a magnetic system. Sections 1.4 to 1.8 address different kinds of topological spin textures in magnetism, in particular a domain wall, vortex, meron, bubble, and skyrmion.

1.2 Topology

1.2.1 Topological Equivalence and Invariants

Topology studies the properties of topological spaces which are invariant under a continuous transformation, called topological equivalence. One kind of topological equivalence is homeomorphism. Suppose X and Y to be topological spaces. A function f: $X \rightarrow Y$ is called a homeomorphism when it is bijection (i.e., one-to-one and surjective), continuous, and has a continuous inverse function f^{-1} (Armstrong 1983). When such a function exists, X and Y are homeomorphic. As an example, Figure 1.1 shows the homeomorphism of a polyhedron and a sphere. For any point x on the surface of the polyhedron in Figure 1.1a, we can draw a line passing through both the point x and the center of gravity O of the polyhedron, and reach the point $f(x)$ of the sphere with its center of gravity also at O. Doing the same procedure, we can map the polyhedron to the sphere point by point, and the faces of the polyhedron project to curvilinear polygons on the sphere as shown in Figure 1.1b. Similarly, we can project the sphere to the polyhedron point by point as a continuous inverse procedure. Therefore, a polyhedron and a sphere are homeomorphic, and from a topological viewpoint they are the same.

Another example of homeomorphism is shown in Figure 1.2. In topology, these four figures are considered to be the "same space" (Armstrong 1983). A special homeomorphism from space (c) to space (d) is as follows: the points of space (c) are specified by cylindrical

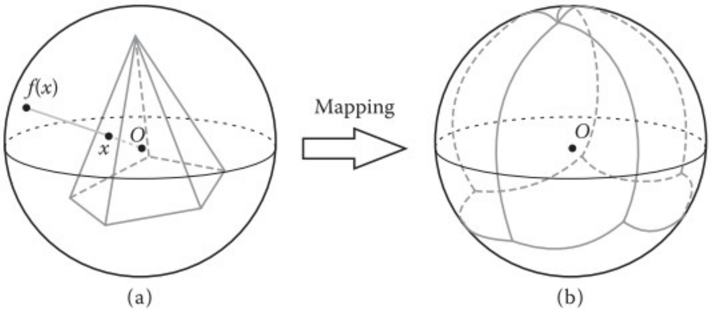

FIGURE 1.1 Continuous mapping from a regular polyhedron to a sphere. (a) The regular polyhedron with the centre of gravity at point O before mapping. (b) After mapping, the faces of the polyhedron becomes curvilinear polygons on the sphere.

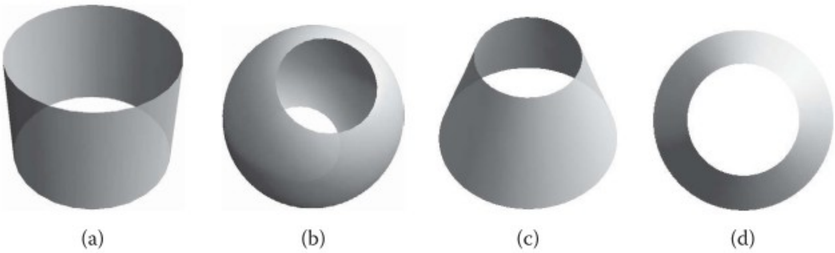

FIGURE 1.2 (a) A cylinder with finite height, excluding the two circles at the ends. (b) A sphere with two holes at the north and south poles. (c) A frustum given by the equation $z = -3\sqrt{x^2 + y^2} + 10$. (d) An annulus specified by $2 < r < 4$.

polar coordinates (r, θ, z) and those of space (d) by plane polar coordinates (r, θ). For space (c), when θ is zero, we can obtain a line $3x + z = 10$. Mapping this line to space (d) where θ is zero, we can get a line $\{ (x, y) \mid 2 < x < 4, y = 0\}$. For each value of θ varying from 0 to 2π, doing a similar procedure in a continuous manner, we can project space (c) to space (d).

Another type of topological equivalence is called homotopy equivalence. Suppose that $f, g: X \to Y$ are maps. If there is a map $F: X \times I \to Y$ such that $F(x, 0) = f(x)$ and $F(x, 1) = g(x)$ for all points $x \in X$, f is homotopic to g (Armstrong 1983), as shown in Figure 1.3a. The equivalence class of loop f is denoted by $[f]$. The set of homotopy classes of loops in X based at x forms the fundamental group under the multiplication $[f]\circ[g] \equiv [f \circ g]$ and is written as $\pi_1(X, x)$ (Braun 2012). The fundamental group may either be Abelian or non-Abelian. Figure 1.3c shows an example of a space with a non-Abelian fundamental group (Mermin 1979). Though loops f and g are freely homotopic, they are not homotopic at the base point, because one cannot deform the loop f into the loop g while holding

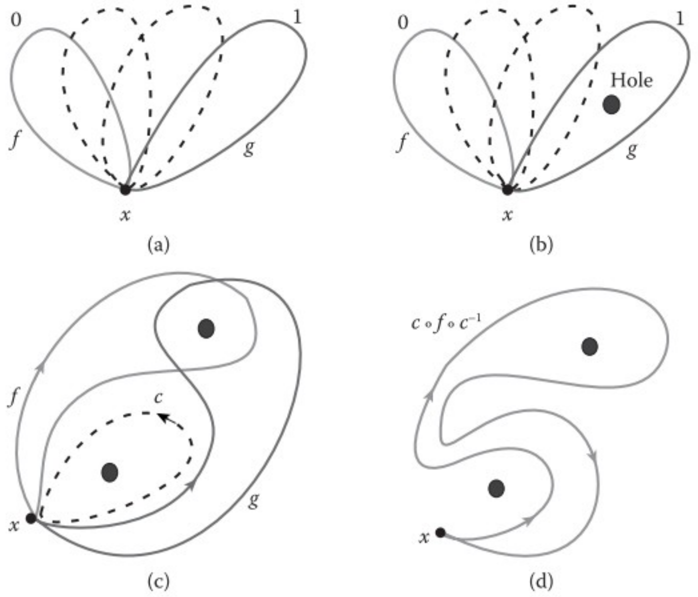

FIGURE 1.3 (a) Two loops f and g are homotopic. (b) f and g are homotopically inequivalent. (c) Loops f and g are not homotopic at the base point x even though they are freely homotopic. (d) A loop $c \circ f \circ c^{-1}$ is homotopic at x to g, where c is the dashed loop in (c).

the base point x. Figure 1.3d shows that g and $c \circ f \circ c^{-1}$ are homotopic. Since f is not homotopic at x to g, $c \circ f$ is not homotopic to $f \circ c$, thus the fundamental group is non-Abelian.

Homotopy theory is used in description and classification of topological defects. A topological defect exists when the mapping from real space S^n to an order-parameter space S^m cannot be shrunk into a single point. In other words, topological defects exist when $\pi_n(S^m) \neq 0$. The nth homotopy group of the n-sphere is isomorphic to the group of integers $\pi_n\left(S^n\right) \cong \mathbb{Z}$ for all $n \geq 1$ (Braun 2012). Therefore, topological defects corresponding to $\pi_n(S^n) \neq 0$ can be characterized by the winding number.

A topological invariant, such as a geometric property of a space, the Euler number, or a group constructed from the space, is a property of a topological space which is preserved by a homotopy (Armstrong 1983). That is, if a space X possesses a topological property, every space topologically equivalent to X possesses that property. According to the property, if a topological invariant of two spaces are calculated to be different, we can conclude that the two spaces cannot continuously be deformed into each other. In topology, a common problem is to develop ways to decide whether two topological spaces are topologically equivalent or not.

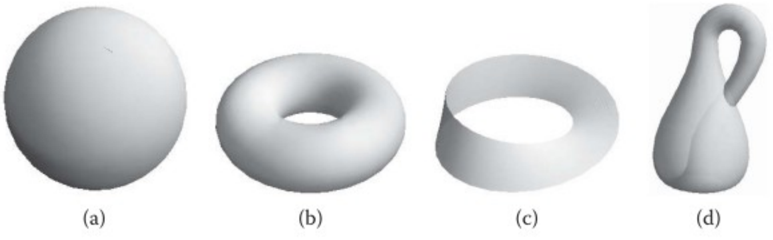
1.2.2 Surfaces and Knots

Topology has to deal with the topological equivalence of spaces. Spaces with bounded configurations occurring naturally in Euclidean space are interesting, such as the unit circle, torus, Möbius strip, Klein bottle, and so on. Figure 1.4 shows some interesting examples existing in three-dimensional (3D) space. The former two spaces are orientable, which have consistent 'orientation' over the entire surfaces, while the latter two are nonorientable.

The Möbius strip, as an important two-dimensional (2D) object in topology, has only one side and one edge and therefore arouses much attention. To prove that the Möbius strip has only one side, starting from a central point of the "edges" of the Möbius strip and drawing a line along the strip's surface until you return to the starting point without lifting the pen, you will find the line is continuous, which proves that the strip has only one side. Cutting the Möbius strip along the center line yields an amazing result: a single strip with a 2π twist, rather than two separate strips. The long strip is not a Möbius strip anymore because it has two edges. Interestingly, if you cut around the Möbius strip one-third of the way from the edge, it creates two strips: one is a Möbius strip with one-third of the width and the same length of the original one, and the other is a longer non-Möbius strip with one-third of the width and twice the length of the original strip.

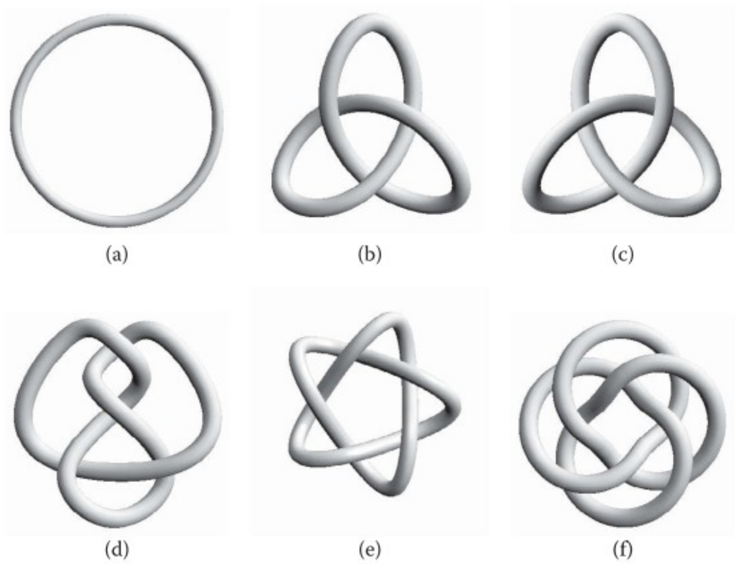
A drastic change such as tearing apart or gluing parts together can destroy the topological equivalence of a space (Sarma et al. 2006). For example, gluing two Möbius strips together along their edges can produce the Klein bottle, but the Möbius strip is not topologically equivalent to the Klein bottle. This procedure cannot be done in ordinary 3D Euclidean space without creating self-intersections but can be represented without crossing itself in four-dimensional (4D) space (Martin et al. 2010).

In topology, apart from the various surfaces, knots are also interesting objects. A knot is a subspace of 3D Euclidean space which is not homeomorphic to the circle (Armstrong 1983). Figure 1.5 shows a few



(a) (b) (c) (d)

FIGURE 1.4 Some surfaces in Euclidean space: (a) sphere; (b) torus; (c) Möbius strip; and (d) Klein bottle.



(a) (b) (c)

examples of knots. The unit circle is called a trivial knot or unknot (Figure 1.5a). We cannot convert any of the knots in Figure 1.5b, d through f into the trivial one, nor any one into another simply by wobbling the string around (Armstrong 1983). To realize the transformation, we must cut the string and make up the knot we need, which means in some sense that these knots are all different.

Two knots k_1 and k_2 are topologically equivalent if there is a homeomorphism f of 3D Euclidean space which satisfies that $f(k_1) = k_2$ (Armstrong 1983). Reflection in a plane as a good homeomorphism can transform a knot into its mirror image, but a chiral knot is an exception which is not equivalent to its mirror image, as shown in Figure 1.5b and c. These two trefoil knots have opposite chiralities, left-handed and right-handed, which are mirror images of each other. But, these two knots are not equivalent to each other, that is, they are not amphichiral. The chirality of a knot is a knot invariant.

1.2.3 Winding Numbers

In mathematics, the winding number of a closed planar curve for a given point is the total number of times the curve travels around the point (Mcintyre and Cairns 1993), which is an integer. The sign of the

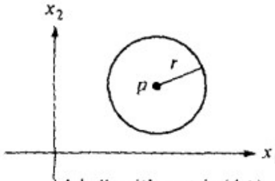
9. Determine the interior, the closure, the limit points, and the isolated points of each of the following subsets of $\mathbb{R}$:
   (a) the interval $[0,1)$,
   (b) the set of rational numbers,
   (c) $\{m + n\pi : m \text{ and } n \text{ positive integers}\}$,
   (d) $\left\{\frac{1}{m} + \frac{1}{n} : m \text{ and } n \text{ positive integers}\right\}$.
10. Let f be a real-valued function on $\mathbb{R}$. Show that there exist $M > 0$ and a nonempty open subset U of $\mathbb{R}$ such that for any $s \in U$, there is a sequence $\{s_n\}$ satisfying $s_n \rightarrow s$ and $|f(s_n)| \leq M$, $n \geq 1$.

4. PRODUCTS OF METRIC SPACES

Let $(X_1,d_1),\ldots,(X_n,d_n)$ be metric spaces. The product set $X = X_1 \times \cdots \times X_n$ consists of all n-tuples $(x_1,\ldots,x_n)$, where $x_k \in X_k$, $1 \leq k \leq n$. There are various ways of making X into a metric space. One possible choice of a metric for X is given by

$$d(x,y) = [d_1(x_1,y_1)^2 + \cdots + d_n(x_n,y_n)^2]^{1/2}, \tag{4.1}$$

where $x = (x_1,\ldots,x_n)$ and $y = (y_1,\ldots,y_n)$. This metric on the product stems from the formula for the metric on $\mathbb{R}^n = \mathbb{R} \times \cdots \times \mathbb{R}$ in terms of the metric on the component spaces $\mathbb{R}$. An open ball in $\mathbb{R}^2 = \mathbb{R} \times \mathbb{R}$ with the metric (4.1) is simply a disc.



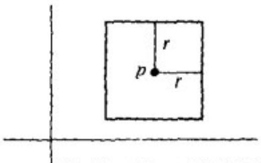
A ball, with metric (4.1)

There are other possible choices of a metric for X, which are convenient for certain problems. Two of them are given by

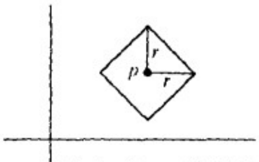
$$d(x,y) = \max(d_1(x_1,y_1),\ldots,d_n(x_n,y_n)), \tag{4.2}$$

$$d(x,y) = d_1(x_1,y_1) + \cdots + d_n(x_n,y_n). \tag{4.3}$$

Open balls in $\mathbb{R} \times \mathbb{R}$ with the metrics (4.2) and (4.3) are squares and diamonds, respectively. In dealing with many problems, it is not important which metric is



A ball, with metric (4.2)



A ball, with metric (4.3)

introduced in the product space, so long as the metric behaves reasonably. One property that each of the above metrics enjoys is the following.

(4.4) A sequence $\{x^{(j)} = (x_k^{(j)})\}_{j=1}^{\infty}$ converges to $x = (x_1, \ldots, x_n)$ in X if and only if for each k the sequence of component entries $\{x_k^{(j)}\}_{j=1}^{\infty}$ converges to x_k in X_k.

The following result shows that all metrics satisfying (4.4) determine the same family of open sets in X, and it describes the structure of these open sets explicitly.

4.1 Theorem: Suppose that d is a metric on $X = X_1 \times \cdots \times X_n$ that satisfies (4.4). Then the open sets in (X,d) are the unions of product sets of the form $U_1 \times \cdots \times U_n$, where U_j is an open subset of X_j, $1 \leq j \leq n$.

Proof: First note that if E_j is a closed subset of X_j, $1 \leq j \leq n$, then $E_1 \times \cdots \times E_n$ is closed in X. Indeed, if $\{x^{(i)}\}_{i=1}^{\infty}$ is a sequence in $E_1 \times \cdots \times E_n$ that converges to $x \in X$, then the coordinate sequences $\{x_k^{(i)}\}_{i=1}^{\infty}$ converge to x_k, $1 \leq k \leq n$. Since $x_k^{(i)} \in E_k$, also $x_k \in E_k$ and $x \in E_1 \times \cdots \times E_n$. It follows that $E_1 \times \cdots \times E_n$ is closed, as asserted.

Now suppose that U_k is an open subset of X_k, $1 \leq j \leq n$. By the preceding remarks, the set

$$X_1 \times \cdots \times X_{k-1} \times (X_k \backslash U_k) \times X_{k+1} \times \cdots \times X_n$$

is closed in X. Its complement

$$V^{(k)} = X_1 \times \cdots \times X_{k-1} \times U_k \times X_{k+1} \times \cdots \times X_n$$

is then open in X. Hence

$$U_1 \times \cdots \times U_n = V^{(1)} \cap \cdots \cap V^{(n)}$$

is open in X and any union of such products is open in X.

To complete the proof, it suffices to show that every open subset of X is a union of such product sets. For this, it suffices to show that if U is open in X and if $x \in U$, then there exist open sets U_k in X_k, $1 \leq k \leq n$, such that $x \in U_1 \times \cdots \times U_n \subseteq U$. We will argue by contradiction.

Let $x \in U$ and suppose that x is contained in no such product set. In particular, for each positive integer m, the product of open balls $B(x_1;1/m) \times \cdots \times B(x_n;1/m)$ is not contained in U. Hence there exists $x^{(m)} \in X \backslash U$ such that

$$d_k(x_k^{(m)},x_k) < 1/m, \qquad 1 \leq k \leq n.$$

Evidently, the sequence $\{x_k^{(m)}\}_{m=1}^{\infty}$ converges to x_k, $1 \leq k \leq n$. By (4.4), $x^{(m)}$ converges to x. Since $X \backslash U$ is closed, x belongs to $X \backslash U$. This contradiction establishes the theorem. □

Another property of the metrics (4.1) to (4.3) is that

$$(4.5) \qquad d_k(x_k,y_k) \leq d(x,y), \qquad x,y \in X,\ 1 \leq k \leq n.$$

Condition (4.5) neither implies nor is implied by condition (4.4). It is clear though that, if a metric d on X satisfies (4.5) and if $\{x^{(m)}\}_{m=1}^{\infty}$ converges in (X,d) to x, then the component sequences $\{x_k^{(m)}\}_{m=1}^{\infty}$ converge to x_k, $1 \le k \le n$.

4.2 Theorem: Let $(X_1,d_1),\ldots,(X_n,d_n)$ be complete metric spaces. Let d be a metric on $X = X_1 \times \cdots \times X_n$ that satisfies (4.4) and (4.5). Then (X,d) is complete.

Proof: Let $\{x^{(j)}\}_{j=1}^{\infty}$ be a Cauchy sequence in X. The estimate (4.5) yields

$$d_k(x_k^{(i)},x_k^{(j)}) \le d(x^{(i)},x^{(j)}).$$

Since the right-hand side tends to 0 as $i,j \to \infty$, $\{x_k^{(i)}\}_{i=1}^{\infty}$ is a Cauchy sequence in X_k. Consequently there exists a point $x_k \in X_k$ such that $x_k^{(i)} \to x_k$ as $i \to \infty$. Set $x = (x_1,\ldots,x_n)$. By (4.4), $x^{(i)} \to x$ as $i \to \infty$. Hence X is complete. □

4.3 Corollary: The n-dimensional Euclidean space $\mathbb{R}^n$, with the usual metric

$$|x - y| = [(x_1 - y_1)^2 + \cdots + (x_n - y_n)^2]^{1/2}, \qquad x,y \in \mathbb{R}^n,$$

is complete.

In the sequel, we shall refer to the product metric space $X = X_1 \times \cdots \times X_n$ without specifying a metric for X. One can select one's own favorite metric for the product, as long as it satisfies (4.4) and (4.5).

EXERCISES

1. Prove that the functions on $X \times X$ given by (4.1), (4.2), and (4.3) are metrics.
2. For each of the metrics (4.1), (4.2), and (4.3) on the plane $\mathbb{R}^2$, sketch the open ball $B(0;1)$. What inclusion relations hold between these balls?
3. Prove that each of the metrics (4.1), (4.2), and (4.3) has property (4.4).
4. Determine the interior, the closure, the limit points, and the isolated points of each of the following subsets of $\mathbb{R}^2$:
   (a) $\{(x,y) : 0 < x^2 + y^2 < 1\}$,
   (b) $\{(x,0) : x \in \mathbb{R}\}$,
   (c) $\{(m,n) : m \text{ and } n \text{ positive integers}\}$,
   (d) $\left\{\left(\frac{1}{m},\frac{1}{n}\right) : m \text{ and } n \text{ positive integers}\right\}$.
5. Prove that if $\tilde{X}_j$ is the completion of X_j, $1 \le j \le n$, then $\tilde{X}_1 \times \cdots \times \tilde{X}_n$ is the completion of $X = X_1 \times \cdots \times X_n$.
6. Let (X_k,d_k), $1 \le k \le n$, be metric spaces. Let d be a metric on $X = X_1 \times \cdots \times X_n$ such that the open subsets of (X,d) are precisely the unions of sets of the form $U_1 \times \cdots \times U_n$, where U_k is an open subset of X_k, $1 \le$

$k \leq n$. Show that d satisfies (4.4). *Note:* This establishes the converse to Theorem 4.1.

7. Let (X_k,d_k), $1 \leq k < \infty$, be metric spaces and let $X = \Pi_{k=1}^{\infty} X_k$ be their Cartesian product, that is, let X be the set of sequences $(x_1,x_2,\ldots)$, where $x_j \in X_j$ for $1 \leq j < \infty$.
   (a) Show that
   $$d(x,y) = \sum_{j=1}^{\infty} \frac{1}{2^j} \min(1,d_j(x_j,y_j))$$
   is a metric on X.
   (b) Show that a sequence $\{x^{(k)}\}_{k=1}^{\infty}$ converges in X if and only if $\{x_j^{(k)}\}_{k=1}^{\infty}$ converges in X_j for each $j \geq 1$.
   (c) Show that the open sets in X are precisely the unions of sets of the form $U_1 \times \cdots \times U_m \times X_{m+1} \times X_{m+2} \times \cdots$, where $m \geq 1$ and U_j is open in X_j, $1 \leq j \leq m$.

5. COMPACTNESS

In analysis it is often important to know when a property that is valid at each point of a space is in some sense uniformly valid over the space. For instance, we shall be concerned in Section 6 with the question of when a function that is continuous at each point of a space is in fact uniformly continuous on the space. The condition under which such uniformity tends to occur for sets in $\mathbb{R}^n$ is that the set be closed and bounded. However, this condition of being closed and bounded, for sets in an arbitrary metric space, does not guarantee that the set has the properties we desire. There is another condition, called *compactness,* that does guarantee that the set has these properties. There is a certain class of properties that finite sets have trivially, that are retained by compact sets. For instance, it will be seen that every continuous real-valued function on a compact space is bounded and assumes its maximum and minimum values.

Our aim in this section is to define the notion of compactness and to prove an important characterization (Theorem 5.1) of compact metric spaces. Most of the section will be devoted to the proof of Theorem 5.1, which is somewhat involved and conceptually difficult. During the course of the section, we shall return to subsets of $\mathbb{R}^n$ and show that the notion of compactness for a set in $\mathbb{R}^n$ is equivalent to the previously mentioned condition of being closed and bounded. This latter theorem is the celebrated Heine-Borel Theorem, and Theorem 5.1 may be regarded as a powerful extension of the Heine-Borel Theorem. We now formulate the appropriate ideas in a general metric space situation.

A family $\{U_\alpha\}_{\alpha \in A}$ of sets is said to *cover* a set S if S is contained in the union of the U_α's. An *open cover* of a metric space X is a family of open subsets of X that covers X. A metric space X is *compact* if every open cover has a finite subcover. In other words, X is compact if, whenever $\{U_\alpha\}_{\alpha \in A}$ is an open cover of X, there are finitely many of the U_α's, say $U_{\alpha_1},\ldots,U_{\alpha_m}$, such that

$$X \subset U_{\alpha_1} \cup \cdots \cup U_{\alpha_m}.$$

A metric space X is *totally bounded* if for each $\varepsilon > 0$, there exists a finite number of open balls of radius ε that cover X. Our main object in this section is to establish the following theorem. Both the theorem and the ideas entering into the proof are of the utmost importance.

5.1 Theorem: The following are equivalent for a metric space X:

(5.1) X is compact.

(5.2) Every sequence in X has a convergent subsequence.

(5.3) X is totally bounded and complete.

Proof: The proof of Theorem 5.1 will take most of this section. For now, we content ourselves with proving the straightforward implications (5.1) $\Rightarrow$ (5.2) $\Rightarrow$ (5.3).

Suppose that X is compact. Let $\{y_j\}_{j=1}^{\infty}$ be a sequence in X. Suppose that for each $x \in X$, there exists $\varepsilon = \varepsilon(x) > 0$ such that only finitely many terms of the sequence $\{y_j\}$ lie in $B(x;\varepsilon(x))$. The set of open balls $\{B(x;\varepsilon(x)) : x \in X\}$ forms an open cover of X. (Note the use of X as the index set for the cover!) Since X is compact, there is a finite subcover

$$X = B(x_1;\varepsilon(x_1)) \cup \cdots \cup B(x_m;\varepsilon(x_m)).$$

Since y_j belongs to $B(x_i;\varepsilon(x_i))$ for only finitely many indices j, we conclude that there is a grand total of only finitely many positive integers, an absurdity. This contradiction shows that there exists $x \in X$ such that each ball $B(x;\varepsilon)$ contains infinitely many terms of the sequence $\{y_j\}$.

Now we construct a convergent subsequence of $\{y_j\}$ as follows. Choose j_1 so that $y_{j_1} \in B(x;1)$. Since $y_j \in B(x;1/2)$ for infinitely many j, we can choose $j_2 > j_1$ such that $y_{j_2} \in B(x;1/2)$. Continuing in this manner, we find $j_1 < j_2 < \cdots$ such that $y_{j_n} \in B(x;1/n)$. Then $\{y_{j_n}\}_{n=1}^{\infty}$ is a subsequence of $\{y_j\}$ that converges to x. We have proved that (5.1) implies (5.2).

Next, suppose that (5.2) is valid. Let $\{x_j\}$ be a Cauchy sequence in X. By (5.2), $\{x_j\}$ has a convergent subsequence. By Lemma 2.2, the sequence $\{x_j\}$ itself converges. Hence X is complete.

Now assume still that (5.2) is valid and let $\varepsilon > 0$. We wish to cover X by a finite number of open balls of radius ε. Let $y_1 \in X$ be arbitrary. If $B(y_1;\varepsilon) \neq X$, let y_2 be any point in $X \backslash B(y_1;\varepsilon)$. Having chosen $y_1, \ldots, y_n$, we let y_{n+1} be any point in $X \backslash (\cup_{j=1}^{n} B(y_j;\varepsilon))$, provided the union does not coincide with X; otherwise we stop. The points $y_1, y_2, \ldots$ constructed in this manner satisfy

$$d(y_k,y_j) \geq \varepsilon, \qquad 1 \leq j < k.$$

If the procedure for selecting the y_j's does not terminate, then the sequence $\{y_j\}_{j=1}^{\infty}$ has no convergent subsequence. It follows that the choice of some y_{n+1} is impossible, so that X is covered by the n open balls of radius ε and centers $y_1, \ldots, y_n$. In particular, X is totally bounded, and (5.2) implies (5.3).

We shall return later to the proof of Theorem 5.1. First we discuss the notion of total boundedness in more detail and introduce various other notions.

A metric space X is *bounded* if there exists $b > 0$ such that $d(x,y) \leq b$ for all $x,y \in X$.

5.2 Lemma: A totally bounded metric space is bounded.

Proof: Let X be totally bounded. Choose $x_1, \ldots, x_m \in X$ such that the balls $B(x_j;1)$, $1 \le j \le m$, cover X. Let

$$b = 2 + \max\{d(x_j,x_k) : 1 \le j,k \le m\}.$$

An appropriate application of the triangle inequality shows that $d(x,y) < b$ for all $x,y \in X$, so that X is bounded. □

5.3 Lemma: Any subspace of a totally bounded metric space is totally bounded.

Proof: Let Y be a subspace of the totally bounded space X and let $\varepsilon > 0$. Since X is totally bounded, there are points $x_1, \ldots, x_n \in X$ such that the balls $B(x_j;\varepsilon/2)$ cover X. We can arrange the x_j's so that $B(x_j;\varepsilon/2) \cap Y \neq \emptyset$ for the indices $1 \le j \le m$, while $B(x_j;\varepsilon/2)$ does not meet Y for $m + 1 \le j \le n$. Then the balls $B(x_j;\varepsilon/2)$, $1 \le j \le m$, cover Y. Let y_j be any point in $B(x_j;\varepsilon/2) \cap Y$, $1 \le j \le m$. The triangle inequality shows that

$$B(x_j;\varepsilon/2) \subset B(y_j;\varepsilon).$$

Consequently the m open balls $B(y_j;\varepsilon) \cap Y$ in the subspace Y cover Y. □

5.4 Lemma: A subset E of $\mathbb{R}^n$ is totally bounded if and only if E is bounded.

Proof: The forward implication follows from Lemma 5.2. For the reverse implication, suppose that E is bounded. Then E is contained in a cube of the form $T = [-b,b] \times \cdots \times [-b,b]$ for some large $b > 0$. By Lemma 5.3, it suffices to show that T is totally bounded. For this, let $\varepsilon > 0$. Then the balls $B(\varepsilon j;\varepsilon)$ cover T, where $j = (j_1, \ldots, j_n)$ ranges over all integral lattice points of $\mathbb{R}^n$ which satisfy $\varepsilon|j_i| \le 2b$, $1 \le i \le n$. (An integral lattice point of $\mathbb{R}^n$ is by definition a point whose coordinates are integers.) Since there are only finitely many such lattice points, T is totally bounded. □

Now a subspace of $\mathbb{R}^n$ is complete if and only if it is closed, by Theorems 2.3 and 2.4. Consequently a subspace of $\mathbb{R}^n$ is totally bounded and complete if and only if it is closed and bounded. Theorem 5.1 then yields the following important theorem about subsets of $\mathbb{R}^n$.

5.5 Theorem *(Heine-Borel Theorem):* The following are equivalent for a subspace E of $\mathbb{R}^n$.

(5.1)′ E is compact.

(5.2)′ Every sequence in E has a convergent subsequence.

(5.3)′ E is closed and bounded.

Of course, the Heine-Borel Theorem is not established until the proof of Theorem 5.1 is complete.

The following theorem shows that (5.3) implies (5.2), so that the two are equivalent.

5.6 Theorem: Let X be a totally bounded metric space. Then every sequence in X has a Cauchy subsequence.

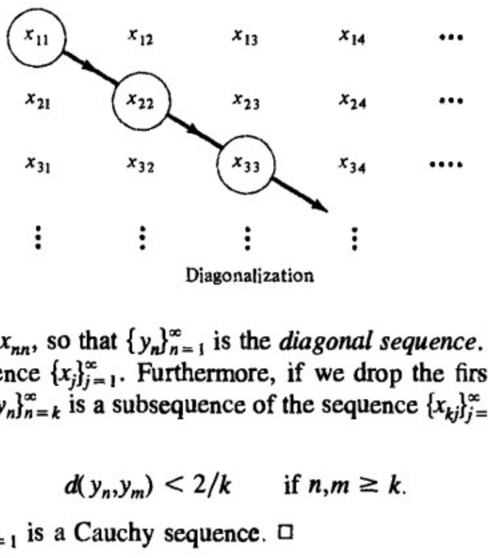
Proof: We shall use a diagonalization procedure to prove the theorem. It is important that one add this technique to one's bag of tricks.

Let $\{x_j\}_{j=1}^{\infty}$ be a sequence in X. For convenience, we rewrite the sequence in the form $\{x_{1j}\}_{j=1}^{\infty}$. By induction, we construct sequences $\{x_{kj}\}_{j=1}^{\infty}$, $k \geq 2$, with the following properties:

(i) $\{x_{kj}\}_{j=1}^{\infty}$ is a subsequence of $\{x_{k-1,j}\}_{j=1}^{\infty}$, $k \geq 2$.

(ii) $\{x_{kj}\}_{j=1}^{\infty}$ is contained in a ball of radius $1/k$, $k \geq 2$.

Indeed, suppose that $k \geq 2$ and that we already have the sequences $\{x_{ij}\}_{j=1}^{\infty}$ for $i < k$. Let $B_1, \ldots, B_n$ be a finite number of open balls of radius $1/k$ that cover X. Since there are infinitely many indices j and only finitely many balls, there must exist at least one ball, say B_m, such that $x_{k-1,j} \in B_m$ for infinitely many $j \geq 1$. Now let x_{k1} be the first of the $x_{k-1,j}$'s that belong to B_m, let x_{k2} be the second, etc. Then $\{x_{kj}\}_{j=1}^{\infty}$ has properties (i) and (ii).



Diagonalization

Now set $y_n = x_{nn}$, so that $\{y_n\}_{n=1}^{\infty}$ is the *diagonal sequence*. It is a subsequence of the original sequence $\{x_j\}_{j=1}^{\infty}$. Furthermore, if we drop the first $k - 1$ terms, the resulting sequence $\{y_n\}_{n=k}^{\infty}$ is a subsequence of the sequence $\{x_{kj}\}_{j=1}^{\infty}$. In particular, (ii) shows that

$$d(y_n, y_m) < 2/k \qquad \text{if } n,m \geq k.$$

It follows that $\{y_n\}_{n=1}^{\infty}$ is a Cauchy sequence. □

A metric space X is *separable* if there is a dense subset of X that is countable. In other words, X is separable if and only if there is a sequence $\{x_j\}_{j=1}^{\infty}$ in X that is dense in X. (There may be repetitions among the x_j's.)

The real numbers $\mathbb{R}$ form a separable metric space. Indeed, the set $\mathbb{R}_0$ of rational numbers forms a countable dense subset of $\mathbb{R}$. Similarly, $\mathbb{R}^n$ is separable since the set of points of $\mathbb{R}^n$ with rational coordinates is countable.

5.7 Theorem: A subspace of a separable metric space is separable.

Proof: Suppose that X is a metric space with a dense subset $\{x_j\}_{j=1}^{\infty}$ and let Y be a subspace of X. Consider pairs of indices (j,n) such that

$$(*) \qquad B(x_j;1/n) \cap Y$$

is not empty. For such pairs (j,n), let y_{jn} be any point in the intersection (*). The $\{y_{jn}\}$ form a countable subset of Y. We claim that the y_{jn} are dense in Y.

Let $y \in Y$ and let $n \geq 1$. Then there exists j such that $d(x_j,y) < 1/n$. In particular, the intersection (*) is nonempty, so that y_{jn} is defined and $d(x_j,y_{jn}) < 1/n$. Then

$$d(y,y_{jn}) < d(y,x_j) + d(x_j,y_{jn}) < 2/n.$$

Letting $n \rightarrow \infty$, we find that y is adherent to the set $\{y_{jn}\}$, so that the closure of the double sequence is Y. □

5.8 Theorem: A totally bounded metric space is separable.

Proof: Let n be a positive integer. Then there exist $x_{n1},\ldots,x_{n,m_n}$ such that the open balls with centers at the x_{nj} and radii $1/n$ cover X. The family $\{x_{nj} : 1 \leq j \leq m_n, 1 \leq n < \infty\}$ is then a countable subset of X. For each $x \in X$ and each integer n, there is an x_{nj} such that $d(x_{nj},x) < 1/n$. Consequently the x_{nj} are dense in X. □

A *base of open sets* for a metric space X is a family $\mathcal{B}$ of open subsets of X such that every open subset of X is the union of sets in $\mathcal{B}$. For instance, the family of open balls forms a base of open sets for a metric space, as does the family of open balls with rational radii. Theorem 4.1 shows that the family of sets of the form $U_1 \times \cdots \times U_n$, where U_j is open in X_j, forms a base of open sets for a product metric space $X_1 \times \cdots \times X_n$.

5.9 Lemma: A family $\mathcal{B}$ of open subsets of a metric space X is a base of open sets if and only if for each $x \in X$ and each open neighborhood U of x, there exists $V \in \mathcal{B}$ such that $x \in V$ and $V \subset U$.

Proof: If $\mathcal{B}$ is a base, the set U above is the union of sets in $\mathcal{B}$, and so the condition of the lemma is evidently valid. Conversely, suppose that the condition given in the lemma holds. Let U be an open subset of X. For each $x \in U$, there is $V_x \in \mathcal{B}$ such that $x \in V_x$ and $V_x \subset U$. Then

$$U = \cup\{V_x : x \in U\}$$

represents U as a union of sets in $\mathcal{B}$, so that $\mathcal{B}$ is a base of open sets. □

A metric space satisfies the *second axiom of countability*, or is *second-countable*, if there is a base of open sets that is at most countable. In other words, X is second-countable if there is a sequence $\{U_n\}_{n=1}^{\infty}$ of open sets such that each open set U is the union of the U_n's it contains.

5.10 Theorem: A metric space is second-countable if and only if it is separable.

Proof: Suppose first that X is a separable metric space. Let $\{x_j\}_{j=1}^{\infty}$ be a dense sequence in X. Consider the family of open sets

$$\mathcal{B} = \{B(x_j;1/n) : j \geq 1,\ n \geq 1\}.$$

Let U be an open subset of X and let $x \in U$. For some $n \geq 1$, we have $B(x;2/n) \subset U$. Choose j so that $d(x_j,x) < 1/n$. Then $x \in B(x_j;1/n)$, and the triangle inequality shows that $B(x_j;1/n) \subset B(x;2/n) \subset U$. Consequently $\mathcal{B}$ is a base of open sets. Since $\mathcal{B}$ is countable, X is second-countable.

Conversely, suppose that X is second-countable. Let $\{U_n\}_{n=1}^{\infty}$ be a sequence of open sets in X that form a base. Let x_n be any point in U_n, $n \geq 1$. Then every nonempty open subset of X contains a point of the sequence $\{x_n\}$, so that the sequence is dense in X, and X is separable. □

The following theorem is the trickiest part of the circle of ideas covered in this section.

5.11 Theorem *(Lindelöf's Theorem):* Suppose the metric space X is second-countable. Then every open cover of X has a countable subcover.

Proof: Let $\{U_\alpha\}_{\alpha\in A}$ be an open cover of X, where A is some index set. Let $\mathcal{B}$ be a countable base of open sets. Let $\mathcal{C}$ be the subset of $\mathcal{B}$ consisting of those sets $V \in \mathcal{B}$ such that $V \subset U_\alpha$ for some α. We claim that $\mathcal{C}$ is a cover of X. Indeed, if $x \in X$, then there is some index α such that $x \in U_\alpha$. By Lemma 5.9, there is $V \in \mathcal{B}$ such that $x \in V$ and $V \subset U_\alpha$. In particular, $V \in \mathcal{C}$, so that $\mathcal{C}$ indeed covers X.

Now for each $V \in \mathcal{C}$, select one index $\alpha = \alpha(V)$ such that $V \subset U_{\alpha(V)}$. Then the sets $\{U_{\alpha(V)} : V \in \mathcal{C}\}$ cover X. Since $\mathcal{B}$ is countable, so is $\mathcal{C}$, so that the $U_{\alpha(V)}$'s form a countable subcover of X. □

Proof of Theorem 5.1 (concluded): As remarked earlier, Theorem 5.6 shows that (5.3) implies (5.2), so that the conditions (5.2) and (5.3) are equivalent.

Suppose that (5.2) and (5.3) are valid. It suffices to show that every open cover of X has a finite subcover.

By Theorem 5.8, X is separable, so that by Theorem 5.10, X is second-countable. By Theorem 5.11 every open cover of X has a countable subcover. It suffices to show then that if $\{U_n\}_{n=1}^{\infty}$ is a sequence of open subsets of X that cover X, then there is an integer m such that $X = U_1 \cup \cdots \cup U_m$.

Suppose that this is not the case, that is, that $U_1 \cup \cdots \cup U_m \neq X$ for all m. For each m, let x_m be any point in $X \backslash (U_1 \cup \cdots \cup U_m)$. By (5.3), the sequence $\{x_m\}$ has a subsequence that converges to some point $x \in X$. Since $x_j \in X\backslash(U_1 \cup \cdots \cup U_m)$ for all $j \geq m$ and since $X\backslash(U_1 \cup \cdots \cup U_m)$ is closed, $x \in X\backslash(U_1 \cup \cdots \cup U_m)$.

Since this is true for all m, $x \in X \setminus (\cup_{k=1}^{\infty} U_k)$ and the U_k do not cover X. This contradiction establishes the theorem. □

We state the following corollary to Theorems 5.1, 5.8, and 5.10 for emphasis.

5.12 Theorem: A compact metric space is separable and second-countable.

EXERCISES

1. Give an example of a totally bounded metric space which is not compact.
2. Give an example of a complete metric space which is not compact.
3. Show directly that a compact metric space is totally bounded.
4. Let $\{U_\alpha\}_{\alpha \in A}$ be a finite open cover of a compact metric space X.
   (a) Show that there exists $\varepsilon > 0$ such that for each $x \in X$, the open ball $B(x;\varepsilon)$ is contained in one of the U_α's.

Remark: Such an ε is called a *Lebesgue number* of the cover.

   (b) Show that if at least one of the U_α's is a proper subset of X, then there is a largest Lebesgue number for the cover.

5. Prove that the product of a finite number of compact metric spaces is compact.
6. A metric space is a *Polish space* if it is separable and if there is an equivalent metric for which it is complete. Prove that any closed subspace of a Polish space is Polish.

Remark: An important school of Polish mathematicians made deep contributions to the study of point-set topology during the period between the world wars. The terminology "Polish" recognizes the work of the Polish school on this important class of spaces. For more on Polish spaces, see Exercises 6.14 and 6.15.

7. Let $B(S)$ be the metric space of bounded real-valued functions on the set S, with the metric of uniform convergence on S (defined in Section 1). Show that $B(S)$ is separable if and only if S is finite.

   Hint: For any subset T of S, define $\chi_T \in B(S)$ by

$$\chi_T(s) = \begin{cases} 1, & s \in T, \\ 0, & s \notin T. \end{cases}$$

   Then the balls $B(\chi_T;1/2)$ are disjoint.

8. Let (X,d) be a bounded metric space and let $\mathscr{C}$ be the family of nonempty closed subsets of X. Show that

$$\rho(E,F) = \max\left(\sup_{x \in E} d(x,F),\ \sup_{y \in F} d(y,E)\right)$$

   defines a metric on $\mathscr{C}$. Show that $\mathscr{C}$ is compact whenever X is compact.

you could begin by clarifying what this is all about, before we plunge into the details? What is the roadmap, so to speak?

Me: To begin with, I will show you that the equations of motion describing gravity in *any diffeomorphism-invariant theory* can be given [2] a suggestive thermodynamic reinterpretation (Sections 2.2, 2.3). Second, taking a cue from this, I can formulate a variational principle for a suitably defined entropy functional – involving both gravity and matter – which will lead to the field equations of gravity [3,4] without varying the metric tensor as a dynamical variable (Section 2.4).

Harold: Suppose I have an action for gravity plus matter (in D dimensions)

$$A = \int d^D x \sqrt{-g} \left[L(R^{ab}_{cd}, g^{ab}) + L_{\text{matt}}(g^{ab}, q_A) \right] \tag{2.1}$$

where L is any scalar built from metric and curvature and L_{matt} is the matter Lagrangian depending on the metric and some matter variables q_A. (I will assume L does not involve derivatives of curvature tensor, to simplify the discussion.) If I vary g^{ab} in the action I will get some equations of motion (see, e.g., [5,6]), say, $2E_{ab} = T_{ab}$ where E_{ab} is[2]

$$E_{ab} = P_a^{cde} R_{bcde} - 2\nabla^c \nabla^d P_{acdb} - \frac{1}{2} L g_{ab}; \qquad P^{abcd} \equiv \frac{\partial L}{\partial R_{abcd}} \tag{2.2}$$

Now, you are telling me that (i) you can give a thermodynamic interpretation to the equation $2E_{ab} = T_{ab}$ just because it comes from a scalar Lagrangian and (ii) you can also derive it from an entropy maximization principle. I admit it is fascinating. But why should I take this approach as more fundamental, conceptually, than the good old way of just varying the total Lagrangian $L + L_{\text{matt}}$ and getting $2E_{ab} = T_{ab}$? Why is it more than a curiosity?

Me: That brings me to the third aspect of the formulation which I will discuss towards the end (Section 2.5). In my approach, I can provide a natural explanation to several puzzling aspects of gravity and horizon thermodynamics, all of which have to be thought of as mere algebraic accidents in the conventional approach you mentioned. Let me give an analogy. In Newtonian gravity, the fact that inertial mass is equal to the gravitational mass is an algebraic accident without any fundamental explanation. But in a geometrical theory of gravity based on the principle of equivalence, this fact finds a natural explanation. Similarly, I think we can make progress by identifying key facts which have no explanation in the conventional approach and providing them a natural explanation from a different perspective. You will also see that this approach connects up several pieces of conventional theory in an elegant manner.

Einstein's new theory. Using the Schwarzschild solution to describe the spherically symmetric gravitational field of the Sun, Einstein was able to determine the orbit of Mercury according to general relativity, and amazingly the prediction gave a rotation of 43 seconds, in excellent agreement with observation. This was the first experimental test of the theory and provided very compelling evidence in support of it. The test is particularly compelling because the theory was not designed specifically to meet this challenge—it just turned out that it did so, after the theory had been fashioned on the basis of fundamental considerations by Einstein on the nature of space, time, and gravitation.

More recently, the general relativistic prediction of perihelion precession has been confirmed by observations of the binary pulsar discovered by Hulse and Taylor in 1974. This system, which will be discussed in more detail in Section 5.11, consists of two very compact stars in a very tight orbit around each other. The perihelion precession is orders of magnitude larger than that of Mercury; the prediction of about 4 degrees per year agrees closely with the measured value.

Radar time-delay

A way of investigating the curvature of space produced by the Sun, say, is to measure the delay in the travel-time of a radar beam passing near it, as compared with the travel time if the space were flat. Early experiments were performed by sending a radar beam from Earth and measuring the round trip time after it was returned by a reflector on the surface of Venus or Mercury or onboard a Mariner spacecraft. As the path of the radar beam moved nearer to the Sun as the relative positions of the Earth and the reflector changed, the travel time varied (see Fig. 5.35). In a more recent experiment by Shapiro in 1976, the radar travelled to Mars and was sent back by reflectors both on the surface of the planet and in a spacecraft in orbit around it. The round trip time for signals passing near the Sun was measured and found to agree well with the values calculated from general relativity. Because of the curvature of space, the distance was found to be larger by about 37 km out of a total distance of 378 million km from Earth to Mars. The radar travel time was about 42 minutes for the round trip.

The Global Positioning System

An intriguing application of, and testing ground for, relativity lies in the setting up of the Global Positioning System (GPS). The basic idea is that an observer should be able to determine his or her position in space and time with extreme accuracy by using signals from a network of satellites. In the current system, there are twenty-four satellites in various orbits around the Earth, arranged such that four or more of them are almost always visible from any place on Earth. Each satellite carries an extremely accurate and stable atomic clock, and signals from this are emitted from the satellite. Ground-based monitoring stations collect data which is processed and re-transmitted to the satellites. The user has a small computer which uses information from the satellites to solve for its position, time,

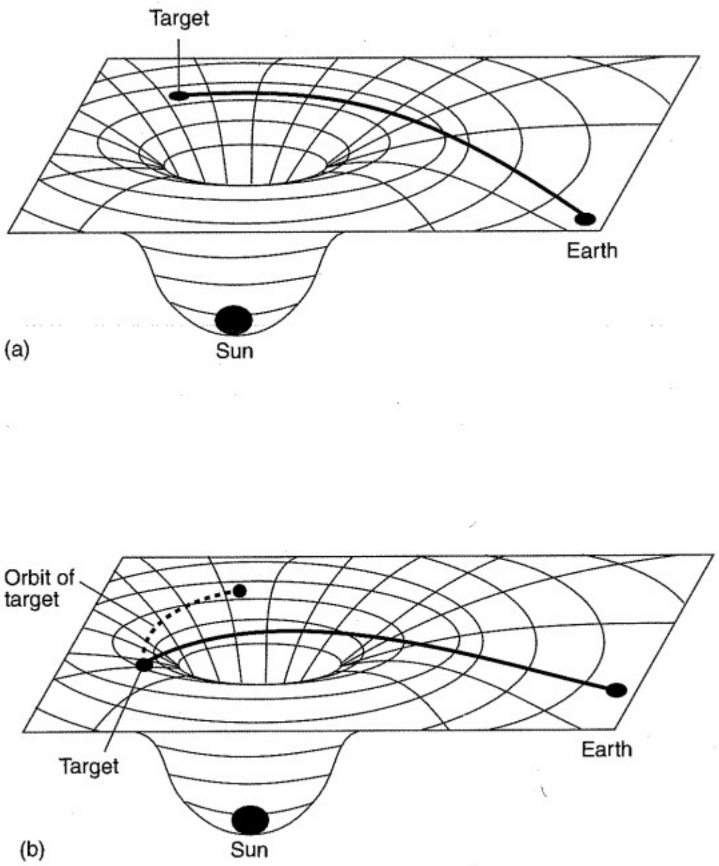

Fig. 5.35 The gravitational field of the Sun produces curvature in space, which is represented here by a 'rubber sheet' picture. (a) When the target planet is far from the Sun, the radar path is on the 'flat' part of the sheet. (b) As the target approaches the Sun, the radar has greater and greater distance to cover because of the 'dip' in the sheet, so the travel time is longer.

and velocity. The accuracy is extremely impressive, and can be as good as 5–10 cm in position.

Although the velocities of the clocks are small and the gravitational fields are weak, relativistic effects like time dilation and gravitational frequency shift would cause errors much larger than possible errors in the accuracy of the cesium clocks used, and so they need to be taken into account. A natural consequence of this is that the GPS provides a way of testing the theory of relativity. Data from the GPS satellites recorded by the TOPEX satellite (in orbit primarily to measure the height of the sea) is providing the first explicit measurements of the periodic part of the combined effect of time dilation and gravitational frequency shifts on an orbiting receiver. Preliminary analysis of the data gives an agreement between theory and experiment to within 2.5 per cent. (For more details, see 'The global positioning system' by T. A. Herring, *Scientific American*, February 1996, 32–38.)

5.10 Gravitational waves

Einstein realized more than 80 years ago that his theory predicted the existence of gravitational waves, but it is only relatively recently that any progress has been made on detecting them. In this section, we shall first look at the nature of gravitational waves and then at possible sources for their emission. In Section 5.11, we shall discuss methods of detecting them, both by experiments with bars and interferometers and also less directly through study of the energy decrease of a system which is best explained by the emission of such waves.

The nature of gravitational waves

Gravitational waves are fluctuations in the metric tensor which describes the curvature of space–time. One can think of them as ripples which travel through space–time, usually as a result of rotation or other changes in the body producing the gravitational field.

We shall look first at a particularly simple way in which Einstein's equations can have wave solutions. This is in the case when the gravitational field in empty space is weak, so that the metric tensor can be written as its flat-space value η^{ij} plus a small perturbation h^{ij}. The 'linearized field equations' are derived from Einstein's equations by ignoring terms in h^{ij}-squared and higher powers. We obtain a set of linear second-order partial differential equations for h^{ij}, and with a particular choice of coordinates called the Lorentz gauge (see Section 5.5) they take the form in empty space of the wave equation for the combination of components $\bar{h}^{ij}$ defined by $\bar{h}^{ij} = h^{ij} - \frac{1}{2}\eta^{ij}\eta_{kl}h^{kl}$. This equation has precisely the same form as the equation describing electromagnetic waves, which means that gravitational waves, like their electromagnetic counterparts, travel with the speed of light.

As in the electromagnetic case, the wave equation here has *plane wave* solutions

$$\bar{h}^{ij} = A^{ij}\sin(\omega t + \mathbf{k}.\mathbf{x}) \tag{5.10}$$

(or cosine of the same argument) where A^{ij} and $k_i = (\omega, \mathbf{k})$ are constants. There is already a restriction on A^{ij} because of the choice of the Lorentz gauge, and it can be restricted further to what is known as the *transverse traceless* gauge. Traceless means that if A^{ij} is written as a matrix, the sum of its diagonal components is zero. To understand what we mean by transverse, let us choose our axes so that the wave is travelling in the z-direction, so $k_i = (\omega, 0, 0, \omega)$. Then our gauge condi-

Kinematics of cosmological models

In cosmology, the matter components allow us to make a physically motivated choice of preferred motion. For example, we could choose the CMB frame, in which the radiation dipole vanishes, or the frame in which the total momentum density of all components vanishes. Such a choice corresponds to a preferred 4-velocity field u^a that generates a family of preferred world lines. We can then make a 1+3 split relative to u^a, in order to relate the physics and geometry to the observations. In this chapter we discuss how to do this for the kinematics of cosmological models; the following chapter will consider the dynamics.

The (real or fictitious) observers are comoving with the matter-defined 4-velocity u^a, and we can call the observers and the 4-velocity ‘fundamental’. If we change our choice of fundamental 4-velocity, the kinematics and dynamics transform in a well-defined way, as discussed in the following chapter.

4.1 Comoving coordinates

To describe the spacetime geometry it is convenient to use comoving (Lagrangian) coordinates, adapted to the fundamental world lines. These are locally defined as follows.[1]

(1) Choose a surface S that intersects each world line once only (note that no unique choice is available in general). Label each world line where it intersects this surface; as the surface is three-dimensional, three labels y^i, $(i = 1,2,3)$, are required to label all the world lines.

(2) Extend this labelling off the surface S by maintaining the same labelling for the world lines at later and earlier times. Thus the y^i are *comoving coordinates*: the value of the coordinate is maintained along each world line, and in fact the world lines (and so the fundamental particles) are labelled by these coordinates.

(3) Define a time coordinate t along the fluid flow lines (it must be a function that increases along each flow line).

Then (t, y^i) are *comoving coordinates* adapted to the flow lines. Note that the surfaces $t =$const will in general not be orthogonal to the fundamental world lines; indeed, in general it is not possible to choose a time coordinate for which these surfaces are orthogonal (see Section 4.6 below).

---

[1] In this section we are not concerned about possible global problems with coordinates; these are considered in Section 6.7.

The coordinate freedoms available which preserve this form are (a) *time transformations* $t' = t'(t, y^i),\ y^{i'} = y^i$, corresponding to a new choice of time surfaces, and (b) *relabelling of the world lines* by choosing new coordinates in the initial surface: $t' = t,\ y^{i'} = y^{i'}(y^i)$.

A particular choice for t which is often convenient is the *normalized time* $s = s_0 + \tau$, where τ is proper time measured along the fundamental world lines from S (positive to the future of S, negative to the past) and s_0 is an arbitrary constant. With this choice, $x^\mu = (s, y^i)$ are *normalized comoving coordinates*, s measuring proper time from the surface S (on S, $s = s_0$) along the world lines, which lie in the intersection in spacetime of the surfaces $y^i =$const. The remaining time freedom is then $s' = s + f(y^i)$, corresponding to choice of the initial surface S. For example, the standard coordinates (t, r, θ, ϕ) in an FLRW universe model (2.65) are such normalized comoving cooordinates.

General coordinates x^μ will be related to the normalized comoving coordinates by a coordinate transformation,

$$x^\mu = x^\mu(s, y^i), \qquad \mu = 0, \ldots, 3, \qquad i = 1, \ldots, 3, \tag{4.1}$$

the spatial parts of which are similar to the transformation from Lagrangian to Eulerian coordinates in Newtonian theory. Indeed one can define Newtonian-like quasi-Eulerian ('fixed', non-comoving) coordinates in general relativity, defined by the physical (proper) distance and direction from some chosen world line in preferred space sections. They can provide a useful alternative to the more usual Lagrangian coordinates when taking the Newtonian limit (for the FLRW case, see Ellis and Rothman (1993)).

In Newtonian theory, because unique spatial sections exist in spacetime, there is a natural time coordinate t, uniquely defined (up to a constant), which measures proper time along all lines. In Newtonian cosmology, one can again choose comoving spatial ('Lagrangian') coordinates y^i as in the relativistic case, obtaining spacetime coordinates (t, y^i).

4.2 The fundamental 4-velocity

The preferred matter motion implies a preferred 4-velocity at each point. Geometrically, this can be depicted as an arrow pointing along the fundamental world lines. If the preferred world lines are given in terms of *local* coordinates x^μ by $x^\mu = x^\mu(\tau)$ where τ is proper time along the world lines, then the preferred 4-velocity is the unit timelike vector

$$u^\mu = \frac{\mathrm{d}x^\mu}{\mathrm{d}\tau} \quad \Rightarrow \quad u^\mu u_\mu = -1. \tag{4.2}$$

The implication follows by considering the integral for proper time along a world line: $\tau = \int [-(\mathrm{d}x^\mu/\mathrm{d}\tau)(\mathrm{d}x^b/\mathrm{d}\tau)g_{ab}]^{1/2}\mathrm{d}\tau = \int (-u^\mu u_\mu)^{1/2}\mathrm{d}\tau$. In normalized comoving coordinates $x^\mu = (s, y^i)$ this becomes

$$u^\mu = \delta^\mu_0 \quad \Leftrightarrow \quad \frac{\mathrm{d}s}{\mathrm{d}\tau} = 1,\ \frac{\mathrm{d}y^i}{\mathrm{d}\tau} = 0. \tag{4.3}$$

These are also sufficient conditions such that the coordinates are normalized comoving coordinates (the curve parameter is proper time, and the vector u^μ is tangent to the direction where all the y^i are constant).

In general coordinates x^μ, this vector will be given by

$$u^\mu = \left(\frac{\partial x^\mu}{\partial s}\right)_{y^i=\text{const}}. \tag{4.4}$$

This is obtained by applying the coordinate transformation (4.1) to (4.3); conversely, specializing the coordinates in (4.4) to normalized comoving coordinates, we recover (4.3).

The component of any vector X^a parallel to u^a is

$$X^a_\parallel = U^a{}_b X^b, \;\; U^a{}_b := -u^a u_b, \tag{4.5}$$

where $U^a{}_b$ is a projection tensor ($U^a{}_b U^b{}_c = U^a{}_c$) into the one-dimensional tangent line ($U^a{}_a = 1$) parallel to u^a ($U^a{}_b u^b = u^a$). For example, the fundamental 4-velocity in an FLRW universe model in the standard coordinates (2.65) is given by $u^\mu = \delta^\mu_0,\;\; u_\mu = -\delta^0_\mu$. Thus in this case $U^\mu{}_\nu = \delta^\mu_0 \delta^0_\nu$.

In Newtonian theory, a 3-velocity v^i representing the average motion of matter at each point will be defined. Lagrangian coordinates (the Newtonian version of comoving coordinates) are characterized by the condition $v^i = 0$.

Exercise 4.2.1 Show that

(a) if we use general comoving coordinates (t, y^i), then $u^\mu = v^{-1}\delta^\mu_0$, where $v(x^\alpha) = \mathrm{d}s/\mathrm{d}t$, and that $u_\mu = g_{\mu 0}/v$, $g_{00} = -v^2$, $u_0 = -v$;
(b) under a time transformation, $t' = t'(t, y^i),\;\; y^{i'} = y^i$, these relations are preserved with $v \to v' = v/(\partial t'/\partial t)$;
(c) (4.4) reduces to (4.3) on using normalized comoving coordinates;
(d) we have normalized comoving coordinates if and only if $u_\mu = g_{\mu 0}$.

4.3 Time derivatives and the acceleration vector

The time derivative of any tensor $S^{a\cdots}{}_{b\dots}$ along the fluid flow lines is

$$\dot{S}^{a\cdots}{}_{b\dots} = u^c \nabla_c S^{a\cdots}{}_{b\dots}, \tag{4.6}$$

and by (2.28) this is of the form

$$\dot{S}^{a\cdots}{}_{b\dots} = \frac{\mathrm{d}}{\mathrm{d}\tau} S^{a\cdots}{}_{b\dots} + S^{c\cdots}{}_{b\dots}\Gamma^a{}_{cd}u^d + \cdots - S^{a\cdots}{}_{c\dots}\Gamma^c{}_{bd}u^d - \cdots . \tag{4.7}$$

The first term is the apparent derivative (i.e. the value obtained by only taking the directional derivative of the components) relative to the coordinate frame along the world lines, and the others correct this apparent derivative to give the covariant derivative along the world lines. When a frame which is parallelly propagated along the world lines is used, this reduces

+4 1 - - -

to $\dot{S}^{a\cdots}{}_{b\ldots} = \mathrm{d}S^{a\cdots}{}_{b\ldots}/\mathrm{d}\tau = \partial S^{a\cdots}{}_{b\ldots}/\partial\tau + S^{a\cdots}{}_{b\ldots,i}u^i$ (the last term vanishes if comoving coordinates are used).

A particular application of time differentiation is the derivative of the 4-velocity itself in its own direction: this determines the acceleration vector,

$$\dot{u}^a = u^b\nabla_b u^a \;\Rightarrow\; \dot{u}^a u_a = 0, \tag{4.8}$$

which vanishes if and only if the flow lines are geodesics. Physically, this is the case if they represent motion under gravity and inertia alone, i.e. no non-gravitational force acts (see Section 3.1.2). From this definition,

$$\nabla_b u_a = h_a{}^c h_b{}^d \nabla_d u_c - \dot{u}_a u_b\,, \tag{4.9}$$

where the first term on the right is orthogonal to u^a, with h_{ab} defined in (4.10).

The corresponding Newtonian derivative is the 'convective derivative' (Batchelor, 1967), $\dot{T}^{ij\cdots}{}_{\ldots k\ell} = \partial T^{ij\cdots}{}_{\ldots k\ell}/\partial t + T^{ij\cdots}{}_{\ldots k\ell,m}v^m$, determining the rate of change of $T^{ij\cdots}{}_{\ldots k\ell}$ relative to the fluid. As we have just seen, this is essentially what is obtained from the general relativity equations if a parallelly propagated frame is used.

Exercise 4.3.1 Show that in normalized comoving coordinates, $\dot{u}^\mu = \Gamma^\mu{}_{00}$, so that $\dot{u}_\mu = \frac{1}{2}(2\partial g_{0\mu}/\partial t - \partial g_{00}/\partial x^\mu)$.

Exercise 4.3.2

(a) Show that the Newtonian analogue of the 'acceleration vector' is $a_i = \dot{v}_i + \Phi_{,i}$ where Φ is the Newtonian gravitational potential. Deduce that even in Newtonian theory, we are unable to separate the gravitational and inertial parts of a_i invariantly if the matter density does not go to zero at infinity. (Hint: see Heckmann and Schucking (1955), Bondi (1960), Trautman (1965)). (Note: when comparing relativistic and Newtonian equations, $\dot{u}^\mu$ should be compared with a_i not $\dot{v}_i$; the difference between the two cases can be considered to arise because in relativity covariant differentiation already has the gravitational effects coded into it.)

(b) Show that when comoving coordinates are used, $a_i = \Phi_{,i}$.

(c) Consider when this form can be obtained as a limit of the relativistic equations in the previous exercise (i.e. when does there exist a scalar potential Φ for $\dot{u}_a$?).

4.4 Projection to give three-dimensional relations

The existence of a preferred velocity at each point implies the existence of preferred rest frames at each point; locally these define surfaces of simultaneity for the fundamental observers.

4.4.1 Orthogonal projection

The (induced) effective metric tensor for these surfaces is the tensor

$$h_{ab} = g_{ab} + u_a u_b\,. \tag{4.10}$$

We see this as follows: from the above definition and (4.2),

$$h^a{}_b h^b{}_c = h^a{}_c,\ \ h^a{}_a = 3,\ \ h^a{}_b u^b = 0, \tag{4.11}$$

that is, $h^a{}_b$ is a projection tensor projecting into the three-dimensional tangent plane orthogonal to u^a.

Any vector X^a can be projected, by means of $h^a{}_b$, to its part $X^a_\perp$ orthogonal to u^a (i.e. its component in the instantaneous rest-space of an observer moving with the 4-velocity u^a):

$$X^a_\perp = h^a{}_b X^b \ \ \Rightarrow \ \ X^a_\perp u_a = 0,\ (X^a_\perp)_\perp = X^a_\perp. \tag{4.12}$$

The projection tensor is the metric tensor for the rest space; for if X^a and Y^b are any vectors orthogonal to u^a ($X^a u_a = 0 = Y^b u_b$), then $\boldsymbol{X}\cdot\boldsymbol{Y} = X^a g_{ab} Y^b = X^a h_{ab} Y^b$, that is, h_{ab} determines scalar products and so angles and magnitudes for all vectors in the rest space of u^a. It corresponds precisely to the Newtonian metric tensor h_{ij} determining magnitudes and angles in Newtonian theory.

U_{ab} and h_{ab} enable projection of any tensor into parts parallel and perpendicular to u^a. A particular example is the metric tensor itself: $g_{\perp ab} = h_a{}^d h_b{}^e g_{de} = h_{ab},\ g_{\| ab} = U_a{}^d U_b{}^e g_{de} = U_{ab}$, so its splitting into parallel and perpendicular parts is given by

$$g_{ab} = h_{ab} + U_{ab} = h_{ab} - u_a u_b\,. \tag{4.13}$$

This shows that the interval $\mathrm{d}s^2$ associated with an arbitrary displacement $x^\mu \to x^\mu + dx^\mu$ can be decomposed by

$$\mathrm{d}s^2 = g_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu = h_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu - (u_\mu \mathrm{d}x^\mu)^2 = (\delta l)^2 - (\delta t)^2 \tag{4.14}$$

into a time difference $\delta t = (U_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu)^{1/2} = (-u_\mu \mathrm{d}x^\mu)$ ($= c\,\delta t$ in units in which $c \neq 1$) and a spatial distance $\delta l = (h_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu)^{1/2}$ as measured by an observer moving with 4-velocity u^μ. This decomposition implies the usual special relativistic length contraction and time dilation formulae (as these quantities are related to the interval in the standard special relativistic way, and all the equations hold for the projection tensors associated with arbitrary 4-velocities; we will get a different decomposition of g_{ab} into U_{ab} and h_{ab} if we choose a different 4-velocity u_a).

For example, in comoving coordinates, $U^{ij} = 0$, $h_{\mu 0} = 0$ in any universe, while the components of U^{ab}, h_{ab} in an orthonormal tetrad $\{\boldsymbol{u}, \boldsymbol{e}_i\}$ are $U^{ab} = \mathrm{diag}(-1,0,0,0)$, $h_{ab} = \mathrm{diag}(0,1,1,1)$. The components of h_{ab} in an FLRW universe in the standard FLRW coordinates (2.65) are $h_{\mu\nu} = a^2(t)\,\mathrm{diag}(0,1,f^2(r),f^2(r)\sin^2\theta)$. In Newtonian theory, we have $\delta l = (h_{ij}\mathrm{d}x^i \mathrm{d}x^j)^{1/2}$, $\delta t = (-U_{ij}\mathrm{d}x^i \mathrm{d}x^j)^{1/2}$ still, but now the flat 3-space metric h_{ij} is given and fixed, and the time metric U^{ij} is also fixed. Using the preferred time coordinate t, $h_{\mu 0} = 0$, $h_{ij} = \delta_{ij}$ (in Cartesian coordinates) and $U^{\mu\nu} = -\delta^\mu_0 \delta^\nu_0$. These relations also follow from (4.13) in the slow-motion limit.

In the sequel we shall very frequently have occasion to project vectors orthogonal to u^a, and to take the traceless parts, orthogonal to u^μ, of rank two symmetric tensors – i.e. the projected symmetric tracefree, or PSTF, parts. For brevity we use angled brackets on indices to denote the PSTF parts. For convenience we use the term PSTF to include projected rank one tensors (vectors). For any V_a and tensor S_{ab}, the PSTF parts are given by

$$V_{\langle a\rangle} = h_a{}^b V_b\,, \quad S_{\langle ab\rangle} = \left\{h_{(a}{}^c h_{b)}{}^d - \tfrac{1}{3}h_{ab}h^{cd}\right\} S_{cd}\,. \tag{4.15}$$

We write equations so that all terms are manifestly PSTF. We continue to use $\perp$ to indicate the projection in other cases. One may note that a general rank two tensor can be written as

$$\begin{aligned} S_{ab} &= (h_a{}^c + U_a{}^c)(h_b{}^d + U_b{}^d)S_{cd} \\ &= \tfrac{1}{3}h_{ab}(h^{cd}S_{cd}) + S_{\langle ab\rangle} + h_a{}^c h_b{}^d S_{[cd]} \\ &\quad - (h_a{}^c S_{cd}u^d)u_b - u_a(u^c S_{cd} h_b{}^d) + u_a u_b (u^c u^d S_{cd})\,. \end{aligned} \tag{4.16}$$

This decomposition splits the tensor into parts irreducible under the rotational freedom in the hyperplane orthogonal to u^a. For the projection of time derivatives we use the notation

$$\dot{V}^{\langle a\rangle} = h^a{}_b \dot{V}^b\,, \tag{4.17}$$

and similarly for $\dot{S}^{\langle ab\rangle}$.

Any skew 2-tensor orthogonal to u^a can be written as

$$A_{ab} = A_{[ab]} = \eta_{abc}A^c \Leftrightarrow A^c = \tfrac{1}{2}\eta^{abc}A_{bc}, \tag{4.18}$$

where the projected alternating tensor η_{abc} was defined in Section 2.7.5. Then in (4.16) all terms can be expressed using u^a, scalars, projected vectors obeying $V_a = V_{\langle a\rangle}$, and PSTF 2-tensors $S_{ab} = S_{\langle ab\rangle}$. Note that such a PSTF tensor has five independent components. By evaluating components in an orthonormal tetrad aligned with u^μ it is easily found that η_{abc} has the same components as the skew object in three-dimensional vector calculus used, for instance, in defining vector products and the curl of a vector.

4.4.2 Orthogonal spatial derivatives

One can project the four-dimensional covariant derivatives to give three-dimensional derivative operators:

$$\overline{\nabla}_c S^{a\cdots}{}_{b\cdots} = h_c{}^f h^a{}_d \cdots h_b{}^e \cdots \nabla_f S^{d\cdots}{}_{e\cdots}\,. \tag{4.19}$$

Other notations for this derivative in the literature are ${}^{(3)}\nabla_a, \widehat{\nabla}_a, \vec{\nabla}_a$ and D_a.

Following Maartens (1997), we define

$$\mathrm{div}\, V = \overline{\nabla}^a V_a\,, \quad (\mathrm{div}\, S)_a = \overline{\nabla}^b S_{ab}\,, \tag{4.20}$$

$$\mathrm{curl}\, V_a = \eta_{abc}\overline{\nabla}^b V^c\,, \quad \mathrm{curl}\, S_{ab} = \eta_{cd(a}\overline{\nabla}^c S_{b)}{}^d\,. \tag{4.21}$$

The covariant div and curl preserve the PSTF property. Note that $\overline{\nabla}$, div and curl are defined as operators in a 3-manifold only if the vorticity vanishes (see below). When vorticity is non-zero, they are only operators in the tangent hyperplane at each point and not on a manifold.

One should be cautious in using three-dimensional concepts and notation in the case with non-zero vorticity – since in that case there are no hypersurfaces to which h_{ab} is everywhere tangent (see Section 4.6). This means in particular that there is in general no three-dimensional manifold in which Poincaré's Lemma can be applied to obtain scalar or vector potentials. However, when vorticity vanishes, we have a powerful covariant spatial calculus of vectors and tensors. Even with vorticity, it dramatically shortens subsequent equations, makes derivations far easier and more transparent and facilitates new insights.

With these definitions we find that

$$\overline{\nabla}_c h_{ab} = 0\,,\ \overline{\nabla}_d \eta_{abc} = 0\,,\ \dot{h}_{ab} = 2u_{(a}\dot{u}_{b)}\,,\ \dot{\eta}_{abc} = 3u_{[a}\eta_{bc]d}\dot{u}^d\,. \tag{4.22}$$

Identities obeyed by div and curl are collected in Section 4.8.

Exercise 4.4.1

(a) Show from (4.14) that the proper time $\mathrm{d}\tau$ experienced by a particle between events P and Q for which an observer O determines coordinates x^μ, $x^\mu + \mathrm{d}x^\mu$, respectively, is $\mathrm{d}\tau = \delta t/\gamma$ where $\gamma = (1 - v^2/c^2)^{-1/2}$ and $v = \delta l/\delta t$ is the velocity of the particle relative to O.

(b) Show that

$$\eta_{abcd} = 2u_{[a}\eta_{b]cd} - 2\eta_{ab[c}u_{d]}\,,\ \eta_{abc}\eta^{def} = 3!h_{[a}{}^d h_b{}^e h_{c]}{}^f\,, \tag{4.23}$$

$$(V_{\langle a\rangle})\dot{} = \dot{V}_{\langle a\rangle} + V_b\dot{u}^b u_a\,. \tag{4.24}$$

(d) Derive (4.22).

4.5 Relative position and velocity

4.5.1 Relative position vectors

Consider a curve $y^i = y^i(v)$ in a surface $S : s = s_0$, where (s, y^i) are comoving coordinates. This curve links a set of fundamental observer world lines (which we shall assume for now are also galaxy world lines) in that surface; at all later times, the same curve links the same set of world lines, that is, the curve is dragged along by the world lines from the surface S to any other surface $s =$ const.

Similarly the vector $\beta^\mu = (\mathrm{d}x^\mu/\mathrm{d}v)\delta v$ tangent to this curve, given in comoving coordinates by $\beta^\mu = (0, \delta y^i)$, where $\delta y^i = (\mathrm{d}y^i/\mathrm{d}v)\delta v$, links the same pair of world lines O: $y^i = c^i =$const and G: $y^i = c^i + \delta y^i$, $\delta y^i =$const, at all times, provided δv is small (so that the displacement represented by the vector is a good approximation to displacement along the curve). This is a *connecting vector* as described in Section 2.4, since it always joins the same pair of fundamental world lines. In general coordinates x^μ, this vector will be given by

$$\beta^\mu = \left(\frac{\partial x^\mu}{\partial y^i}\right)_{s=\text{const}} \delta y^i\ . \tag{4.25}$$

An observer on O would at all times find that the spacetime position defined by β^μ lies on the world line of the galaxy G.

& $8 ; . 1 ! 0 ?

is the correct formula, one has only to show that the covariant derivative of the induced metric is zero and that the torsion vanishes. This follows because

$$h_{ab\|c} = (g_{ef} \mp \overline{n}_e \overline{n}_f)_{;g} h^e{}_a h^f{}_b h^g{}_c = 0,$$

and $$f_{\|ab} = h^e{}_a h^g{}_b f_{;eg} = h^e{}_a h^g{}_b f_{;ge} = f_{\|ba}.$$

The curvature tensor $R'^a{}_{bcd}$ of the induced metric **h** can be related to the curvature tensor $R^a{}_{bcd}$ on $\theta(\mathscr{S})$ and the second fundamental form $\boldsymbol{\chi}$ as follows. If $\mathbf{Y} \in H$ is a vector field on $\theta(\mathscr{S})$, then

$$R'^a{}_{bcd} Y^b = Y^a{}_{\|dc} - Y^a{}_{\|cd}.$$

Now

$$\begin{aligned} Y^a{}_{\|dc} &= (Y^a{}_{\|d})_{\|c} = (\overline{Y}^e{}_{;f} h^g{}_e h^f{}_i)_{;k} h^a{}_g h^i{}_d h^k{}_c \\ &= \overline{Y}^e{}_{;fk} h^a{}_e h^f{}_d h^k{}_c \mp \overline{Y}^e{}_{;f} \overline{n}_e \overline{n}^g{}_{;k} h^f{}_d h^a{}_g h^k{}_c \mp \overline{Y}^e{}_{;f} \overline{n}^f \overline{n}_{i;k} h^a{}_e h^i{}_d h^k{}_c \end{aligned}$$

and $$\overline{Y}^e{}_{;f} \overline{n}_e h^f{}_d = (\overline{Y}^e \overline{n}_e)_{;f} h^f{}_d - \overline{Y}^e \overline{n}_{e;f} h^f{}_d = -\overline{Y}^e \overline{n}_{e;f} h^f{}_d,$$

since $\overline{Y}^e \overline{n}_e = 0$ on $\theta(\mathscr{S})$, therefore

$$R'^a{}_{bcd} Y^b = (R^e{}_{bkf} h^a{}_e h^k{}_c h^f{}_d \pm \chi_{bd} \chi^a{}_c \mp \chi_{bc} \chi^a{}_d)\, Y^b.$$

Since this holds for all $\mathbf{Y} \in H$,

$$R'^a{}_{bcd} = R^e{}_{fgh} h^a{}_e h^f{}_b h^g{}_c h^h{}_d \pm \chi^a{}_c \chi_{bd} \mp \chi^a{}_d \chi_{bc}. \tag{2.34}$$

This is known as Gauss' equation.

Contracting this equation on a and c and multiplying by h^{bd}, one obtains the curvature scalar R' of the induced metric:

$$R' = R \mp 2R_{ab} n^a n^b \pm (\chi^a{}_a)^2 \mp \chi^{ab} \chi_{ab}. \tag{2.35}$$

One can derive another relation between the second fundamental form and the curvature tensor $R^a{}_{bcd}$ on $\theta(\mathscr{S})$ by subtracting the expressions

$$(\chi^a{}_a)_{\|b} = (\overline{n}^a{}_{;d} h^d{}_a)_{;e} h^e{}_b$$

and $$(\chi^a{}_b)_{\|a} = (\overline{n}^c{}_{;d} h^a{}_c h^d{}_e)_{;f} h^f{}_a h^e{}_b,$$

finding $$\chi^a{}_{b\|a} - \chi^a{}_{a\|b} = R_{ef} n^f h^e{}_b. \tag{2.36}$$

This is known as Codacci's equation.

2.8 The volume element and Gauss' theorem

If $\{\mathbf{E}^a\}$ is a basis of one-forms, one can form from it the n-form

$$\boldsymbol{\epsilon} = n!\mathbf{E}^1 \wedge \mathbf{E}^2 \wedge \dots \wedge \mathbf{E}^n.$$

If $\{\mathrm{E}^{a'}\}$, related to $\{\mathrm{E}^{a}\}$ by $\mathrm{E}^{a'} = \Phi^{a'}{}_{a}\mathrm{E}^{a}$, is another basis, the n-form $\boldsymbol{\epsilon}'$ defined by this basis will be related to $\boldsymbol{\epsilon}$ by

$$\boldsymbol{\epsilon}' = \det(\Phi^{a'}{}_{a})\,\boldsymbol{\epsilon},$$

so this form is not unique. However, one can use the existence of the metric to define (in a given basis) the form

$$\boldsymbol{\eta} = |g|^{\frac{1}{2}}\,\boldsymbol{\epsilon}$$

where $g \equiv \det(g_{ab})$. This form has components

$$\eta_{ab\ldots d} = n!\,|g|^{\frac{1}{2}}\,\delta^{1}{}_{[a}\delta^{2}{}_{b}\ldots\delta^{n}{}_{d]}.$$

The transformation law for g will just cancel the determinant, $\det(\Phi^{a'}{}_{a})$, provided that $\det(\Phi^{a'}{}_{a}) > 0$. Therefore if $\mathscr{M}$ is orientable the n-forms $\boldsymbol{\eta}$ defined by coordinate bases of an oriented atlas will be identical, i.e. given an orientation of $\mathscr{M}$, one can define a unique n-form field $\boldsymbol{\eta}$, the *canonical n-form*, on $\mathscr{M}$.

The contravariant antisymmetric tensor

$$\eta^{ab\ldots d} = g^{ae}g^{bf}\ldots g^{dh}\eta_{ef\ldots h}$$

has components

$$\eta^{ab\ldots d} = (-)^{\frac{1}{2}(n-s)}n!\,|g|^{\frac{1}{2}}\,\delta^{[a}{}_{1}\delta^{b}{}_{2}\ldots\delta^{d]}{}_{n},$$

where s is the signature of $\mathbf{g}$ (so $\frac{1}{2}(n-s)$ is the number of negative eigenvalues of the matrix of metric components (g_{ab})). Therefore these tensors satisfy the relations

$$\eta^{ab\ldots d}\eta_{ef\ldots h} = (-)^{\frac{1}{2}(n-s)}n!\,\delta^{a}{}_{[e}\delta^{b}{}_{f}\ldots\delta^{d}{}_{h]}. \tag{2.37}$$

The Christoffel relations imply that the covariant derivatives of $\eta_{ab\ldots d}$ and $\eta^{ab\ldots d}$ with respect to the connection defined by the metric vanish, i.e.

$$\eta^{ab\ldots d}{}_{;e} = 0 = \eta_{ab\ldots d;e}.$$

Using the canonical n-form, one can define the volume (with respect to the metric $\mathbf{g}$) of an n-dimensional submanifold $\mathscr{U}$ as $\dfrac{1}{n!}\displaystyle\int_{\mathscr{U}}\boldsymbol{\eta}$. Thus $\boldsymbol{\eta}$ can be regarded as a positive definite volume measure on $\mathscr{M}$. We shall often use it in this sense, and shall denote it by dv. Note that d is not meant to represent the exterior differential operator here; dv is simply a measure on $\mathscr{M}$. If f is a function on $\mathscr{M}$, one can define its integral over $\mathscr{U}$ with respect to this volume measure as

$$\int_{\mathscr{U}} f\,\mathrm{d}v = \frac{1}{n!}\int_{\mathscr{U}} f\,\boldsymbol{\eta}.$$

With respect to local oriented coordinates $\{x^a\}$, this can be expressed as the multiple integral

$$\int_{\mathscr{U}} f\,|g|^{\frac{1}{2}}\,\mathrm{d}x^1\,\mathrm{d}x^2 \dots \mathrm{d}x^n,$$

which is invariant under a change of coordinates.

If $\mathbf{X}$ is a vector field on $\mathscr{M}$, its contraction with $\boldsymbol{\eta}$ will be an $(n-1)$-form field $\mathbf{X}\,.\,\boldsymbol{\eta}$, where

$$(\mathbf{X}\,.\,\boldsymbol{\eta})_{b\dots d} = X^a \eta_{ab\dots d}.$$

This $(n-1)$-form may be integrated over any $(n-1)$-dimensional compact orientable submanifold $\mathscr{V}$. We write this integral as

$$\int_{\mathscr{V}} X^a \mathrm{d}\sigma_a = \frac{1}{(n-1)!}\int_{\mathscr{V}} \mathbf{X}\,.\,\boldsymbol{\eta},$$

where the canonical form $\boldsymbol{\eta}$ is regarded as defining a measure-valued form $\mathrm{d}\sigma_a$ on the submanifold $\mathscr{V}$. If the orientation of $\mathscr{V}$ is given by the direction of the normal form n_a, then $\mathrm{d}\sigma_a$ can be expressed as $n_a \mathrm{d}\sigma$ where $\mathrm{d}\sigma$ is a positive definite volume measure on the submanifold $\mathscr{V}$. The volume measure $\mathrm{d}\sigma$ is not unique unless the normal n_a is normalized. If n_a is normalized to unit magnitude in a metric $\mathbf{g}$ on $\mathscr{M}$, i.e. $n_a n_b g^{ab} = \pm 1$, then $\mathrm{d}\sigma$ is equal to the volume measure on $\mathscr{V}$ defined by the induced metric on $\mathscr{V}$ (to see this, simply choose an orthonormal basis with $n_a g^{ab}$ as one of the basis vectors).

Using the canonical form, one can derive Gauss' formula from Stokes' theorem: for any compact n-dimensional submanifold $\mathscr{U}$ of $\mathscr{M}$,

$$\int_{\partial\mathscr{U}} X^a \mathrm{d}\sigma_a = \frac{1}{(n-1)!}\int_{\partial\mathscr{U}} \mathbf{X}\,.\,\boldsymbol{\eta} = \frac{1}{(n-1)!}\int_{\mathscr{U}} \mathrm{d}(\mathbf{X}\,.\,\boldsymbol{\eta}).$$

But

$$\begin{aligned}(\mathrm{d}(\mathbf{X}\,.\,\boldsymbol{\eta}))_{a\dots de} &= (-)^{n-1}(X^g \eta_{g[a\dots d})_{;e]} \\ &= (-)^{n-1}\delta^s{}_{[a}\dots\delta^t{}_d\,\delta^u{}_{e]}\,\eta_{gs\dots t}X^g{}_{;u} \\ &= (-)^{(n-1)-\frac{1}{2}(n-s)}\frac{1}{n!}\eta^{s\dots tu}\eta_{a\dots de}\eta_{gs\dots t}X^g{}_{;u} \\ &= \eta_{a\dots de}\,\delta^s{}_{[s}\dots\delta^t{}_t\,\delta^u{}_{g]}X^g{}_{;u} \\ &= n^{-1}\eta_{a\dots de}X^g{}_{;g},\end{aligned}$$

on using relation (2.37) twice. Therefore

$$\int_{\partial\mathscr{U}} X^a\,\mathrm{d}\sigma_a = \int_{\mathscr{U}} X^g{}_{;g}\,\mathrm{d}v$$

holds for any vector field $\mathbf{X}$; this is Gauss' theorem. Note that the orientation on $\mathscr{U}$ for which this theorem is valid is that given by the normal form $\boldsymbol{\eta}$ such that $\langle \mathbf{n}, \mathbf{X} \rangle$ is positive if $\mathbf{X}$ is a vector which points out of $\mathscr{U}$. If the metric $\mathbf{g}$ is such that $g^{ab}n_a n_b$ is negative, the vector $g^{ab}n_b$ will point into $\mathscr{U}$.

2.9 Fibre bundles

Some of the geometrical properties of a manifold $\mathscr{M}$ can be most easily examined by constructing a manifold called a fibre bundle, which is locally a direct product of $\mathscr{M}$ and a suitable space. In this section we shall give the definition of a fibre bundle and shall consider four examples that will be used later: the tangent bundle $T(\mathscr{M})$, the tensor bundle $T^r_s(\mathscr{M})$, the bundle of linear frames or bases $L(\mathscr{M})$, and the bundle of orthonormal frames $O(\mathscr{M})$.

A C^k *bundle* over a C^s ($s \geqslant k$) manifold $\mathscr{M}$ is a C^k manifold $\mathscr{E}$ and a C^k surjective map $\pi: \mathscr{E} \to \mathscr{M}$. The manifold $\mathscr{E}$ is called the total space, $\mathscr{M}$ is called the base space and π the projection. Where no confusion can arise, we will denote the bundle simply by $\mathscr{E}$. In general, the inverse image $\pi^{-1}(p)$ of a point $p \in \mathscr{M}$ need not be homeomorphic to $\pi^{-1}(q)$ for another point $q \in \mathscr{M}$. The simplest example of a bundle is a *product bundle* $(\mathscr{M} \times \mathscr{A}, \mathscr{M}, \pi)$ where $\mathscr{A}$ is some manifold and the projection π is defined by $\pi(p, v) = p$ for all $p \in \mathscr{M}$, $v \in \mathscr{A}$. For example, if one chooses $\mathscr{M}$ as the circle S^1 and $\mathscr{A}$ as the real line R^1, one constructs the cylinder C^2 as a product bundle over S^1.

A bundle which is locally a product bundle is called a fibre bundle. Thus a bundle is a *fibre bundle* with fibre $\mathscr{F}$ if there exists a neighbourhood $\mathscr{U}$ of each point q of $\mathscr{M}$ such that $\pi^{-1}(\mathscr{U})$ is isomorphic with $\mathscr{U} \times \mathscr{F}$, in the sense that for each point $p \in \mathscr{U}$ there is a diffeomorphism ϕ_p of $\pi^{-1}(p)$ onto $\mathscr{F}$ such that the map ψ defined by $\psi(u) = (\pi(u), \phi_{\pi(u)})$ is a diffeomorphism $\psi: \pi^{-1}(\mathscr{U}) \to \mathscr{U} \times \mathscr{F}$. Since $\mathscr{M}$ is paracompact, we can choose a locally finite covering of $\mathscr{M}$ by such open sets $\mathscr{U}_\alpha$. If $\mathscr{U}_\alpha$ and $\mathscr{U}_\beta$ are two members of such a covering, the map

$$(\phi_{\alpha, p}) \circ (\phi_{\beta, p}{}^{-1})$$

is a diffeomorphism of $\mathscr{F}$ onto itself for each $p \in (\mathscr{U}_\alpha \cap \mathscr{U}_\beta)$. The inverse images $\pi^{-1}(p)$ of points $p \in \mathscr{M}$ are therefore necessarily all diffeomorphic to $\mathscr{F}$ (and so to each other). For example, the Möbius strip is a fibre bundle over S^1 with fibre R^1; we need two open sets $\mathscr{U}_1$, $\mathscr{U}_2$

4

The physical significance of curvature

In this chapter we consider the effect of space–time curvature on families of timelike and null curves. These could represent flow lines of fluids or the histories of photons. In § 4.1 and § 4.2 we derive the formulae for the rate of change of vorticity, shear and expansion of such families of curves; the equation for the rate of change of expansion (Raychaudhuri's equation) plays a central role in the proofs of the singularity theorems of chapter 8. In § 4.3 we discuss the general inequalities on the energy–momentum tensor which imply that the gravitational effect of matter is always to tend to cause convergence of timelike and of null curves. A consequence of these energy conditions is, as is seen in § 4.4, that conjugate or focal points will occur in families of non-rotating timelike or null geodesics in general space–times. In § 4.5 it is shown that the existence of conjugate points implies the existence of variations of curves between two points which take a null geodesic into a timelike curve, or a timelike geodesic into a longer timelike curve.

4.1 Timelike curves

In chapter 3 we saw that if the metric was static there was a relation between the magnitude of the timelike Killing vector and the Newtonian potential. One was able to tell whether a body was in a gravitational field by whether, if released from rest, it would accelerate with respect to the static frame defined by the Killing vector. However, in general, space–time will not have any Killing vectors. Thus one will not have any special frame against which to measure acceleration; the best one can do is to take two bodies close together and measure their relative acceleration. This will enable one to measure the gradient of the gravitational field. If one thinks of the metric as being analogous to the Newtonian potential, the gradient of the Newtonian field would correspond to the second derivatives of the metric. These are described by the Riemann tensor. Thus one would expect that the relative acceleration of two neighbouring bodies would be related to some components of the Riemann tensor.

In order to investigate this relation more precisely we shall examine the behaviour of a congruence of timelike curves with timelike unit tangent vector **V** ($g(\mathbf{V},\mathbf{V}) = -1$). These curves could represent the histories of small test particles, in which case they would be geodesics, or they might represent the flow lines of a fluid. If this were a perfect fluid, then by (3.10)

$$(\mu+p)\dot{V}^a = -p_{;b}h^{ab}, \tag{4.1}$$

where $\dot{V}^a = V^a{}_{;b}V^b$ is the acceleration of the flow lines and $h^a{}_b = \delta^a{}_b + V^aV_b$ is the tensor which projects a vector $\mathbf{X}\in T_q$ into its component in the subspace H_q of T_q orthogonal to V. One may also think of h_{ab} as the metric in H_q (cf. §2.7).

Suppose $\lambda(t)$ is a curve with tangent vector $\mathbf{Z} = (\partial/\partial t)_\lambda$. Then one may construct a family $\lambda(t,s)$ of curves by moving each point of the curve $\lambda(t)$ a distance s along the integral curves of **V**. If one now defines **Z** as $(\partial/\partial t)_{\lambda(t,s)}$ it follows from the definition of the Lie derivative (see §2.4) that $L_\mathbf{V}\mathbf{Z} = 0$ or in other words that

$$\frac{\mathrm{D}}{\partial s}Z^a = V^a{}_{;b}Z^b. \tag{4.2}$$

One may interpret **Z** as representing the separation of points equal distances from some arbitrary initial points along two neighbouring curves. If one adds a multiple of **V** to **Z** then this vector will represent the separation of points on the same two curves but at different distances along the curves. It is really only the separation of neighbouring curves that one is interested in, not the separation of particular points on these curves. One is thus concerned only with **Z** modulo a component parallel to **V**, i.e. only with the projection of **Z** at each point q into the space Q_q consisting of equivalence classes of vectors which differ only by addition of a multiple of **V**. This space can be represented as the subspace H_q of T_q consisting of vectors orthogonal to **V**. The projection of **Z** into H_q will be denoted by ${}_\perp Z^a = h^a{}_b Z^b$. In the case of a fluid one can regard ${}_\perp\mathbf{Z}$ as the distance between two neighbouring particles of the fluid as measured in their rest frame.

From (4.2) it follows that

$${}_\perp\frac{\mathrm{D}}{\partial s}({}_\perp Z^a) = V^a{}_{;b}\,{}_\perp Z^b. \tag{4.3}$$

This gives the rate of change of the separation of two infinitesimally neighbouring curves as measured in H_q. Operating again with $\mathrm{D}/\partial s$ and projecting into H_q, one finds

$$h^a{}_b \frac{\mathrm{D}}{\partial s}\left(h^b{}_c \frac{\mathrm{D}}{\partial s}{}_\perp Z^c\right) = h^a{}_b(V^b{}_{;cd\,\perp}Z^c V^d + V^b{}_{;c}V^c{}_{;d}V_e Z^e V^d$$
$$+ V^b{}_{;c}V^c V^e{}_{;d}Z_e V^d + V^b{}_{;c}h^c{}_e Z^e{}_{;d}V^d).$$

Changing the order of the derivatives in the first term and using (4.2), this reduces to

$$h^a{}_b \frac{\mathrm{D}}{\partial s}\left(h^b{}_c \frac{\mathrm{D}}{\partial s}{}_\perp Z^c\right) = -R^a{}_{bcd\,\perp}Z^c V^b V^d + h^a{}_b \dot{V}^b{}_{;c\,\perp}Z^c + \dot{V}^a \dot{V}_{b\,\perp}Z^b. \quad (4.4)$$

This equation, known as the deviation or Jacobi equation, gives the relative acceleration, i.e. the second time derivative of the separation, of two infinitesimally neighbouring curves as measured in H_q. We see that this depends only on the Riemann tensor if the curves are geodesics.

In Newtonian theory, the acceleration of each particle is given by the gradient of the potential Φ and therefore the relative acceleration of two particles with separation Z^a is $\Phi_{;ab}Z^b$. Thus the Riemann tensor term $R_{abcd}V^b V^d$ is analogous to the Newtonian $\Phi_{;ac}$. The effect of this 'tidal force' term can be seen, for example, by considering a sphere of particles freely falling towards the earth. Each particle moves on a straight line through the centre of the earth but those nearer the earth fall faster than those further away. This means that the sphere does not remain a sphere but is distorted into an ellipsoid with the same volume.

In order to investigate the deviation equation further we shall introduce dual orthonormal bases $\mathbf{E}_1$, $\mathbf{E}_2$, $\mathbf{E}_2$, $\mathbf{E}_4$ and $\mathbf{E}^1$, $\mathbf{E}^2$, $\mathbf{E}^3$, $\mathbf{E}^4$ of T_q and $T^*{}_q$ at some point q on an integral curve $\gamma(s)$ of $\mathbf{V}$, with $\mathbf{E}^4 = \mathbf{V}$. One would like to propagate them along $\gamma(s)$ to obtain similar such bases at each point of $\gamma(s)$. However, if one parallelly propagates them along $\gamma(s)$ (i.e. so that $\mathrm{D}/\partial s$ of each vector is zero) $\mathbf{E}_4$ will not remain equal to $\mathbf{V}$, and $\mathbf{E}_1$, $\mathbf{E}_2$, $\mathbf{E}_3$ will not remain orthogonal to $\mathbf{V}$, unless $\gamma(s)$ is a geodesic. We therefore introduce a new derivative along $\gamma(s)$ called the *Fermi derivative* $\mathrm{D_F}/\partial s$. This is defined for a vector field $\mathbf{X}$ along $\gamma(s)$ by:

$$\frac{\mathrm{D_F}\mathbf{X}}{\partial s} = \frac{\mathrm{D}\mathbf{X}}{\partial s} - g\left(\mathbf{X}, \frac{\mathrm{D}\mathbf{V}}{\partial s}\right)\mathbf{V} + g(\mathbf{X}, \mathbf{V})\frac{\mathrm{D}\mathbf{V}}{\partial s}.$$

It has the properties:

(i) $\dfrac{\mathrm{D_F}}{\partial s} = \dfrac{\mathrm{D}}{\partial s}$ if $\gamma(s)$ is a geodesic;

(ii) $\dfrac{\mathrm{D_F}\mathbf{V}}{\partial s} = 0$;

(iii) if $\mathbf{X}$ and $\mathbf{Y}$ are vector fields along $\gamma(s)$ such that

$$\frac{\mathrm{D_F}\mathbf{X}}{\partial s} = 0 = \frac{\mathrm{D_F}\mathbf{Y}}{\partial s},$$

then $g(\mathbf{X}, \mathbf{Y})$ is constant along $\gamma(s)$;

(iv) if $\mathbf{X}$ is a vector field along $\gamma(s)$ orthogonal to $\mathbf{V}$ then

$$\frac{\mathrm{D_F}\mathbf{X}}{\partial s} = {}_\perp\!\left(\frac{\mathrm{D}\mathbf{X}}{\partial s}\right).$$

(This last property shows that the Fermi derivative is a natural generalization of the derivative $\mathrm{D}/\partial s$.)

Thus, if one propagates an orthonormal basis of T_q along $\gamma(s)$ so that the Fermi derivative of each basis vector is zero, one obtains an orthonormal basis at each point of $\gamma(s)$, with $\mathbf{E}_4 = \mathbf{V}$. The vectors $\mathbf{E}_1$, $\mathbf{E}_2$, $\mathbf{E}_2$ may be interpreted as giving a non-rotating set of axes along $\gamma(s)$. These could be realized physically by small gyroscopes pointing in the direction of each vector.

The definition of the Fermi derivative along $\gamma(s)$ can be extended from vector fields to arbitrary tensor fields by the usual rules:

(i) $\mathrm{D_F}/\partial s$ is a linear mapping of tensor fields of type (r, s) along $\gamma(s)$ to tensor fields of type (r, s), which commutes with contractions;

(ii) $\dfrac{\mathrm{D_F}}{\partial s}(\mathbf{K}\otimes\mathbf{L}) = \dfrac{\mathrm{D_F}\mathbf{K}}{\partial s}\otimes\mathbf{L} + \mathbf{K}\otimes\dfrac{\mathrm{D_F}\mathbf{L}}{\partial s}$;

(iii) $\dfrac{\mathrm{D_F}f}{\partial s} = \dfrac{\mathrm{d}f}{\mathrm{d}s}$, where f is a function.

From these rules it follows that the dual basis $\mathbf{E}^1$, $\mathbf{E}^2$, $\mathbf{E}^3$, $\mathbf{E}^4$ of $T^*{}_q$ is also Fermi-propagated along $\gamma(s)$. Using Fermi derivatives, (4.3) and (4.4) may be written as:

$$\frac{\mathrm{D_F}}{\partial s}\,{}_\perp Z^a = V^a{}_{;b}\,{}_\perp Z^b, \tag{4.5}$$

$$\frac{\mathrm{D^2{}_F}}{\partial s^2}\,{}_\perp Z^a = -R^a{}_{bcd}\,{}_\perp Z^c V^b V^d + h^a{}_b \dot{V}^b{}_{;c}\,{}_\perp Z^c + \dot{V}^a \dot{V}_b\,{}_\perp Z^b. \tag{4.6}$$

One may express these equations in terms of the Fermi-propagated dual bases. As $\perp\mathbf{Z}$ is orthogonal to $\mathbf{V}$ it will have components with respect to $\mathbf{E}_1$, $\mathbf{E}_2$, $\mathbf{E}_2$ only. Thus it may be expressed as $Z^\alpha \mathbf{E}_\alpha$ where we adopt the convention that Greek indices take the values 1, 2, 3 only. Then (4.5) and (4.6) can be written in terms of ordinary derivatives:

$$\frac{\mathrm{d}}{\mathrm{d}s} Z^\alpha = V^\alpha{}_{;\beta} Z^\beta, \tag{4.7}$$

$$\frac{\mathrm{d}^2}{\mathrm{d}s^2} Z^\alpha = (-R^\alpha{}_{4\beta4} + \dot{V}^\alpha{}_{;\beta} + \dot{V}^\alpha \dot{V}_\beta)\, Z^\beta \tag{4.8}$$

where $V^\alpha{}_{;\beta}$ are the components of $V^a{}_{;b}$ for which $a = \alpha$ and $b = \beta$. As the components Z^α obey the first order linear ordinary differential equation (4.7), they can be expressed in terms of their values at some point q by:

$$Z^\alpha(s) = A_{\alpha\beta}(s)\, Z^\beta|_q, \tag{4.9}$$

where $A_{\alpha\beta}(s)$ is a 3×3 matrix which is the unit matrix at q and satisfies

$$\frac{\mathrm{d}}{\mathrm{d}s} A_{\alpha\beta}(s) = V_{\alpha;\gamma} A_{\gamma\beta}(s). \tag{4.10}$$

In the case of a fluid the matrix $A_{\alpha\beta}$ can be regarded as representing the shape and orientation of a small element of fluid which is spherical at q. This matrix can be written as

$$A_{\alpha\beta} = O_{\alpha\delta} S_{\delta\beta} \tag{4.11}$$

where $O_{\alpha\beta}$ is an orthogonal matrix with positive determinant and $S_{\alpha\beta}$ is a symmetric matrix. These will both be chosen to be the unit matrix at q. The matrix $O_{\alpha\beta}$ may be thought of as representing the rotation that neighbouring curves have undergone with respect to the Fermi-propagated basis while $S_{\alpha\beta}$ represents the separation of these curves from $\gamma(s)$. The determinant of $S_{\alpha\beta}$, which equals the determinant of $A_{\alpha\beta}$, may be thought of as representing the three-volume of the element of the surface orthogonal to $\gamma(s)$ marked out by the neighbouring curves.

At q where $A_{\alpha\beta}$ is the unit matrix, $\mathrm{d}O_{\alpha\beta}/\mathrm{d}s$ is antisymmetric and $\mathrm{d}S_{\alpha\beta}/\mathrm{d}s$ is symmetric. Thus the rate of rotation of neighbouring curves at q is given by the antisymmetric part of $V_{\alpha;\beta}$ while the rate of change of their separation from $\gamma(s)$ is given by the symmetric part of $V_{\alpha;\beta}$ and the rate of change of volume is given by the trace of $V_{\alpha;\beta}$. We therefore define the vorticity tensor as

$$\omega_{ab} = h_a{}^c h_b{}^d V_{[c;d]}, \tag{4.12}$$

the expansion tensor as

$$\theta_{ab} = h_a{}^c h_b{}^d V_{(c;d)}, \tag{4.13}$$

and the volume expansion as

$$\theta = \theta_{ab}h^{ab} = V_{a;\,b}h^{ab} = V^{a}{}_{;\,a}. \tag{4.14}$$

We further define the shear tensor as the trace free part of θ_{ab},

$$\sigma_{ab} = \theta_{ab} - \tfrac{1}{3}h_{ab}\theta, \tag{4.15}$$

and the vorticity vector as

$$\omega^{a} = \tfrac{1}{2}\eta^{abcd}V_{b}\omega_{cd} = \tfrac{1}{2}\eta^{abcd}V_{b}V_{c;\,d}. \tag{4.16}$$

The covariant derivative of the vector V may be expressed in terms of these quantities;

$$V_{a;\,b} = \omega_{ab} + \sigma_{ab} + \tfrac{1}{3}\theta h_{ab} - \dot{V}_{a}V_{b}. \tag{4.17}$$

This decomposition of the gradient of the fluid velocity vector is directly analogous to that in Newtonian hydrodynamics.

In the Fermi-propagated orthonormal basis the vorticity and expansion can be expressed in terms of the matrix $A_{\alpha\beta}$ and its inverse $A^{-1}{}_{\alpha\beta}$:

$$\omega_{\alpha\beta} = -A^{-1}{}_{\gamma[\alpha}\frac{\mathrm{d}}{\mathrm{d}s}A_{\beta]\gamma}, \tag{4.18}$$

$$\theta_{\alpha\beta} = A^{-1}{}_{\gamma(\alpha}\frac{\mathrm{d}}{\mathrm{d}s}A_{\beta)\gamma}, \tag{4.19}$$

$$\theta = (\det \mathrm{A})^{-1}\frac{\mathrm{d}}{\mathrm{d}s}(\det \mathrm{A}). \tag{4.20}$$

From the deviation equation (4.8) it follows that

$$\frac{\mathrm{d}^{2}}{\mathrm{d}s^{2}}A_{\alpha\beta} = (-R_{\alpha4\gamma4} + \dot{V}_{\alpha;\,\gamma} + \dot{V}_{\alpha}\dot{V}_{\gamma})A_{\gamma\beta}. \tag{4.21}$$

This equation enables one to calculate the propagation of the vorticity, shear and expansion along the integral curves of V if one knows the Riemann tensor.

Multiplying by $A^{-1}{}_{\beta\gamma}$ and taking the antisymmetric part, one obtains

$$\frac{\mathrm{d}}{\mathrm{d}s}\omega_{\alpha\beta} = 2\omega_{\gamma[\alpha}\theta_{\beta]\gamma} + \dot{V}_{[\alpha;\,\beta]}. \tag{4.22}$$

Thus the propagation of vorticity depends on the antisymmetric gradient of the acceleration but not the 'tidal force'. Another form of the above equation is

$$\frac{\mathrm{d}}{\mathrm{d}s}(A_{\gamma\alpha}\omega_{\gamma\delta}A_{\delta\beta}) = A_{\gamma\alpha}\dot{V}_{[\gamma;\,\delta]}A_{\delta\beta}. \tag{4.23}$$

Therefore $A_{\gamma\alpha}\omega_{\gamma\delta}A_{\delta\beta}$ is a constant matrix if the curves are geodesics; in particular, if the curves are geodesics and the vorticity vanishes at one point on a curve, it will vanish at all points on the curve. If the curves are the flow lines of a perfect fluid it follows from (4.1) that

$$\dot{V}_{[\alpha;\beta]} = -\frac{1}{\mu+p}\omega_{\alpha\beta}\frac{\mathrm{d}p}{\mathrm{d}s}.$$

If the fluid is isentropic, this implies the conservation law:

$$WA_{\gamma\alpha}\omega_{\gamma\delta}A_{\delta\beta} = \text{constant}, \tag{4.24}$$

where

$$\log W = \int\frac{\mathrm{d}p}{\mu+p}.$$

This conservation law is the relativistic form of the Newtonian vorticity conservation law. In the geodesic or pressure-free case, this takes the usual form that the magnitude of the vorticity vector is inversely proportional to the area of a cross-section orthogonal to the vorticity vector of an element of the fluid. When the pressure is non-zero, there is an extra relativistic effect arising from the fact that compression of the fluid does work on the fluid and therefore increases the mass and so the inertia of an element of the fluid (cf. (3.9)). This means that the vorticity of a fluid increases less under compression than would otherwise be expected.

Multiplying (4.21) by ${A^{-1}}_{\beta\gamma}$ and taking the symmetric part, one finds

$$\frac{\mathrm{d}}{\mathrm{d}s}\theta_{\alpha\beta} = -R_{\alpha4\beta4}-\omega_{\alpha\gamma}\omega_{\gamma\beta}-\theta_{\alpha\gamma}\theta_{\gamma\beta}+\dot{V}_{(\alpha;\beta)}+\dot{V}_{\alpha}\dot{V}_{\beta}. \tag{4.25}$$

(This equation and (4.23) can be expressed in terms of a general, non-orthonormal, non-Fermi-propagated basis by replacing the ordinary derivatives with Fermi derivatives and projecting everything into the subspace orthogonal to **V**.)

The trace of (4.25) is

$$\frac{\mathrm{d}}{\mathrm{d}s}\theta = -R_{ab}V^aV^b+2\omega^2-2\sigma^2-\tfrac{1}{3}\theta^2+{\dot{V}^a}_{;a}, \tag{4.26}$$

where

$$2\omega^2 = \omega_{ab}\omega^{ab} \geqslant 0,$$

$$2\sigma^2 = \sigma_{ab}\sigma^{ab} \geqslant 0.$$

This equation, which was discovered by Landau and independently by Raychaudhuri, will be of great importance later. From it one sees that vorticity induces expansion as might be expected by analogy with centrifugal force while shear induces contraction. By the field equations, the term $R_{ab}V^aV^b = 4\pi(\mu+3p)$ for a perfect fluid whose flow lines have tangent vectors V^a. Thus one would expect this term also to induce contraction. We shall give a general discussion of the sign of this term in §4.3.

The trace-free part of (4.25) is

$$\frac{\mathrm{D_F}}{\partial s}\sigma_{ab} = -C_{acbd}V^cV^d + \tfrac{1}{2}h_a{}^c h_b{}^d R_{cd} - \omega_{ac}\omega^c{}_b - \sigma_{ac}\sigma^c{}_b$$
$$-\tfrac{2}{3}\theta\sigma_{ab} + h_a{}^c h_b{}^d \dot{V}_{(c;d)} - \tfrac{1}{3}h_{ab}(2\omega^2 - 2\sigma^2 + \dot{V}^a{}_{;a} + \tfrac{1}{2}R_{cd}h^{cd}), \quad (4.27)$$

where C_{abcd} is the Weyl tensor. Since this tensor is trace-free it does not enter directly in the expansion equation (4.26). However since the term $-2\sigma^2$ occurs on the right of the expansion equation, the Weyl tensor produces convergence indirectly by inducing shear. The Riemann tensor can be expressed in terms of the Weyl tensor and the Ricci tensor:

$$R_{abcd} = C_{abcd} - g_{a[d}R_{c]b} - g_{b[c}R_{d]a} - \tfrac{1}{3}Rg_{a[c}g_{d]b}.$$

The Ricci tensor is given by the Einstein equations:

$$R_{ab} - \tfrac{1}{2}g_{ab}R + \Lambda g_{ab} = 8\pi T_{ab}.$$

Thus the Weyl tensor is that part of the curvature which is not determined locally by the matter distribution. However it cannot be entirely arbitrary as the Riemann tensor must satisfy the Bianchi identities:

$$R_{ab[cd;e]} = 0$$

These can be rewritten as

$$C^{abcd}{}_{;d} = J^{abc}, \quad (4.28)$$

where
$$J^{abc} = R^{c[a;b]} + \tfrac{1}{6}g^{c[b}R^{;a]}. \quad (4.29)$$

These equations are rather similar to Maxwell's equations in electrodynamics:

$$F^{ab}{}_{;b} = J^a,$$

where F^{ab} is the electromagnetic field tensor and J^a is the source current. Thus in a sense one could regard the Bianchi identities (4.28) as field equations for the Weyl tensor giving that part of the curvature at a point that depends on the matter distribution at other points. (This approach has been used to analyse the behaviour of gravitational radiation in papers by Newman and Penrose (1962), Newman and Unti (1962) and Hawking (1966*a*).)

5

Exact solutions

Any space–time metric can in a sense be regarded as satisfying Einstein's field equations

$$R_{ab} - \tfrac{1}{2}Rg_{ab} + \Lambda g_{ab} = 8\pi T_{ab}, \tag{5.1}$$

(where we use the units of chapter 3), because, having determined the left-hand side of (5.1) from the metric tensor of the space–time $(\mathcal{M}, \mathbf{g})$, one can *define* T_{ab} as the right-hand side of (5.1). The matter tensor so defined will in general have unreasonable physical properties; the solution will be reasonable only if the matter content is reasonable.

We shall mean by an *exact solution* of Einstein's equations, a space–time $(\mathcal{M}, \mathbf{g})$ in which the field equations are satisfied with T_{ab} the energy–momentum tensor of some specified form of matter which obeys postulate (*a*) ('local causality') of chapter 3, and one of the energy conditions of §4.3. In particular, one may look for exact solutions for empty space ($T_{ab} = 0$), for an electromagnetic field (T_{ab} has the form (3.7)), for a perfect fluid (T_{ab} has the form (3.8)), or for a space containing an electromagnetic field and a perfect fluid. Because of the complexity of the field equations, one cannot find exact solutions except in spaces of rather high symmetry. Exact solutions are also idealized in that any region of space–time is likely to contain many forms of matter, while one can obtain exact solutions only for rather simple matter content. Nevertheless, exact solutions give an idea of the qualitative features that can arise in General Relativity, and so of possible properties of realistic solutions of the field equations. The examples we give will show many types of behaviour which will be of interest in later chapters. We shall discuss solutions with particular reference to their global properties. Many of these global properties have only recently been discovered, although the solutions have been known in a local form for some time.

In § 5.1 and § 5.2 we consider the simplest Lorentz metrics: those of constant curvature. The spatially isotropic and homogeneous cosmological models are described in § 5.3, and their simplest anisotropic generalizations are discussed in § 5.4. It is shown that all such simple models will have a singular origin provided that Λ does not take large positive values. The spherically symmetric metrics which describe the field outside a massive charged or neutral body are examined in § 5.5, and the axially symmetric metrics describing the field outside a special class of massive rotating bodies are described in § 5.6. It is shown that some of the apparent singularities are simply due to a bad choice of coordinates. In § 5.7 we describe the Gödel universe and in § 5.8 the Taub–NUT solutions. These probably do not represent the actual universe but they are of interest because of their pathological global properties. Finally some other exact solutions of interest are mentioned in § 5.9.

5.1 Minkowski space–time

Minkowski space–time $(\mathscr{M}, \eta)$ is the simplest empty space–time in General Relativity, and is in fact the space–time of Special Relativity. Mathematically, it is the manifold R^4 with a flat Lorentz metric η. In terms of the natural coordinates (x^1, x^2, x^3, x^4) on R^4, the metric η can be expressed in the form

$$ds^2 = -(dx^4)^2 + (dx^1)^2 + (dx^2)^2 + (dx^3)^2. \tag{5.2}$$

If one uses spherical polar coordinates (t, r, θ, ϕ) where $x^4 = t$, $x^3 = r\cos\theta$, $x^2 = r\sin\theta\cos\phi$, $x^1 = r\sin\theta\sin\phi$, the metric takes the form

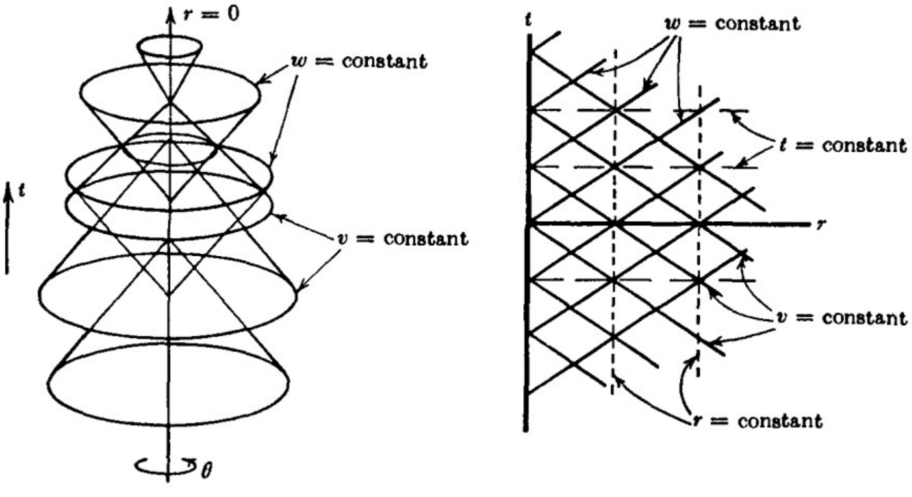
$$ds^2 = -dt^2 + dr^2 + r^2(d\theta^2 + \sin^2\theta\, d\phi^2). \tag{5.3}$$

This metric is apparently singular for $r = 0$ and $\sin\theta = 0$; however this is because the coordinates used are not admissible coordinates at these points. To obtain regular coordinate neighbourhoods one has to restrict the coordinates, e.g. to the ranges $0 < r < \infty$, $0 < \theta < \pi$, $0 < \phi < 2\pi$. One needs two such coordinate neighbourhoods to cover the whole of Minkowski space.

An alternative coordinate system is given by choosing advanced and retarded null coordinates v, w defined by $v = t + r$, $w = t - r$ $(\Rightarrow v \geqslant w)$. The metric becomes

$$ds^2 = -dv\, dw + \tfrac{1}{4}(v-w)^2 (d\theta^2 + \sin^2\theta\, d\phi^2), \tag{5.4}$$

where $-\infty < v < \infty$, $-\infty < w < \infty$. The absence in the metric of terms in dv^2, dw^2 corresponds to the fact that the surfaces $\{w = \text{constant}\}$, $\{v = \text{constant}\}$ are null (i.e. $w_{;a} w_{;b} g^{ab} = 0 = v_{;a} v_{;b} g^{ab}$); see figure 12.



(i) (ii)

FIGURE 12. Minkowski space. The null coordinate $v(w)$ may be thought of as incoming (outgoing) spherical waves travelling at the speed of light; they are advanced (retarded) time coordinates. The intersection of a surface $\{v = \text{constant}\}$ with a surface $\{w = \text{constant}\}$ is a two-sphere.
(i) The v, w coordinate surfaces (one coordinate is suppressed).
(ii) The (t, r) plane; each point represents a two-sphere of radius r.

In a coordinate system in which the metric takes the form (5.2), the geodesics have the form $x^a(v) = b^a v + c^a$ where b^a and c^a are constants. Thus the exponential map $\exp_p\colon T_p \to \mathscr{M}$ is given by

$$x^a(\exp_p \mathbf{X}) = X^a + x^a(p),$$

where X^a are the components of $\mathbf{X}$ with respect to the coordinate basis $\{\partial/\partial x^a\}$ of T_p. Since exp is one–one and onto, it is a diffeomorphism between T_p and $\mathscr{M}$. Thus any two points of $\mathscr{M}$ can be joined by a unique geodesic curve. As exp is defined everywhere on T_p for all p, $(\mathscr{M}, \eta)$ is geodesically complete.

For a spacelike three-surface $\mathscr{S}$, the future (past) Cauchy development $D^+(\mathscr{S})$ $(D^-(\mathscr{S}))$ is defined as the set of all points $q \in \mathscr{M}$ such that each past-directed (future-directed) inextendible non-spacelike curve through q intersects $\mathscr{S}$, cf. § 6.5. If $D^+(\mathscr{S}) \cup D^-(\mathscr{S}) = \mathscr{M}$, i.e. if every inextendible non-spacelike curve in $\mathscr{M}$ intersects $\mathscr{S}$, then $\mathscr{S}$ is said to be a Cauchy surface. In Minkowski space–time, the surfaces $\{x^4 = \text{constant}\}$ are a family of Cauchy surfaces which cover the whole of $\mathscr{M}$. One can however find inextendible spacelike surfaces which are not Cauchy surfaces; for example the surfaces

$$\mathscr{S}_\sigma\colon \{-(x^4)^2 + (x^1)^2 + (x^2)^2 + (x^3)^2 = \sigma = \text{constant}\},$$

where $\sigma < 0, x^4 < 0$, are spacelike surfaces which lie entirely inside the past null cone of the origin O, and so are not Cauchy surfaces (see figure 13). In fact the future Cauchy development of $\mathscr{S}_\sigma$ is the region bounded by $\mathscr{S}_\sigma$ and the past light cone of the origin. By lemma 4.5.2, the timelike geodesics through the origin O are orthogonal to the surfaces $\mathscr{S}_\sigma$. If $r \in D^+(\mathscr{S}_\sigma) \cup D^-(\mathscr{S}_\sigma)$ then the timelike geodesic through r and O is the longest timelike curve between r and $\mathscr{S}_\sigma$. If however r does not lie in $D^+(\mathscr{S}_\sigma) \cup D^-(\mathscr{S}_\sigma)$ there is no longest timelike curve between r and $\mathscr{S}_\sigma$: either r lies in the region $\sigma \geqslant 0$, in which case there is no timelike geodesic through r orthogonal to $\mathscr{S}_\sigma$, or r lies in the region $\sigma < 0$, $x^4 \geqslant 0$, in which case there is a timelike geodesic through r orthogonal to $\mathscr{S}_\sigma$ but this geodesic is not the longest curve between r and $\mathscr{S}_\sigma$ as it contains a conjugate point to $\mathscr{S}_\sigma$ at O (cf. figure 13).

FIGURE 13. A Cauchy surface $\{x^4 = \text{constant}\}$ in Minkowski space-time, and spacelike surfaces $\mathscr{S}_\sigma, \mathscr{S}_{\sigma'}$ which are not Cauchy surfaces. The normal geodesics to the surfaces $\mathscr{S}_\sigma, \mathscr{S}_{\sigma'}$ all intersect at O.

To study the structure of infinity in Minkowski space-time, we shall use the interesting representation of this space-time given by Penrose. From the null coordinates v, w, we define new null coordinates in which the infinities of v, w have been transformed to finite values; thus we define p, q by $\tan p = v$, $\tan q = w$ where $-\frac{1}{2}\pi < p < \frac{1}{2}\pi$, $-\frac{1}{2}\pi < q < \frac{1}{2}\pi$ (and $p \geqslant q$). Then the metric of $(\mathscr{M}, \boldsymbol{\eta})$ takes the form

$$\mathrm{d}s^2 = \sec^2 p \sec^2 q(-\mathrm{d}p\,\mathrm{d}q + \tfrac{1}{4}\sin^2(p-q)(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2)).$$

The physical metric $\boldsymbol{\eta}$ is therefore conformal to the metric $\bar{\mathbf{g}}$ given by

$$\mathrm{d}\bar{s}^2 = -4\mathrm{d}p\,\mathrm{d}q + \sin^2(p-q)(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2). \tag{5.5}$$

This metric can be reduced to a more usual form by defining

$$t' = p+q, \quad r' = p-q,$$

where
$$-\pi < t'+r' < \pi, \quad -\pi < t'-r' < \pi, \quad r' \geqslant 0; \tag{5.6}$$

(5.5) is then

$$\mathrm{d}\bar{s}^2 = -(\mathrm{d}t')^2 + (\mathrm{d}r')^2 + \sin^2 r'(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2). \tag{5.7}$$

Thus the whole of Minkowski space–time is given by the region (5.6) of the metric

$$\mathrm{d}s^2 = \tfrac{1}{4}\sec^2(\tfrac{1}{2}(t'+r'))\sec^2(\tfrac{1}{2}(t'-r'))\,\mathrm{d}\bar{s}^2$$

where $\mathrm{d}\bar{s}^2$ is determined by (5.7); the coordinates t, r of (5.3) are related to t', r' by

$$2t = \tan(\tfrac{1}{2}(t'+r')) + \tan(\tfrac{1}{2}(t'-r')),$$
$$2r = \tan(\tfrac{1}{2}(t'+r')) - \tan(\tfrac{1}{2}(t'-r')).$$

Now the metric (5.7) is locally identical to that of the Einstein static universe (see § 5.3), which is a completely homogeneous space–time. One can analytically extend (5.7) to the whole of the Einstein static universe, that is one can extend the coordinates to cover the manifold $R^1 \times S^3$ where $-\infty < t' < \infty$ and r', θ, ϕ are regarded as coordinates on S^3 (with coordinate singularities at $r' = 0$, $r' = \pi$ and $\theta = 0$, $\theta = \pi$ similar to the coordinate singularities in (5.3); these singularities can be removed by transforming to other local coordinates in a neighbourhood of points where (5.7) is singular). On suppressing two dimensions, one can represent the Einstein static universe as the cylinder $x^2+y^2 = 1$ imbedded in a three-dimensional Minkowski space with metric $\mathrm{d}s^2 = -\mathrm{d}t^2 + \mathrm{d}x^2 + \mathrm{d}y^2$ (the full Einstein static universe can be imbedded as the cylinder $x^2+y^2+z^2+w^2 = 1$ in a five-dimensional Euclidean space with metric $\mathrm{d}s^2 = -\mathrm{d}t^2 + \mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2 + \mathrm{d}w^2$, cf. Robertson (1933)).

One therefore has the situation: the whole of Minkowski space–time is conformal to the region (5.6) of the Einstein static universe, that is, to the shaded area in figure 14. The boundary of this region may therefore be thought of as representing the conformal structure of infinity of Minkowski space–time. It consists of the null surfaces $p = \frac{1}{2}\pi$ (labelled $\mathscr{I}^+$) and $q = -\frac{1}{2}\pi$ (labelled $\mathscr{I}^-$) together with points $p = \frac{1}{2}\pi$, $q = \frac{1}{2}\pi$ (labelled i^+), $p = \frac{1}{2}\pi$, $q = -\frac{1}{2}\pi$ (labelled i^0) and $p = -\frac{1}{2}\pi$, $q = -\frac{1}{2}\pi$ (labelled i^-). Any future-directed timelike geodesic in Minkowski space approaches i^+ (i^-) for indefinitely large positive (negative) values of its affine parameter, so one can regard any timelike geodesic as originating at i^- and finishing at i^+ (cf. figure 15(i)). Similarly one can regard null geodesics as originating at $\mathscr{I}^-$ and ending at $\mathscr{I}^+$, while spacelike geodesics both originate and end at i^0. Thus one may regard i^+ and i^- as representing future and past timelike infinity, $\mathscr{I}^+$ and $\mathscr{I}^-$ as representing future and past null infinity, and i^0 as representing spacelike infinity. (However non-geodesic curves do not

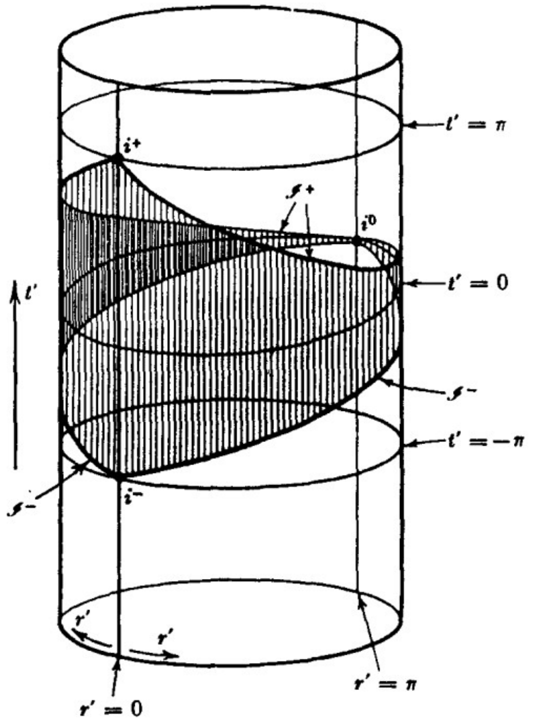

FIGURE 14. The Einstein static universe represented by an imbedded cylinder; the coordinates θ, ϕ have been suppressed. Each point represents one half of a two-sphere of area $4\pi \sin^2 r'$. The shaded region is conformal to the whole of Minkowski space–time; its boundary (part of the null cones of i^+, i^0 and i^-) may be regarded as the conformal infinity of Minkowski space–time.

obey these rules; e.g. non-geodesic timelike curves may start on $\mathscr{I}^-$ and end on $\mathscr{I}^+$.) Since any Cauchy surface intersects all timelike and null geodesics, it is clear that it will appear as a cross-section of the space everywhere reaching the boundary at i^0.

(ii) The Penrose diagram of Minkowski space–time; each point represents a two-sphere, except for i^+, i^0 and i^-, each of which is a single point, and points on the line $r = 0$ (where the polar coordinates are singular).

One can also represent the conformal structure of infinity by drawing a diagram of the (t', r') plane, see figure 15 (ii). As in figure 12 (ii), each point of this diagram represents a sphere S^2, and radial null geodesics are represented by straight lines at ± 45°. In fact, the structure of infinity in any spherically symmetric space–time can be represented by a diagram of this sort, which we shall call a *Penrose diagram*. On such diagrams we shall represent infinity by single lines, the origin of polar coordinates by dotted lines, and irremovable singularities of the metric by double lines.

The conformal structure of Minkowski space we have described is what one would regard as the 'normal' behaviour of a space–time at infinity; we shall encounter different types of behaviour in later sections.

Finally, we mention that one can obtain spaces locally identical to $(\mathscr{M}, \eta)$ but with different (large scale) topological properties by identifying points in $\mathscr{M}$ which are equivalent under a discrete isometry without a fixed point (e.g. identifying the point (x^1, x^2, x^3, x^4) with the point $(x^1, x^2, x^3, x^4 + c)$, where c is a constant, changes the topological structure from R^4 to $R^3 \times S^1$, and introduces closed timelike lines into the space–time). Clearly, $(\mathscr{M}, \eta)$ is the universal covering space for all such derived spaces, which have been studied in detail by Auslander and Markus (1958).

5.2 De Sitter and anti-de Sitter space–times

The space–time metrics of constant curvature are locally characterized by the condition $R_{abcd} = \frac{1}{12}R(g_{ac}g_{bd} - g_{ad}g_{bc})$. This equation is equivalent to $C_{abcd} = 0 = R_{ab} - \frac{1}{4}Rg_{ab}$; thus the Riemann tensor is determined by the Ricci scalar R alone. It follows at once from the contracted Bianchi identities that R is constant throughout space–time; in fact these space–times are homogeneous. The Einstein tensor is

$$R_{ab} - \tfrac{1}{2}Rg_{ab} = -\tfrac{1}{4}Rg_{ab}.$$

One can therefore regard these spaces as solutions of the field equations for an empty space with $\Lambda = \frac{1}{4}R$, or for a perfect fluid with a constant density $R/32\pi$ and a constant pressure $-R/32\pi$. However the latter choice does not seem reasonable, as in this case one cannot have both the density and the pressure positive; in addition, the equation of motion (3.10) is indeterminate for such a fluid.

The space of constant curvature with $R = 0$ is Minkowski space–time. The space for $R > 0$ is *de Sitter space–time*, which has the topology $R^1 \times S^3$ (see Schrödinger (1956) for an interesting account of this space). It is easiest visualized as the hyperboloid

$$-v^2 + w^2 + x^2 + y^2 + z^2 = \alpha^2$$

in flat five-dimensional space R^5 with metric

$$-\mathrm{d}v^2 + \mathrm{d}w^2 + \mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2 = \mathrm{d}s^2$$

(see figure 16). One can introduce coordinates (t, χ, θ, ϕ) on the hyperboloid by the relations

$$\alpha \sinh(\alpha^{-1}t) = v, \quad \alpha \cosh(\alpha^{-1}t) \cos\chi = w,$$

$$\alpha \cosh(\alpha^{-1}t) \sin\chi \cos\theta = x, \quad \alpha \cosh(\alpha^{-1}t) \sin\chi \sin\theta \cos\phi = y,$$

$$\alpha \cosh(\alpha^{-1}t) \sin\chi \sin\theta \sin\phi = z.$$

(i) (ii)

FIGURE 16. De Sitter space–time represented by a hyperboloid imbedded in a five-dimensional flat space (two dimensions are suppressed in the figure).

(i) Coordinates (t, χ, θ, ϕ) cover the whole hyperboloid; the sections $\{t = \text{constant}\}$ are surfaces of curvature $k = +1$.

(ii) Coordinates $(\hat{t}, \hat{x}, \hat{y}, \hat{z})$ cover half the hyperboloid; the surfaces $\{\hat{t} = \text{constant}\}$ are flat three-spaces, their geodesic normals diverging from a point in the infinite past.

In these coordinates, the metric has the form

$$ds^2 = -dt^2 + \alpha^2 . \cosh^2(\alpha^{-1}t) . \{d\chi^2 + \sin^2\chi(d\theta^2 + \sin^2\theta\, d\phi^2)\}.$$

The singularities in the metric at $\chi = 0$, $\chi = \pi$ and at $\theta = 0$, $\theta = \pi$, are simply those that occur with polar coordinates. Apart from these trivial singularities, the coordinates cover the whole space for $-\infty < t < \infty$, $0 \leqslant \chi \leqslant \pi$, $0 \leqslant \theta \leqslant \pi$, $0 \leqslant \phi \leqslant 2\pi$. The spatial sections of constant t are spheres S^3 of constant positive curvature and are Cauchy surfaces. Their geodesic normals are lines which contract monotonically to a minimum spatial separation and then re-expand to infinity (see figure 16 (i)).

One can also introduce coordinates

$$\hat{t} = \alpha \log \frac{w+v}{\alpha}, \quad \hat{x} = \frac{\alpha x}{w+v}, \quad \hat{y} = \frac{\alpha y}{w+v}, \quad \hat{z} = \frac{\alpha z}{w+v}$$

on the hyperboloid. In these coordinates, the metric takes the form

$$ds^2 = -d\hat{t}^2 + \exp(2\alpha^{-1}\hat{t})(d\hat{x}^2 + d\hat{y}^2 + d\hat{z}^2).$$

However these coordinates cover only half the hyperboloid as $\hat{t}$ is not defined for $w+v \leqslant 0$ (see figure 16 (ii)).

The region of de Sitter space for which $v+w > 0$ forms the space–time for the *steady state* model of the universe proposed by Bondi and Gold (1948) and Hoyle (1948). In this model, the matter is supposed to move along the geodesic normals to the surfaces $\{\hat{t} = \text{constant}\}$. As the matter moves further apart, it is assumed that more matter is continuously created to maintain the density at a constant value. Bondi and Gold did not seek to provide field equations for this model, but Pirani (1955), and Hoyle and Narlikar (1964) have pointed out that the metric can be considered as a solution of the Einstein equations (with $\Lambda = 0$) if in addition to the ordinary matter one introduces a scalar field of negative energy density. This 'C'-field would also be responsible for the continual creation of matter.

The steady state theory has the advantage of making simple and definite predictions. However from our point of view there are two unsatisfactory features. The first is the existence of negative energy, which was discussed in § 4.3. The other is the fact that the space–time is extendible, being only half of de Sitter space. Despite these aesthetic objections, the real test of the steady state theory is whether its predictions agree with observations or not. At the moment it seems that they do not, though the observations are not yet quite conclusive.

de Sitter space is geodesically complete; however, there are points in the space which cannot be joined to each other by any geodesic. This is in contrast to spaces with a positive definite metric, when geodesic completeness guarantees that any two points of a space can be joined by at least one geodesic. The half of de Sitter space which represents the steady state universe is not complete in the past (there are geodesics which are complete in the full space, and cross the boundary of the steady state region; they are therefore incomplete in that region).

To study infinity in de Sitter space–time, we define a time coordinate t' by

$$t' = 2\arctan(\exp \alpha^{-1} t) - \tfrac{1}{2}\pi,$$

where

$$-\tfrac{1}{2}\pi < t' < \tfrac{1}{2}\pi. \tag{5.8}$$

Then

$$ds^2 = \alpha^2 \cosh^2(\alpha^{-1}t') \, . \, d\bar{s}^2,$$

where $d\bar{s}^2$ is given by (5.7) on identifying $r' = \chi$. Thus the de Sitter space is conformal to that part of the Einstein static universe defined by (5.8) (see figure 17 (i)). The Penrose diagram of de Sitter space is accordingly as in figure 17 (ii). One half of this figure gives the Penrose

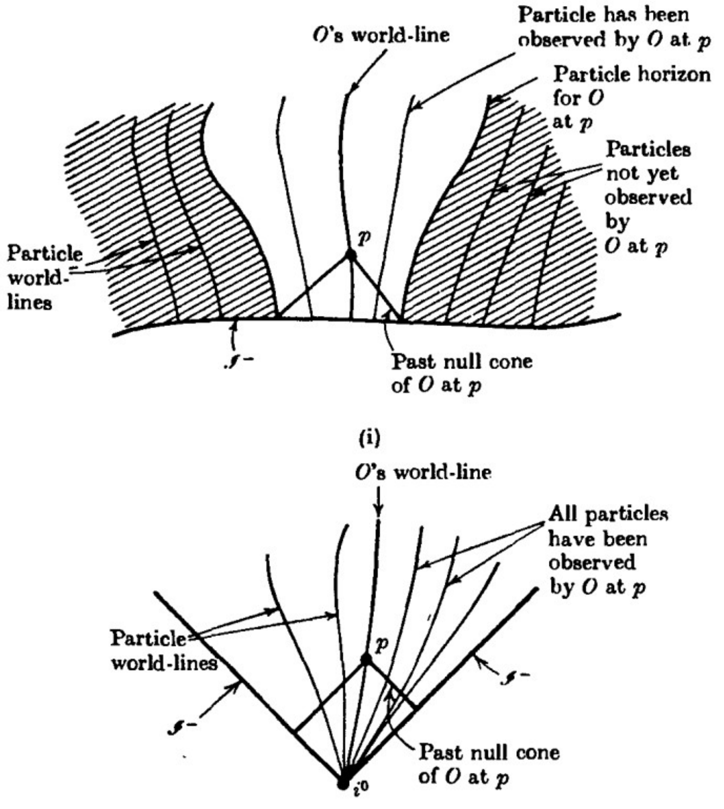
diagram of the half of de Sitter space-time which constitutes the steady state universe (figure 17 (iii)).

One sees that de Sitter space has, in contrast to Minkowski space, a spacelike infinity for timelike and null lines, both in the future and the past. This difference corresponds to the existence in de Sitter space-time of both particle and event horizons for geodesic families of observers.

In de Sitter space, consider a family of particles whose histories are timelike geodesics; these must originate at the spacelike infinity $\mathscr{I}^-$ and end at the spacelike infinity $\mathscr{I}^+$. Let p be some event on the world-



O's world-line

(i) The particle horizon defined by a congruence of geodesic curves when past null infinity $\mathscr{I}^-$ is spacelike.

(ii) Lack of such a horizon if $\mathscr{I}^-$ is null.

line of a particle O in this family, i.e. some time in its history (proper time measured along O's world-line). The past null cone of p is the set of events in space–time which can be observed by O at that time. The world-lines of some other particles may intersect this null cone; these particles are visible to O. However, there can exist particles whose world-lines do not intersect this null cone, and so are not yet visible to O. At a later time O can observe more particles, but there still exist particles not visible to O at that time. We say that the division of particles into those seen by O at p and those not seen by O at p, is the *particle horizon* for the observer O at the event p; it represents the history of those particles lying at the limits of O's vision. Note that it is determined only when the world-lines of all the particles in the family are known. If some particle lies on the horizon, then the event p is the event at which the particle's creation light cone intersects O's world-line. In Minkowski space, on the other hand, all the other particles are visible at any event p on O's world-line if they move on timelike geodesics. As long as one considers only families of geodesic observers, one may think of the existence of the particle horizon as a consequence of past null infinity being spacelike (see figure 18).

All events outside the past null cone of p are events which are not, and never have been, observable by O up to the time represented by the event p. There is a limit to O's world-line on $\mathscr{I}^+$. In de Sitter space–time, the past null cone of this point (obtained by a limiting process in the actual space–time, or directly from the conformal space–time) is a boundary between events which will at some time be observable by O, and those that will never be observable by O. We call this surface the *future event horizon* of the world-line. It is the boundary of the past of the world-line. In Minkowski space–time, on the other hand, the limiting null cone of any geodesic observer includes the whole of space–time, so there are no events which a geodesic observer will never be able to see. However if an observer moves with uniform acceleration his world-line may have a future event horizon. One may think of the existence of a future event horizon for a geodesic observer as being a consequence of $\mathscr{I}^+$ being spacelike (see figure 19).

Consider the event horizon for the observer O in de Sitter space–time and suppose that at some proper time (event p) on his world-line, his light cone intersects the world-line of the particle Q. Then Q is always visible to O at times after p. However there is on Q's world-line an event r which lies on O's future event horizon; O can never see later events on Q's world-line than r. Moreover an infinite proper time elapses on O's world-line from any given point till he observes r, but a finite proper time elapses along Q's world-line from any given event to r, which is a perfectly ordinary event on his world-line. Thus O sees a finite part of Q's history in an infinite time; expressed more physically, as O observes Q he sees a redshift which approaches infinity as O observes points on Q's world-line which approach r. Correspondingly, Q never sees beyond some point on O's world-line, and sees nearby points on O's world-line only with a very large redshift.

At any point on O's world-line, the future null cone is the boundary of the set of events in space–time which O can influence at and after that time. To obtain the maximal set of events in space–time that O could at any time influence, we take the future light cone of the limit

FIGURE 19

(i) The future event horizon for a particle O which exists when future infinity $\mathscr{I}^+$ is spacelike; also the past event horizon which exists when past infinity $\mathscr{I}^-$ is spacelike.

(ii) If future infinity consists of a null $\mathscr{I}^+$ and i^0, there is no future event horizon for a geodesic observer O. However an accelerating observer R may have a future event horizon.

point of O's world-line on past infinity $\mathscr{I}^-$; that is, we take the boundary of the future of the world-line (which can be regarded as O's creation light cone). This has a non-trivial existence for a geodesic observer only if the past infinity $\mathscr{I}^-$ is spacelike (and is in fact then O's past event horizon). It is clear from the above discussion that in the steady state universe, which has a null past infinity for timelike and null geodesics and a spacelike future infinity, any fundamental observer has a future event horizon but no past particle horizon.

One can obtain other spaces which are locally equivalent to the de Sitter space, by identifying points in de Sitter space. The simplest such identification is to identify antipodal points p, p' (see figure 16) on the hyperboloid. The resulting space is not time orientable; if time increases in the direction of the arrow at p, the antipodal identification implies it must increase in the direction of the arrow at p', but one cannot continuously extend this identification of future and past half null cones over the whole hyperboloid. Calabi and Markus (1962) have studied in detail the spaces resulting from such identifications; they show in particular that an arbitrary point in the resulting space can be joined to any other point by a geodesic if and only if it is not time orientable.

The space of constant curvature with $R < 0$ is called *anti-de Sitter space*. It has the topology $S^1 \times R^3$, and can be represented as the hyperboloid

$$-u^2 - v^2 + x^2 + y^2 + z^2 = 1$$

in the flat five-dimensional space R^5 with metric

$$\mathrm{d}s^2 = -(\mathrm{d}u)^2 - (\mathrm{d}v)^2 + (\mathrm{d}x)^2 + (\mathrm{d}y)^2 + (\mathrm{d}z)^2.$$

There are closed timelike lines in this space; however it is not simply connected, and if one unwraps the circle S^1 (to obtain its covering space R^1) one obtains the universal covering space of anti-de Sitter space which does not contain any closed timelike lines. This has the topology of R^4. We shall in future mean by 'anti-de Sitter space', this universal covering space.

It can be represented by the metric

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + \cos^2 t\,\{\mathrm{d}\chi^2 + \sinh^2\chi(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2)\}. \quad (5.9)$$

This coordinate system covers only part of the space, and has apparent singularities at $t = \pm\frac{1}{2}\pi$. The whole space can be covered by coordinates $\{t', r, \theta, \phi\}$ for which the metric has the static form

$$\mathrm{d}s^2 = -\cosh^2 r\,\mathrm{d}t'^2 + \mathrm{d}r^2 + \sinh^2 r(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2).$$

In this form, the space is covered by the surfaces $\{t' = \text{constant}\}$ which have non-geodesic normals.

To study the structure at infinity, define the coordinate r' by

$$r' = 2\arctan(\exp r) - \tfrac{1}{2}\pi, \quad 0 \leqslant r' < \tfrac{1}{2}\pi.$$

Then one finds $\mathrm{d}s^2 = \cosh^2 r\,\mathrm{d}\bar{s}^2$, where $\mathrm{d}\bar{s}^2$ is given by (5.7); that is, the whole of anti-de Sitter space is conformal to the region $0 \leqslant r' < \frac{1}{2}\pi$ of the Einstein static cylinder. The Penrose diagram is shown in figure 20; null and spacelike infinity can be thought of as a timelike surface in this case. This surface has the topology $R^1 \times S^2$.

FIGURE 20

(i) Universal anti-de Sitter space is conformal to one half of the Einstein static universe. While coordinates (t', r, θ, ϕ) cover the whole space, coordinates (t, χ, θ, ϕ) cover only one diamond-shaped region as shown. The geodesics orthogonal to the surfaces $\{t = \text{constant}\}$ all converge at p and q, and then diverge out into similar diamond-shaped regions.

(ii) The Penrose diagram of universal anti-de Sitter space. Infinity consists of the timelike surface $\mathscr{I}$ and the disjoint points i^+, i^-. The projection of some timelike and null geodesics is shown.

One cannot find a conformal transformation which makes timelike infinity finite without pinching off the Einstein static universe to a point (if a conformal transformation makes the time coordinate finite it also scales the space sections by an infinite factor), so we represent timelike infinity by the disjoint points i^+, i^-.

The lines $\{\chi, \theta, \phi \text{ constant}\}$ are the geodesics orthogonal to the surfaces $\{t = \text{constant}\}$; they all converge to points q (respectively, p) in the future (respectively, past) of the surface, and this convergence is the reason for the apparent (coordinate) singularities in the original metric form. The region covered by these coordinates is the region between the surface $t = 0$ and the null surfaces on which these normals become degenerate.

The space has two further interesting properties. First, as a consequence of the timelike infinity, there exists no Cauchy surface whatever in the space. While one can find families of spacelike surfaces (such as the surfaces $\{t' = \text{constant}\}$) which cover the space completely, each surface being a complete cross-section of the space-time, one can find null geodesics which never intersect any given surface in the family. Given initial data on any such surface, one cannot predict beyond the Cauchy development of the surface; thus from the surface $\{t = 0\}$, one can predict only in the region covered by the coordinates t, χ, θ, ϕ. Any attempt to predict beyond this region is prevented by fresh information coming in from the timelike infinity.

Secondly, corresponding to the fact that the geodesic normals from $t = 0$ all converge at p and q, all the past timelike geodesics from p expand out (normal to the surfaces $\{t = \text{constant}\}$) and reconverge at q. In fact, all the timelike geodesics from any point in this space (to either the past or future) reconverge to an image point, diverging again from this image point to refocus at a second image point, and so on. The future timelike geodesics from p therefore never reach $\mathscr{I}$, in contrast to the future null geodesics which go to $\mathscr{I}$ from p and form the boundary of the future of p. This separation of timelike and null geodesics results in the existence of regions in the future of p (i.e. which can be reached from p by a future-directed timelike line) which cannot be reached from p by any geodesic. The set of points which can be reached by future-directed timelike lines from p is the set of points lying beyond the future null cone of p; the set of points which can be reached from p by future-directed timelike geodesics is the interior of the infinite chain of diamond-shaped regions similar to that covered by coordinates (t, χ, θ, ϕ). One notes that all points in the Cauchy development of the surface $t = 0$ can be reached from this surface by a unique geodesic normal to this surface, but that a general point outside this Cauchy development cannot be reached by any geodesic normal to the surface.

5.3 Robertson–Walker spaces

So far, we have not considered the relation of exact solutions to the physical universe. Following Einstein, we can ask: can one find space–times which are exact solutions for some suitable form of matter and which give a good representation of the large scale properties of the observable universe? If so, we can claim to have a reasonable 'cosmological model' or model of the physical universe.

However we are not able to make cosmological models without some admixture of ideology. In the earliest cosmologies, man placed himself in a commanding position at the centre of the universe. Since the time of Copernicus we have been steadily demoted to a medium sized planet going round a medium sized star on the outer edge of a fairly average galaxy, which is itself simply one of a local group of galaxies. Indeed we are now so democratic that we would not claim that our position in space is specially distinguished in any way. We shall, following Bondi (1960), call this assumption the *Copernican principle*.

A reasonable interpretation of this somewhat vague principle is to understand it as implying that, when viewed on a suitable scale, the universe is approximately spatially homogeneous.

By spatially homogeneous, we mean there is a group of isometries which acts freely on $\mathscr{M}$, and whose surfaces of transitivity are spacelike three-surfaces; in other words, any point on one of these surfaces is equivalent to any other point on the same surface. Of course, the universe is not exactly spatially homogeneous; there are local irregularities, such as stars and galaxies. Nevertheless it might seem reasonable to suppose that the universe is spatially homogeneous on a large enough scale.

While one can build mathematical models fulfilling this requirement of homogeneity (see next section), it is difficult to test homogeneity directly by observation, as there is no simple way of measuring the separation between us and distant objects. This difficulty is eased by the fact that we can, in principle, fairly easily observe *isotropies* in extragalactic observations (i.e. we can see if these observations are the same in different directions, or not), and isotropies are closely con-

'()*' ' '+ ' . ! +4 1
2 6663 - A ! -!
& 8 6 8 0 4

modes will be the solutions in a small neighbourhood about the saddle point permitted by the linearised equations (given existence of solutions to the non-linear equations, linearisation will not prevent corresponding linearised solutions existing).)

The point is that these modes can exist as linearisations of the FLRW model; if they do not occur, then initial data has been chosen to set these modes precisely to zero (rather than being made very small), which requires very special initial conditions. Thus these modes will occur in almost all almost-FLRW universes. Hence, if one believes in generality arguments, they will occur in the real universe. When they occur, they will at early and late times grow until the model is very far from a FLRW geometry (while being arbitrarily close to an FLRW model for a very long time, as per the previous theorem).

Exercise: Most studies of CBR anisotropies and nucleosynthesis are carried out for the Bianchi types that allow FLRW models as special cases (see Figure 3). Show that Bianchi models can approximate FLRW models for extended periods even if they do not belong to those types. What kinds of CBR anisotropies can occur in these models? (See e.g. [51].)

7. Almost-FLRW universes

The real universe is *not* FLRW because of all the structure it contains, and (because of the non-linearity of the EFE) the other exact solutions we can attain have higher symmetry than the real universe. Thus in order to obtain realistic models we can compare with detailed observations we need to approximate, aiming to obtain 'almost-FLRW' models representing a universe that is FLRW-like on a large scale but allowing for generic inhomogeneities on a small scale.

7.1. GAUGE PROBLEM

The major problem in studying perturbed models is the *gauge problem*, due to the fact that there is *no* identifiable fixed background model in General Relativity. One can start with a unique FLRW universe model with metric $\overline{g}_{ab}$ in some coordinate system, and perturb it to obtain a more realistic model: $\overline{g}_{ab} \to g_{ab} = \overline{g}_{ab} + \delta g_{ab}$, but then the process has no unique inverse: the background model $\overline{g}_{ab}$ is not uniquely determined by the lumpy universe model g_{ab} (no unique tensorial averaging process has been defined that will recover $\overline{g}_{ab}$ from g_{ab}). Many choices can be made. However, the usual variables describing perturbations depend on the way the (fictitious) background model $\overline{g}_{ab}$ is fitted to the real universe g_{ab}; these variables can be given any values one wants by changing this correspondence.[26] For example, the *dimensionless density contrast* δ representing a density perturbation is usually defined by

$$\delta(x) = \frac{\mu(x) - \overline{\mu}(x)}{\mu(x)} , \tag{184}$$

where $\mu(x)$ is the actual value of the density at the point x, while $\overline{\mu}(x)$ is the (fictitious) background value there, determined by the chosen mapping of the background model into the realistic lumpy model (Ellis and Bruni [197]). This quantity can be given any value we desire by altering that map; we can for example set it to zero by choosing the real surfaces of constant density to be the background surfaces of constant time and, hence, of constant density. Consequently, perturbation equations written in terms of this variable have as solution both physical modes and gauge modes, the latter corresponding to variation of gauge choice rather than to physical variation.

One way to solve this is by very carefully keeping track of the gauge used and the resulting gauge freedom; see Ma and Bertschinger [198] and Prof. Bertschinger's lectures here. The alternative is to use gauge-invariant variables. A widely used and fundamentally important set of such variables are those introduced by Bardeen [199], and used for example by Bardeen, Steinhardt and Turner [200]. Another possibility is use of Gauge-Invariant and 1+3 Covariant ('GIC') variables, i.e. variables that are gauge-invariant and also $1 + 3$ covariantly defined so that they have a clear geometrical meaning, and can be examined in any desired coordinate system. That is what will be pursued here.

In more detail: our aim is to examine perturbed models by using $1 + 3$ covariant variables defined in the real space-time (not the background), deriving exact equations for these variables in that space-time, and then approximating by linearising about a RW geometry to get the linearised equations describing the evolution of density inhomogeneities in almost-FLRW universes. How do we handle gauge invariance in this approach? We rely on the

> **Gauge Invariance Lemma** (Stewart and Walker [201]): If a quantity $T^{\cdots}{}_{\cdots}$ vanishes in the background space-time, then it is gauge-invariant (to all orders).

---

[26] This is often represented implicitly rather than explicitly, by assuming that points with the same coordinate values in the background space and more realistic model map to each other; then the gauge freedom is contained in the coordinate freedom available in the realistic universe model.

[The proof is straightforward : If $\overline{T}^{\cdots}{}_{\cdots} = 0$, then $\delta T^{\cdots}{}_{\cdots} = T^{\cdots}{}_{\cdots} - \overline{T}^{\cdots}{}_{\cdots} = T^{\cdots}{}_{\cdots}$, which is manifestly independent of the mapping Φ from $\overline{S}$ to S (it does not matter how we map $\overline{T}^{\cdots}{}_{\cdots}$ from $\overline{S}$ to S when $\overline{T}^{\cdots}{}_{\cdots}$ vanishes).] The application to almost-FLRW models follows (see Ellis and Bruni [197]), where we use an order-of-magnitude notation as follows: Given a smallness parameter ϵ, $\mathcal{O}[n]$ denotes $\mathcal{O}(\epsilon^n)$, and $A \approx B$ means $A - B = \mathcal{O}[2]$ (i.e. these variables are equivalent to $\mathcal{O}[1]$). When $A \approx 0$ we shall regard A as vanishing when we linearise (for it is zero to the accuracy of relevant first-order calculations). Then,

- Zero-order variables are μ, p, Θ, and their time derivatives, $\dot{\mu}$, $\dot{p}$, $\dot{\Theta}$,
- First-order variables are $\dot{u}^a$, σ_{ab}, ω^a, q^a, π_{ab}, E_{ab}, H_{ab}, X_a, Z_a, and their time and space derivatives.

As these first-order variables all vanish in exact FLRW universes, provided u^a is uniquely defined in the realistic (lumpy) almost-FLRW universe model, they are all uniquely defined GIC variables. Thus this set of variables provides what we wanted: $1+3$ covariant variables characterising departures from a FLRW geometry (and, in particular, the spatial inhomogeneity of a universe) that are gauge-invariant when the universe is almost-FLRW. Because they are tensors defined in the real space-time, we can evaluate them in any coordinate system we like in that space-time.

7.1.1. *Key variables*

Two simple gauge-invariant quantities give us the information we need to discuss the time evolution of density fluctuations. The basic quantities we start with are the orthogonal projections of the energy density gradient, i.e. the vector $X_a \equiv \tilde{\nabla}_a \mu$, and of the expansion gradient, i.e. the vector $Z_a \equiv \tilde{\nabla}_a \Theta$. The first can be determined (a) from virial theorem estimates and large-scale structure observations (as, e.g., in the POTENT programme), (b) by observing gradients in the numbers of observed sources and estimating the mass-to-light ratio (Kristian and Sachs [98], Eq. (39)), and (c) by gravitational lensing observations. However, these do not directly correspond to the quantities usually calculated; but two closely related quantities do. The first is the *comoving fractional density gradient*:

$$\mathcal{D}_a \equiv S \frac{X_a}{\mu} , \tag{185}$$

which is gauge-invariant and dimensionless, and represents the spatial density variation over a fixed comoving scale. Note that S, and so $\mathcal{D}_a$, is defined only up to a constant by equation (25); this allows it to represent the density variation between any neighbouring worldlines. The vector $\mathcal{D}_a$ can be separated into a magnitude $\mathcal{D}$ and direction e_a

$$\mathcal{D}_a = \mathcal{D}\, e_a \ , \ e_a e^a = 1 \ , \ e_a u^a = 0 \quad \Rightarrow \quad \mathcal{D} = (\mathcal{D}_a \mathcal{D}^a)^{1/2} \ . \tag{186}$$

The magnitude $\mathcal{D}$ is the gauge-invariant variable[27] that most closely corresponds to the intention of the usual $\delta = \delta\mu/\mu$ given in (184). The crucial difference from the usual definition is that $\mathcal{D}$ represents a (real) spatial fluctuation, rather than a (fictitious) time fluctuation, and does so in a GIC manner. An important auxiliary variable in what follows is the *comoving spatial expansion gradient:*

$$\mathcal{Z}_a \equiv S\, Z_a \ . \tag{187}$$

The issue now is, can we find a set of equations determining how these variables evolve? Yes we can; they follow from the $1+3$ covariant exact equations of the previous sections.

7.2. DYNAMICAL EQUATIONS

We can determine exact propagation equations along the fluid flow lines for the quantities defined in the previous section, and then linearise these to the almost-FLRW case. The basic linearised equations are given by Hawking [22] (see his equations (13) to (19)); we add to them the linearised propagation equations for the gauge-invariant spatial gradients defined above [197].

7.2.1. *Growth of inhomogeneity*

Taking the spatial gradient of the equation of energy conservation (37) (for the case of a perfect fluid), we find [197]

$$\tilde{\nabla}_a(\dot{\mu}) + \Theta\, \tilde{\nabla}_a(\mu + p) + (\mu + p)\, \tilde{\nabla}_a\Theta = 0 \ ,$$

i.e.

$$h^b{}_a \nabla_b(u^c\nabla_c\mu) + \Theta\,(X_a + \tilde{\nabla}_a p) + (\mu + p)\, Z_a = 0 \ .$$

Using Leibniz' Rule and changing the order of integration in the second-derivative term (and noting that the pressure-gradient term cancels on using the momentum conservation equation (38)), we obtain the *fundamental equation for the growth of inhomogeneity*:

$$\dot{X}^{\langle a\rangle} + \tfrac{4}{3}\,\Theta\, X^a \;=\; -\,(\mu + p)\, Z^a - \sigma^a{}_b\, X^b + \eta^{abc}\,\omega_b\, X_c \ , \tag{188}$$

with source term Z^a. On taking the gradient of the Raychaudhuri equation (29) we find the companion equation for that source term:

$$\begin{aligned} \dot{Z}^{\langle a\rangle} + \Theta\, Z^a \;=\; & -\tfrac{1}{2}\, X^a - \sigma^a{}_b\, Z^b + \eta^{abc}\,\omega_b\, Z_c + \dot{u}^a\, \mathcal{R} - 2\, \tilde{\nabla}^a(\sigma^2 - \omega^2) \\ & + \tilde{\nabla}^a(\tilde{\nabla}_b \dot{u}^b + \dot{u}_b \dot{u}^b) \ , \end{aligned} \tag{189}$$

---

[27] Or, equivalently in the linear case, the spatial divergence of $\mathcal{D}_a$.

4. Gravitational lenses in Cosmology

The extension of the lens equations to a cosmological context raises some technical difficulties because the background in which the objects are embedded is not flat. The aim of this section is to clarify these points. However, readers that are not familiar with cosmology can jump to section 5.

The basic equations, that describe jointly the evolution of the expansion parameter and the mean density, are the following,

$$\begin{aligned} 3\,\ddot{a} &= -4\pi G\,\rho\,a + \Lambda\,a; && (15)\\ \dot{a}^2 &= \frac{1}{a}\left[\frac{8\pi\,G}{3}\,\rho\,a^3 - k\,a + \frac{\Lambda\,a^3}{3}\right]. && (16)\end{aligned}$$

where Λ is a possible cosmological constant and k a possible curvature term. The Hubble constant reads,

$$H = \frac{\dot{a}}{a} = \sqrt{\frac{8\pi\,G}{3}\,\rho - \frac{k}{a^2} + \frac{\Lambda\,a^3}{3}}. \tag{17}$$

To simplify the discussions the reduced quantities are introduced,

$$\Omega = \frac{8\pi\,G}{3\,H^2}\,\rho \quad\text{and}\quad \lambda = \frac{\Lambda}{3\,H^2}. \tag{18}$$

They have an index 0 when they are taken at present time.

4.1. THE ANGULAR DISTANCES

We consider an object of size l (either because of its proper size or because of a peculiar physical process) at redshift z. When this size l is seen under an angle α, then by definition,

$$\alpha = \frac{l}{\mathcal{D}_0}, \tag{19}$$

where $\mathcal{D}_0$ is the angular distance. This is the distance at which this object would be in an Euclidean metric. What is then the relationship between $\mathcal{D}_0$ and z? The Friedmann-Robertson-Walker metric is given by,

$$\mathrm{d}s^2 = -c^2\,\mathrm{d}t^2 + a^2(t)\left(\frac{\mathrm{d}x^2}{1-k\,x^2} + x^2\mathrm{d}\theta^2 + x^2\,\sin^2\theta\,\mathrm{d}\varphi^2\right). \tag{20}$$

The fact that the size of this object is l means that it takes a time interval $\mathrm{d}t = l/c$ for light to travel to one end to the other. The corresponding angle $\alpha = \mathrm{d}\theta$ can be obtained by writing $\mathrm{d}s = 0$ with $\mathrm{d}x = 0, \mathrm{d}\varphi = 0$, which gives

$$l = a(t)\, x\, \alpha. \tag{21}$$

The angular *comoving* distance is thus given by $\mathcal{D}_0(z) = x(z)$. The expression of $x(z)$ can then be computed by the relation $\mathrm{d}s = 0$ along the line of sight with $\mathrm{d}\theta = 0$ and $\mathrm{d}\varphi = 0$,

$$\int_{t_0}^{t_1} \frac{c\,\mathrm{d}t}{a} = \int_0^{x(z)} \frac{\mathrm{d}x}{\sqrt{1-kx^2}} \equiv \chi(z). \tag{22}$$

For an open Universe, $k < 0$, and we have,

$$x(z) = \mathcal{D}_0(z) = \frac{1}{\sqrt{-k}} \sinh[\sqrt{-k}\ \chi(z)]. \tag{23}$$

Obviously when $k = 0$, $x = \chi$.

The relation $\chi(z)$ depends on the function $a(t)$ for a given cosmology, and therefore on the matter content of the Universe, on Λ and k . For instance, for an Einstein-de Sitter Universe, in the matter dominated era, we have

$$a(t) = \left(\frac{t}{t_0}\right)^{2/3}, \tag{24}$$

so that,

$$x(z) = \int_{t_0}^{t_1} t^{-2/3}\mathrm{d}t = 3(t_0^{1/3} - t_1^{1/3})t_0^{2/3}, \quad H_0 = \frac{2}{3\,t_0}, \tag{25}$$

and eventually,

$$\mathcal{D}_0(z) = \chi(z) = \frac{c}{H_0}\left(2 - \frac{2}{\sqrt{1+z}}\right). \tag{26}$$

This is the comoving angular distance for an Einstein-de Sitter Universe. More generally we have an explicit solution if $\Lambda = 0$ only. Finally the lens equation also requires the angular distance between two different redshifts z_1 and z_2. The calculation is actually quite simple. This distance is given formally by $\mathcal{D}_0(z_2)$ when it is calculated at a time when the observer is at redshift z_1. k being time independent we should formally have,

$$\mathcal{D}_0(z_1, z_2) = \frac{1}{\sqrt{-k}} \sinh[\sqrt{-k}\ (\chi(z_2, z_1))], \tag{27}$$

and to compute $\chi(z_2, z_1)$ one only needs to remark,

$$\chi(z_2, z_1) \equiv \int_{t_1}^{t_2} \frac{c\,\mathrm{d}t}{a} = \chi(z_2) - \chi(z_1), \tag{28}$$

which gives the expression of the angular distance we need. Eventually, it is fruitful to notice that,

$$\frac{c\,\mathrm{d}t}{a} = -\frac{c\,\mathrm{d}z}{H}, \tag{29}$$

which gives,

$$\mathcal{D}_0(z_1, z_2) = \frac{c}{H_0\sqrt{1-\Omega_0-\lambda_0}} \sinh\left[H_0\sqrt{1-\Omega_0-\lambda_0}\ \int_{z_1}^{z_2} \frac{\mathrm{d}z}{H(z)}\right], \tag{30}$$

and

$$\mathcal{D}_0(z) = \frac{c}{H_0\sqrt{1-\Omega_0-\lambda_0}} \sinh\left[H_0\sqrt{1-\Omega_0-\lambda_0}\ \int_{0}^{z} \frac{\mathrm{d}z'}{H(z')}\right]. \tag{31}$$

The whole geometrical part of the lens equation is thus established.

4.2. GEOMETRIC OPTICS IN A WEAKLY INHOMOGENEOUS UNIVERSE

What is now the source term for the deflection angle? We should first notice that in absence of lenses the light rays follow the geodesics of the Friedmann-Robertson-Walker metric. And in the applications we are interested in, the metric fluctuations are always weak. These fluctuations are given by, $G\,M/(R\,c^2)$. For instance, for

- 1 star: $M = 1\,M_\odot$, $R = 7\,10^5$km, $\delta\phi \approx 10^{-6}$;
- 1 galaxy cluster: $M = 10^{15}\,M_\odot$, $R = 1$Mpc $= 3\,10^{19}$km, $\delta\phi \approx 10^{-5}$.

The metric inhomogeneities are thus always extremely weak, even in the most extreme cosmological situations.

Following[3] Sachs (1961), we consider two nearby geodesics, $\mathcal{L}$ and $\mathcal{L}'$, in a light bundle in an FRW Universe with small metric fluctuations. We denote α_i the bi-dimensional angular distance between $\mathcal{L}$ and $\mathcal{L}'$ as it is seen by the observer. This is the distance in the image plane, that is the difference between the angular coordinates with which the photons arrive. We denote $\xi_i(z)$ the real distance between $\mathcal{L}$ and $\mathcal{L}'$ at redshift z (see Fig. 3). It implies that the geodesics are straight enough so that light always travels towards the observer. We also assume that the deflections are small enough so that it is possible to make the small angle approximation,

$$\xi_i(z) = a\ \mathcal{D}_{ij}(z)\ \alpha_j, \tag{32}$$

---

[3] See Misner, Thorne and Wheeler for an exhaustive presentation of the geometric optics.

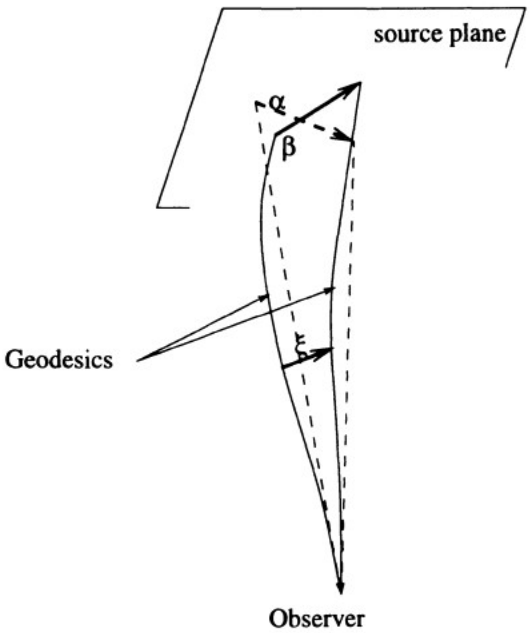

Figure 3. Sketch showing the geometrical quantities that appear in Eq. 32

that is that we assume the the position vector ξ_i can be obtained by a simple linear transform of the angular coordinates. For an homogeneous space $\mathcal{D}_{ij}(z)$ is simply given by $\mathcal{D}_0(z)\,\delta^K_{ij}$ where δ^K_{ij} is the Kronecker symbol. Obviously $\mathcal{D}_{ij}$ changes as a function of redshift along the trajectories. The "virtual" angular position in the source plane is then given by the ratio of the real distance (at time of light emission for instance) by the angular distance of the emitter in an homogeneous space,

$$\vec{\beta} = \frac{\vec{\xi}(z)}{a\mathcal{D}_0(z)}. \tag{33}$$

The amplification matrix, or rather its inverse, $\mathcal{A}^{-1}$, is then given by,

$$\mathcal{A}^{-1}(z) = \frac{\mathcal{D}_{ij}(z)}{a\mathcal{D}_0(z)}. \tag{34}$$

for a source plane at redshift z.

Sachs (1961) gave the master equation which governs the evolution of the distance between the geodesics. The derivation of this equation goes beyond these lecture notes and I give only the final answer (as it has been given by Seitz, Schneider and Ehlers 1994),

$$\frac{\mathrm{d}^2[a\ \mathcal{D}_{ij}(\vec{\beta}, z)]}{\mathrm{d}\eta^2} = a(z)\mathcal{R}_{ik}(\vec{\beta}, z)\ \mathcal{D}_{kj}(\vec{\beta}, z) \tag{35}$$

where the derivatives are taken with respect to η,

$$\mathrm{d}\eta = -\frac{\mathrm{d}a}{H(a)} = -a\ \mathrm{d}t, \quad \eta(z=0) = 0. \tag{36}$$

with the boundary conditions,

$$(\mathcal{D}_{ij})_{z=0} = 0; \quad \left(\frac{\mathrm{d}\mathcal{D}_{ij}}{\mathrm{d}\eta}\right)_{z=0} = \frac{c}{H_0}. \tag{37}$$

The matrix $\mathcal{R}_{ij}$ represents the tidal effects. It can by written in terms of the gravitational potential ϕ given by,

$$\Delta_x \phi = 4\pi\, G\, \overline{\rho}\, a^2\, \delta_{\mathrm{mass}}. \tag{38}$$

The Laplacian is taken with respect of the comoving angular distances. We have

$$\mathcal{R}_{ij} = -\frac{4\pi\, G\, \overline{\rho}}{H_0^2\, a^2} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} - \frac{2}{H_0^2\, a^2} \begin{pmatrix} \phi_{,11} & \phi_{,12} \\ \phi_{,21} & \phi_{,22} \end{pmatrix}. \tag{39}$$

Since $8\pi\, G\, \overline{\rho}\, a^3 = 3H_0^2\, \Omega_0$, (e.g. Eq. 18) for an homogeneous Universe we have,

$$\mathcal{R}_{ij}^{(0)} = -\frac{3}{2}\,(1+z)^5\, \Omega_0\, \delta_{ij}^K \tag{40}$$

(the superscript (0) means here that it is the value of $\mathcal{R}$ without perturbations). In this case the matrix $\mathcal{D}_{ij}$ is proportional to δ_{ij}^K and we have,

$$\frac{\mathrm{d}^2[a\ \mathcal{D}_0(z)]}{\mathrm{d}\eta^2} = -\frac{3}{2}(1+z)^4\, \Omega_0\, \mathcal{D}_0(z). \tag{41}$$

We recover in fact the comoving angular distance the expression of which we know,

$$\mathcal{D}_0(z) = \frac{c}{H_0\sqrt{1-\Omega_0-\lambda_0}} \sinh\left[\sqrt{1-\Omega_0-\lambda_0} \int_0^z \frac{\mathrm{d}z'}{E(z')}\right], \tag{42}$$

with

$$E(z) = \frac{H(z)}{H_0} = \sqrt{\lambda_0 + (1+z)^2(1-\Omega_0-\lambda_0) + (1+z)^3\Omega_0}. \tag{43}$$

This integral has a closed form only when the cosmological constant, Λ, is zero.

4.3. THE LINEARIZED EQUATION OF GEOMETRIC OPTICS

We can remark that the equation (35) is not linear since $\mathcal{D}$ is not simply proportional to $\mathcal{R}$. This expresses the fact that the deformation of the angular distance is made all along the light trajectory by multiple deflections.

The general resolution of Eq. (35) is in general very complicated. It can however handled when it is linearized. Let's assume we can expand $\mathcal{D}_{ij}$ with respect of the local density contrast,

$$\mathcal{D}_{ij}(z) = \mathcal{D}_0 + \mathcal{D}_{ij}^{(1)} + \dots \tag{44}$$

It implies that, at first order,

$$\frac{\mathrm{d}^2[a\ \mathcal{D}_{ij}^{(1)}(\vec{\beta}, z)]}{\mathrm{d}\eta^2} - a(z)\mathcal{R}_{ik}^{(0)}(\vec{\beta}, z)\mathcal{D}_{kj}^{(1)}(\vec{\beta}, z) = -3\Omega_0(1+z)^4\mathcal{D}_0(z)\varphi_{,ij}(\vec{\beta}, z) \tag{45}$$

with,

$$\left(\mathcal{D}_{ij}^{(1)}\right)_{z=0} = 0, \quad \left(\frac{\mathrm{d}\mathcal{D}_{ij}^{(1)}}{\mathrm{d}\eta}\right)_{z=0} = 0, \tag{46}$$

and we define the field φ so that,

$$\Delta_x\varphi = \delta_{\mathrm{mass}}(\vec{\beta}, z) = \frac{\Delta_x\phi}{4\pi G\,\overline{\rho}\,a^2}. \tag{47}$$

To solve this differential equation it is easier to write it with the variable z. It then reads,

$$\begin{aligned} &\frac{\mathrm{d}^2[a\ \mathcal{D}_{ij}^{(1)}(\vec{\beta}, z)]}{\mathrm{d}z^2} + \frac{1}{E(z)}\frac{\mathrm{d}E(z)}{\mathrm{d}z}\frac{\mathrm{d}\mathcal{D}_{ij}^{(1)}(\vec{\beta}, z)}{\mathrm{d}z} - \\ &-\frac{1}{1+z}\frac{1}{E(z)}\frac{\mathrm{d}E(z)}{\mathrm{d}z}\mathcal{D}_{ij}^{(1)}(\vec{\beta}, z) + \frac{3}{2}\frac{\Omega_0(1+z)}{E^2(z)}\mathcal{D}_{ij}^{(1)}(\vec{\beta}, z) = \\ &\qquad -3\frac{\Omega_0(1+z)}{E^2(z)}\mathcal{D}_0(\vec{\beta}, z)\varphi_{,ij}(\vec{\beta}, z). \end{aligned} \tag{48}$$

The differential homogeneous equation it is associated with has two known solutions. One describes the angular distance $\mathcal{D}_0$, the other is given by,

$$\mathcal{U}_0(z) = \frac{1}{\sqrt{1-\Omega_0-\lambda_0}}\cosh\left[\sqrt{1-\Omega_0-\lambda_0}\int_0^z \frac{\mathrm{d}z'}{E(z')}\right], \tag{49}$$

The general solution of 48 then reads,

$$\mathcal{D}_{ij}^{(1)}(\vec{\beta}, z) = -3\Omega_0\int_0^z \mathrm{d}z'\frac{(1+z')\mathcal{D}_0(z')\varphi_{,ij}(z')}{E^2(z)}\frac{\mathcal{U}_0(z)\mathcal{D}_0(z') - \mathcal{U}_0(z')\mathcal{D}_0(z)}{\mathcal{U}_0'(z')\mathcal{D}_0(z') - \mathcal{U}_0(z')\mathcal{D}_0'(z')}, \tag{50}$$

which, after elementary mathematical transforms, gives,

$$\mathcal{D}_{ij}^{(1)}(\vec{\beta}, z) = -3\,\Omega_0 \int_0^z \frac{\mathrm{d}z'}{E(z)} \frac{1}{\sqrt{1-\Omega_0-\lambda_0}} \times$$

$$\times \sinh\left[\sqrt{1-\Omega_0-\lambda_0}\int_z^{z'} \frac{\mathrm{d}z''}{E(z'')}\right](1+z')\mathcal{D}_0(z')\varphi_{,ij}(z'). \qquad (51)$$

It can be rewritten by introducing the physical distance χ along the line of sight. We eventually have,

$$\mathcal{A}^{-1}(z) = \mathrm{Id} - \frac{3\,\Omega_0}{(c/H_0)^2}\int_0^{\chi(z)} \mathrm{d}\chi' \frac{\mathcal{D}_0(z', z)\mathcal{D}_0(z')}{\mathcal{D}_0(z)}(1+z')\varphi_{,ij}(z'), \qquad (52)$$

where the angular distances $\mathcal{D}_0(z)$ and $\mathcal{D}_0(z, z')$ are comoving. This equation actually gives the expression of the amplification matrix for a non-trivial background. We find that the amplification matrix is given by the superposition of lens effects of the different mass layers. We can remark that the lens term is given by the gravitational potential, ϕ, that is by the potential the source term of which is given by the density contrast.

Note finally that this equation is valid in two limit cases, either for a single lens plane with an arbitrary strength or the superposition of any number of weak lenses. This equation naturally extents the previous result, (10), obtained for a single lens in an Euclidean background. The higher orders of Eq. (35) give the intrinsic lens coupling effects (i.e. their nonlinear parts). We will not consider them here.

5. Galaxy clusters as gravitational lenses

The study of galaxy clusters has become a very active field since the discovery of the first gravitational arc by Soucail et al. (1988) in Abell cluster A370. Galaxy clusters give the most dramatic example of gravitational lens effects in a cosmological context. The difficulty is however to describe the shape of their mass distribution.

5.1. THE ISOTHERMAL PROFILE

For an isothermal profile we assume that the local density $\rho(r)$ behaves like,

$$\rho(r) = \rho_0 \left(\frac{r}{r_0}\right)^{-2}. \qquad (53)$$

With such a density profile the total mass is not finite. So this is not a realistic description but it is a good starting point for the central part of

Topology and Topology Change in General Relativity

GARY W. GIBBONS

1 INTRODUCTION

The organisers have asked us to review the progress of some aspect of general relativity and cosmology in which they have a particular interest and to introduce their remarks by describing its relation to their interaction with Dennis Sciama. It is a great pleasure for me to do so and also to pay tribute to the inspiration that he, and his style of doing physics, has been to me over the years. In particular I have tried to follow his example by asking simple physical questions and trying to answer them with the simplest appropriate tools available. For that reason in what follows I shall not give extensive mathematical details but refer the reader to the references. Moreover because of the personal nature of the review I have made no attempt to include in those references every paper on the subject, especially where the story is widely known and can be read up in standard textbooks. For the same reason I have perhaps erred in including too many papers of my own.

I became a Research student of Dennis Sciama in October 1969 after being enthralled by his marvelously lucid and exciting Part III lectures on General Relativity. When Dennis left for Oxford a year later I transferred to Stephen Hawking, himself a former student of Dennis. I can thus be said to be the answer to a riddle in that I am the academic son of my father's son. The problem that Dennis originally suggested to me was to give an upper bound to the proportion of the rest mass of a gravitating system's rest which could be lost in gravitational radiation - a question which was at that time very topical because of Weber's claims to have observed substantial amounts of gravitational radiation coming from the galactic centre.

I failed to make much headway on that particular problem, unlike my next supervisor who spectacularly solved one aspect of it - that involving black holes, about which I knew almost literally nothing at that time - with his celebrated Area Theorem. However, as all good Ph.D. problems should, it did set me thinking about numerous things including my subject today, topology and topology change in general relativity, and I would like to describe some of my thoughts over the years on this subject, at the same time trying to put them in a more general context.

I shall begin by considering the classical theory and then pass on to the necessarily more speculative quantum theory. I will restrict myself to the case of four spacetime dimensions, and I will concentrate on two particular theories: pure general relativity (with no matter) and Einstein-Maxwell theory. Much of what I have to say can be readily extended to more complicated theories, as I shall indicate briefly at the end, but these two simple theories already exhibit in essence the basic ideas and at the same time indicate the great richness of possible physical effects one can expect.

2 THE CLASSICAL THEORY

2.1 The Einstein-Rosen Bridge

The most direct way of answering the question Dennis had posed seemed at first to be to examine the motion of 'point particles' à la E.I.H. I read many papers on this subject and understood very little of them. However the one thing that did strike me was that the point particle picture seemed rather inappropriate in general relativity because it involved extrapolating the gravitational field of the particle inside its Schwarzschild radius. I found far more appealing the view, espoused in the famous paper of Einstein and Rosen (1935) in which they first described the "Einstein-Rosen Bridge" in the Schwarzschild solution, that one should look for everywhere non-singular solutions of the non-linear field equations representing a particle. Nowadays we call such solutions "solitons" and their use has become commonplace: the topological defects such as magnetic monopoles we now consider in cosmology are of course just solutions of this sort. Einstein and Rosen were greatly impressed by the non-trivial (spatial) topology of their throat, which seemed to be responsible for the existence of the solution and absence of singularities. Sadly however the singularities were still there lurking, as it were, in the full Kruskal spacetime rather than in space at one time. Indeed this conflict between the Hamiltonian and Lagrangian viewpoints, i.e. between space and spacetime is characteristic of our present subject, as it is of a great deal else in gravity.

2.2 Geometrodynamics

Einstein and Rosen's idea was taken up by Wheeler and his group at Princeton and their main results were summarised in that marvelously inspiring book 'Geometrodynamics' (1961). From it I came away with three ideas which are important for our story.

1) That there exist very many non-singular initial data sets which are topologically non-trivial both for pure general relativity and for Einstein-Maxwell theory.
2) In the latter case the non-trivial topology can be responsible for the phenomenon

of "Charge without Charge".

3) The complete duality symmetry between electric and magnetic fields, a symmetry which can even be extended to massless spinor fields using chiral rotations involving γ_5.

2.3 Causal Selection Rules

The existence of topologically non-trivial initial data sets of this sort naturally raises questions about their evolution in time. Can there be transitions for example between spaces of different spatial topologies? One may ask such questions at the most basic kinematical level: what kind of evolutions are possible?, and at the dynamical level: what kind of evolutions will arise if field equations are imposed?

Perhaps the best known results at the purely kinematical level are those of Geroch (1967) which despite their great elegance and beauty have had the somewhat unfortunate effect until very recently of discouraging work on topology change. Let us assume the existence of an everywhere non-singular time-orientable and space-orientable Lorentzian metric g_L on a compact 4-manifold M with a closed but not necessarily connected spacelike boundary $\partial M = \Sigma$. Reinhart and later Geroch had shown that there exist many such spacetimes $\{M, g_L\}$ for every boundary Σ but Geroch also showed that if Σ consists of two components, Σ_i and Σ_f in the past and in the future respectively, and if Σ_i and Σ_f do not have the same topology then the spacetime M must contain closed timelike curves. If on the other hand M does not have closed timelike curves it is topologically the product of a closed time interval and some 3-manifold of fixed topology. Because people have, until recently, been loathe to consider closed timelike curves as physically possible, Geroch's theorem has usually been interpreted as a selection rule forbidding topology change at the classical level. But like most No Go Theorems in physics, its basic assumptions have come to be questioned, and a number of physicists have begun to take seriously closed timelike curves and time machines and even to ask whether the laws of physics forbid in principle the construction of wormholes in the laboratory and their subsequent use as time machines.

2.4 Spinorial Selection Rules

In my opinion a potentially much worse pathology for a spacetime is for it not to admit an $SL(2, C)$ spinor structure, since it is difficult according to our present understanding of matter to imagine a world without fermions described by fundamental spinor fields. If spacetime M is a product of a closed time interval and a compact 3-manifold it must necessarily admit an $SL(2, C)$ spinor structure but if it is not a product it need not. Bichteler (1968) and Geroch (1968,1970) pointed out that the necessary and sufficient condition for the existence of a spinor structure in this case is the vanishing of the second Stiefel Whitney class of the 4-manifold M. Stephen Hawking and I (1992a, 1992b) have recently obtained an interesting extension of Geroch's results. We find that the Lorentzian spacetime M will admit an $SL(2, C)$ spinor structure if and only if a certain mod 2 topological invariant $u(\Sigma)$ of the spacelike boundary vanishes. Since the invariant is additive under disjoint union:

$$u(\Sigma_1 \cup \Sigma_2) = u(\Sigma_1) + u(\Sigma_2) \mod 2$$

one may interpret our result as giving a topological conservation law for 3-manifolds. The invariant takes the value one for S^3 and zero for the wormhole, $S^1 \times S^2$. It follows that it is not possible even in principle to construct a wormhole in the laboratory in order, for example, to build a time machine. However under connected sum our invariant satisfies:

$$u(\Sigma_1 \# \Sigma_2) = u(\Sigma_1) + u(\Sigma_2) + 1 \mod 2.$$

Thus it takes the value zero for the connected sum of two wormholes. Our selection rule therefore allows the construction of a pair of wormholes in the laboratory. On the other hand it does not allow the birth of a single S^3 universe from nothing or a trouser-leg spacetime in which one S^3 universe splits into two, even though there are perfectly good Lorentzian spacetimes of this sort without spinor structure . An example would be CP^2 with three points removed.

Our invariant may be calculated in terms of the mod 2 homology groups of the boundary manifold Σ. It is called by mathematicians the mod 2 Kervaire semi-characteristic. The formula is:

$$u(\Sigma) = \dim_{Z_2}(H_0(\Sigma; Z_2) \oplus H_1(\Sigma; Z_2)) \mod 2.$$

The first term counts the connected components of Σ and the second term counts, roughly speaking, the number of wormholes or handles.

2.5 Singularities

So far we have been ignoring the field equations. If we take them into account we soon encounter more difficulties. The topologically non-trivial initial data sets we have been considering will in general possess apparent horizons and closed trapped surfaces. In the time-symmetric case for example, it is easy to see (Gibbons 1972) that the minimal 2-spheres (they must be topologically spheres if they are truly minimal by a simple application of the formula for the second variation of the area and the Gauss-Bonnet theorem) are also apparent horizons. Thus one expects, by the Singularity Theorems of Penrose and Hawking, that the future evolution will contain spacetime singularities. If our usual beliefs about Cosmic Censorship and Black Hole

Physics are true these singularities should be hidden inside event horizons outside of which the metric should settle down to one of the stationary solutions allowed by the Black Hole Uniqueness Theorems. If this is true, and I have no reason to doubt it, it means that dynamically, apart from providing the apparent horizons, the topology has no real effect on the dynamics. After all the *same* black holes could have been formed from a topologically trivial initial data set just consisting of gravitational waves or from some topologically extremely exotic initial data set, even a non-orientable initial 3-manifold or one allowing "spin without spin". According to our present views all details of any complicated non-trivial topology should in the classical theory of general relativity ultimately be lost in the singularity, and certainly hidden from our view by the event horizon. All of this is in marked contrast to conventional flat space theories admitting solitons where the influence of topology can play a decisive role in the dynamics.

At the classical level therefore it seems that we can conclude at least that:

1) It is difficult to incorporate topology change into the classical theory even at the purely *kinematic* level.
2) If the Einstein Equations hold then dynamics is no respecter of topology.

3 THE QUANTUM THEORY

3.1 Hawking Evaporation and Central Charges

These preliminary conclusions would seem to be reinforced when we turn to the (semi-classical) quantum theory. The classically stable Black Hole final states are no longer stable in the quantum theory but rather undergo Hawking evaporation, ultimately shrinking down to a size below which we cannot reasonably calculate because of our ignorance of the correct theory of quantum gravity. If it is really true that neutral black holes evaporate completely leaving no remnant then it seems reasonable to conclude that topological invariants, unless associated with some conserved charge, are simply not "good quantum numbers" . If the black holes are electrically or magnetically charged however the situation may be different and this is where Wheeler's idea of charge without charge comes in. If a black hole carries a charge which is not carried by the fundamental fields of the theory it can't be radiated away by Hawking evaporation, and it may thus stabilise the hole. In flat space theories with solitons charges of this kind, usually topological in origin, are often called "central" because in the quantum theory they commute with the other observables of the theory.

3.2 Supersymmetry

In supersymmetric theories with N spinorial supercharges Q_i, $i = 1,2,..N$, they may be central charges in the technical sense that central charges appear in the supersymmetry algebra:

$$\{\overline{Q}_i, Q_j\} = \gamma_\mu P^\mu \delta_{ij} + Z_{ij}$$

where $Z_{ij} = -Z_{ji}$ are central charges, and P^μ is the total energy momentum vector of the system. In the simplest case, $N = 2$ when $Z_{12} = -Z_{21} = Z$, it follows that the mass M and central charge Z satisfy the Bogomolnyi bound:

$$M \geq |Z|$$

with equality if and only if the soliton is partially supersymmetric in the sense that it is invariant under half the maximum number of supersymmetries.

The obvious model theory to which to apply these ideas is $N = 2$ supergravity theory, that is the supersymmetric extension of Einstein Maxwell theory.The fundamental degrees of freedom make up a supermultiplet consisting of the graviton, the photon and two (electrically neutral) Majorana gravitini. These three particles carry neither electric nor magnetic charge so either type of "charge without charge" is a candidate as a "central charge" (Gibbons, 1981). Moreover the $N = 2$ supergravity theory shares the duality invariance of its purely bosonic sector provided one extends the symmetry to the spin $\frac{3}{2}$ gravitini by means of precisely the type of chiral rotation to be found in "Geometrodynamics" applied to the spin $\frac{1}{2}$ neutrino field. Gratifyingly the whole story works out rather well. Witten's proof of the Positive Energy Theorem may be extended to the Einstein-Maxwell theory (Gibbons and Hull 1982, Gibbons, Hawking, Horowitz and Perry 1983) to bound from below the mass M of any initial data set regular outside an apparent horizon and carrying total electric charge Q and magnetic charge P consistent with the Cosmic Censorship Hypothesis:

$$M \geq \frac{\sqrt{(Q^2 + P^2)}}{\sqrt{(4\pi G)}}.$$

If one has equality, then any regular solution must be one of the static multi-black hole solutions of Papapetrou and Majumdar admitting 4 out of a possible maximum of 8 Majorana Killing spinors, that is (considered as a Supergravity solution) it has half the maximum number of supersymmetries. It is illuminating to view this from the point of view of the supersymmetric ground states or vacua of the $N = 2$ supergravity theory (Gibbons 1984)

A minimal requirement of a vacuum is that it be spacetime homogeneous, and to be fully supersymmetric it should admit the maximum number of supersymmetries, i.e. 8 Majorana Killing spinors. For the $N = 2$ theory there are two such ground states:

1) Flat spacetime with vanishing electromagnetic field.

2) The Robinson–Bertotti solution, which is homogeneous but anisotropic and whose electromagnetic field is homogeneous in space and time.

The Robinson-Bertotti solution may be thought of as a compactified state of the theory, since it is a metric product of the 2-sphere and 2-dimensional anti-de-Sitter spacetime. Both of these ground states appear to be stable against small perturbations subject to suitable boundary conditions. Now the typical behaviour of a supersymmetric soliton is that it admits half the maximum number of supersymmetries and spatially interpolates between two distinct vacua or ground states of the theory. The extreme Reissner-Nordstrom solution does just that. It is asymptotically flat but in the extreme limit the Einstein-Rosen throat becomes infinitely long and the geometry near the horizon is well approximated by the Robinson-Bertotti solution. In common with other supersymmetric solitons the extreme black holes may be fitted into a so-called shortened supermultiplet (Gibbons 1981, Gibbons and Hull 1982, Gibbons 1982a). One also has solutions in which the asymptotically flat region is replaced by another asymptotically Robinson-Bertotti like region (Whitt 1985). Brill (1992) has recently interpreted these as mediating the splitting of black holes, but in view of the stability of Robinson-Bertotti ground state this interpretation may encounter difficulties, particularly in a supersymmetric theory. The creation of pairs of black holes from a Melvin background, which will be described later, seems to me physically more plausible.

3.3 Solitons and Moduli

As mentioned above, in addition to the single soliton solution, i.e. the extreme Reissner-Nordstrom solution, there are multi-soliton solutions. These describe an arbitrary number, k, say of extreme black holes placed at k arbitrary positions and having k arbitrary masses. The moduli space is given by k distinct points in R^3, possibly quotiented by the symmetric group on k objects if the masses are all equal and the black holes are regarded as being identical. The black holes are in equipoise because, at rest, their gravitational attraction is just balanced by their electromagnetic repulsion. If they are given a small amount of kinetic energy the subsequent motion may be described as a one–parameter family of static solutions or as a curve in the moduli space. The curve is in fact a geodesic with respect to a certain non-flat metric on the moduli space (Gibbons and Ruback 1986, Eardley and Ferrell 1987, 1989) which has been calculated fully in the case $k = 2$ and in the limit of large separations for general k. Although far from the case of astrophysical interest suggested originally by Dennis, and in an approximation in which gravitational radiation is neglected, I feel that it is note-worthy that the original programme of Einstein and Rosen can be carried sufficiently far that equations of motion for solitons can can actually be worked out in considerable detail. One may even consider the non-relativistic quantum mechanics of the solitons by studying a Schroedinger equation on the moduli space (Gibbons and Ruback 1986, Ferrell and Traschen 1992). The quantum mechanics of these solitons from the supergravity point of view has been treated in great detail in a series of papers by the Viennese group (Aichelburg and Embacher 1988).

3.4 Quantum Corrections

I want now to turn to the quantum properties of these supersymmetric solitons. The first and most obvious point to reiterate is that since they have zero surface gravity and hence zero Hawking temperature and because the graviton, photon and gravitini carry no charge, they are stable against thermal evaporation in. In fact a general non-extreme Reissner-Nordstrom black hole can only reduce its mass but not its charge by emitting Hawking radiation. If the ratio M^2/Z^2 exceeds 3/4 it will get hotter as it does so but as soon as this ratio falls below 3/4 the specific heat at constant charge becomes positive and thereafter the evolution slows down and the hole coasts towards the extreme state.

Another question concerns the quantum corrections to the geometry and whether or not the formula for the entropy for example, which may be calculated using a functional integral approach in which one evaluates the partition function for quantum gravity, is still given by one quarter of the area of the event horizon. Since the Papapetrou-Majumdar solutions belong to the general class of Israel-Wilson metrics which include the self-dual multi-centre metrics and all of these metrics admit Killing spinors, it always seemed to me quite likely that the quantum corrections should vanish. Indeed one motivation for studying this type of black hole, despite its lack of obvious astrophysical application, has always been that in supergravity theories the divergence difficulties which make it so difficult to make any kind of definitive prediction about the ultimate outcome of the thermal evaporation process in pure general relativity might to some extent be obviated. This optimism has been recently been reinforced by the work of Renata Kallosh (1992) who has shown, using superfield techniques, that indeed the quantum corrections do cancel in rather the same fashion that they do around self-dual backgrounds.

3.5 Black Hole Pair Creation

This still leaves open the question of why one should not simply ignore solitons of this sort. One might feel that since they appear to be absolutely stable, if the world contained none to begin with they would be irrelevant. The answer to this argument in conventional flat space theories is well known, and is that if it is possible to pair–produce soliton–anti–soliton pairs during high energy collisions or in extremely strong external fields, then it would be *inconsistent* to ignore their existence. In particular closed loops describing virtual soliton-anti-soliton creation and annihilation should in principle be included as a contribution to all processes. This is not necessarily true for neutral black holes which it seems do not correspond to stable states and should not therefore be included in a complete set of intermediate states. Moreover it appears that they cannot be created in pairs in pure general relativity with a vanishing cosmological term, although there are some indications that this is possible if there is a positive cosmological term (Gibbons 1992). Therefore one should ask whether one can pair–produce electrically or magnetically charged black holes using strong electromagnetic fields.

3.6 Real Tunneling Geometries

To answer this question and others about the possibility of topology change via quantum tunneling, I would like to recall the main features of an approach to such tunneling in the path integral approach to quantizing gravity. The basic idea is that one should be able to approximate the path integral by classical paths, i.e. solutions of the classical equations of motion, which have a Lorentzian portion in the future but which may in general be complex. A particularly simple class of complex paths which seem to include all the cases they have arisen "in practice" are those which Hartle and I (Gibbons and Hartle 1990) have called "Real Tunneling Geometries" .

A Real Tunneling Geometry may be regarded as a triple $\{M_R, \Sigma, M_L\}$ consisting of a complete Riemannian manifold M_R with a totally geodesic boundary $\Sigma = \partial M_R$ and a Lorentzian manifold M_L for which Σ is a Cauchy surface with vanishing second fundamental form. By glueing two copies of the Riemannian manifold M_R across the boundary Σ to obtain the double $2M_R$ one obtains a a particular kind of Gravitational Instanton, one admitting a reflection map θ stabilizing the surface Σ. The simplest and most frequently encountered case (at least in the pages of some physics journals if not in the real world) is when M_R is half of the 4-sphere with its standard round metric and M_L is half of de-Sitter spacetime to the future of a surface of time symmetry. This is the basis for many discussions for example of the "creation of the universe from nothing" considered as some sort of tunneling event, with Σ playing the role of the beginning of time. It seems reasonable to take the existence of a solution of the classical equations of motion which has the form of a Real Tunneling Geometry for which the classical action of the the Riemannian portion M_R is finite, as some sort of *a priori* evidence that a tunneling process can take place in which a spacetime or portion of spacetime with spatial topology given by Σ suddenly materializes. By the same token, the non-existence of a solution for a particular topology for Σ may be interpreted as quantum mechanical selection rule forbidding that particular topological transition at the lowest semi -classical level.

3.7 The Ernst-Melvin Instanton

The question that we must now ask is whether there exists a Real Tunneling Geometries involving pairs of black holes. My first thought (Gibbons 1986) was to turn to the C-metrics. These represent uniformly accelerating black holes, charged or neutral, and possess both black hole horizons and acceleration horizons. They have two hypersurface orthogonal Killing fields, one $\frac{\partial}{\partial\phi}$ with closed spacelike orbits corresponding to rotations about the direction of motion. The other $\frac{\partial}{\partial t}$ is timelike near infinity but spacelike behind the two types of horizons. Near infinity it behaves like a boost Killing vector rather than a timelike translation. In general the surface gravities of the two types of horizon are different. However in the special case that the mass M and central charge $Z = \sqrt{(Q^2 + P^2)}/\sqrt{(4\pi G)}$ are equal, the two surface gravities are also equal (and non-zero).

It is not possible to choose a range for the angular coordinate ϕ so as to obtain a metric which is everywhere non-singular outside the horizons. No matter what range one picks there always remain conical singularities which may be interpreted as a cosmic string or a cosmic strut depending upon whether the deficit angle is positive or negative. The strut runs from the acceleration horizon to the south pole of the black hole, where south means rear-most with respect to the direction of the acceleration in this context. The string runs from the north-pole of the black hole horizon to infinity. It is possible, by appropriate choice of the range of ϕ, to eliminate either the strut or the string but not both. This is not surprising physically, and may be seen immediately by noting that the solutions has vanishing ADM mass by virtue of the boost invariance at infinity. By the positive mass theorem, generalized to include horizons (Gibbons, Hawking, Horowitz and Perry 1983), there can be no solution which is non-singular everywhere outside the horizons. If there were, we might try to construct an Instanton or Real Tunneling Geometry by adjusting the surface gravities of the acceleration horizon and the black hole horizon to be equal. We would then have a solution which could be analytically continued to purely imaginary values of the time coordinate t. Its existence would have indicated that flat Minkowski spacetime is unstable to the creation of pairs of charged black holes.

Because of the conical singularities, pair creation of black holes from empty Minkowski spacetime is forbidden. It seems more reasonable to expect that they could be created from some strong external field, so we must turn to solutions generalizing the C-metrics representing charged black holes accelerated by an an external electromagnetic field. Such solutions have been constructed by Ernst. If no black hole is present they reduce to the everywhere non-singular static, cylindrically symmetric Melvin solution which is the metric due to a self-gravitating Maxwell flux-tube. Both the metric and the spacetime are also invariant under boosts in the direction of the flux-tube. In fact it may be considered as a rather degenerate limiting case of the solution representing a super-massive Nielsen-Olesen cosmic string in which the Higgs field has decoupled because its electric charge vanishes.

Ernst was able to show that by an appropriate choice of the strength of the appended electromagnetic field all conical singularities could be eliminated for any allowed ratio of charge to mass. This gives a Lorentzian solution of the Einstein-Maxwell equations, non-singular outside the black hole and acceleration horizons, representing a uniformly accelerating black hole. From the point of view of the original programme of Einstein and Rosen this is a remarkable achievement. More significantly for our present purposes it allows us, by choosing the case $M = \sqrt{(Q^2 + P^2)}/\sqrt{(4\pi G)}$ to obtain a Real Tunneling Geometry with a complete Riemannian portion M_R. The surface Σ has the topology of a Wheeler wormhole, i.e. $S^1 \times S^3$. The solution has two arbitrary constants, the charge or mass of the hole and the strength of the external electromagnetic field.

The amplitude for the creation of pairs depends on the classical action of the Riemannian portion of the complex path. In the limit when the black hole is very small compared with the scale set by the background electromagnetic field one obtains a tunneling pre-factor for the amplitude which agrees with what one would expect if one thought of black holes as a point particles and applied the well known formula due to Schwinger for the rate of their creation (Garfinkle and Strominger 1991).

I believe that the results I have described above clearly indicate that although topology appears not to play an important role in pure general relativity, its effects can be significant in theories like Einstein-Maxwell theory admitting central charges. Moreover the phenomenon of pair creation means that it is inconsistent to ignore it at the quantum level. I have discussed this process above using some of the ideas of what is often called Euclidean Quantum Gravity, but physical intuition strongly suggests that if the semi-classical picture makes any sense at all the this will continue to be true regardless of what formalism one quantizes with.

3.8 Dilatons and Strings

The picture may change radically however if one includes the effects of massless scalar fields such as the dilaton and the axion which arise in supergravity theories, Kaluza-Klein theories, and superstring theory. Currently there is a great deal of activity in this area. I will confine myself to a few remarks which will only hint at the richness and variety of the new considerations that come into play. Because of the coupling of the dilaton and axion to the various abelian gauge fields in these theories, the scalar no-hair theorems no longer hold in the literal sense that the dilaton and axion fields must be spacetime independent. There are still central charges, and if these are non-zero then a black hole must have an associated scalar or pseudoscalar field but its strength is entirely determined by the central charges. There are no independent degrees of freedom connected with the scalars (Gibbons 1982b). It turns out that the thermodynamic properties of this more general class of black holes can be very different from those of Einstein-Maxwell black holes. Moreover they are rather sensitive to the coupling constant governing the interaction between the dilaton and the abelian gauge fields. The value that arises in superstring theory is a critical case (Gibbons and Maeda 1988). This is particularly intriguing because one expects in any case to have to turn to string theory in order to make sense of the quantum theory. This indicates at the very least that its effects on the issue of topology change may well prove to be decisive but that is a topic for some future celebration looking back over the even more distinguished and influential career of Dennis Sciama.

of coordinates, for example polar or Cartesian coordinates, conventional elliptic elements, or Delaunay variables, for a given problem. It also requires discussion of control modeling and parameterization, grid refinement, and transformations of coordinates required for interplanetary flight when a spacecraft leaves the sphere of influence (SOI) of one body and enters another. Another important topic is the successful generation of an initial guess of the solution, that is, a guess of the optimal trajectory that is sufficiently accurate that the NLP solver can improve on it and converge to the local minimum of the objective.

3.2 Transcription Methods

3.2.1 A Basic Collocation Method (Using Hermite Polynomials)

This classic approach transforms an optimal control problem into a nonlinear programming problem. To do this, the state functions $x(t)$ and control functions $u(t)$ are represented by piecewise polynomials and collocation is used to satisfy the differential equations of motion. The first step with this approach is to subdivide the problem into a sequence of smaller trajectory arcs, which we will call phases. The length of each phase is defined as $T_{pi} = E_{i+1} - E_i$. For each phase, the interval $[E_i, E_{i+1}]$ is further subdivided into N segments, as shown in Figure 3.1.

Let the ratio of the length of the jth segment to T_{pi} be denoted as τ_{ji}. Thus, the length of the jth segment in the ith stage is $\tau_{ji}\ T_{pi}$. Using Hermite interpolation, cubic polynomials are defined for each state on each segment using values of the states at the nodes (the boundaries at the segments) and the state time derivatives, as defined by the equations, at the nodes. The values of the states are then selected (by nonlinear programming) to force the interpolated derivatives to agree with the differential equations at the center of the segment. This procedure is illustrated in Figure 3.2.

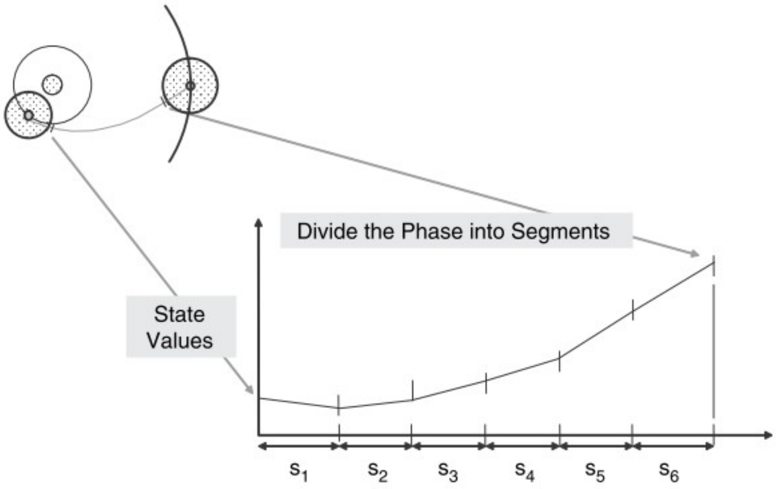

Figure 3.1. Trajectory optimization problem broken into phases.

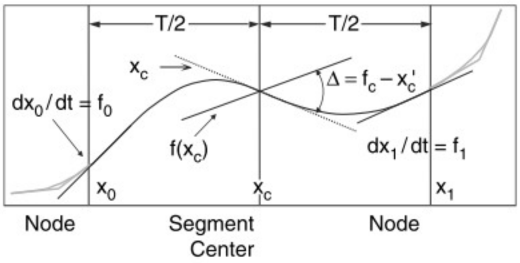

Figure 3.2. Illustration of implicit integration.

The basic procedure can be derived for any polynomial order. The classic cubic derivation is as follows. Let the states x be represented on each segment by cubics of the form

$$x = C_0 + C_1 S + C_2 S^2 + C_3 S^3 \tag{3.1}$$

where to simplify the discussion, the segment length S is transformed such that $S \in [0, 1]$. Let $x(0) = x_0$, $x(l) = x_1$, $dx/ds(0) = x_0'$, $dx/ds(l) = x_1'$. Differentiating Equation (3.1) and evaluating at $S = 0$ and $S = 1$ yields

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 \end{bmatrix} \begin{bmatrix} C_0 \\ C_1 \\ C_2 \\ C_3 \end{bmatrix} = \begin{bmatrix} x_0 \\ x_0' \\ x_1 \\ x_1' \end{bmatrix}. \tag{3.2}$$

Inverting the 4 × 4 matrix yields

$$\begin{bmatrix} C_0 \\ C_1 \\ C_2 \\ C_3 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ -3 & -2 & 3 & -1 \\ 2 & 1 & -2 & 1 \end{bmatrix} \begin{bmatrix} x_0 \\ x_0' \\ x_1 \\ x_1' \end{bmatrix}. \tag{3.3}$$

Now using Equation (3.3), evaluating Equation (3.1) at $S = 1/2$, and transforming to segment length $T = g\tau_{ji}\, T_{pi}$, we see that the interpolated value of x at the center of the segment is

$$x_c = (x_0 + x_1)/2 + T(f_0 + f_1)/8 \tag{3.4}$$

where f_i, is the time rate of change as defined by the equations of motion evaluated at x_i.

(Note $x_0' = Tf[x_0, u(t_0), t_0, \omega]$.) In the same way, the slope at the center

$$x_c' = -3(x_0 - x_1)/2T - (f_0 - f_1)/8$$

is obtained. Evaluating the equations of motion at x_c gives f_c. We can then define the defect (the error in representing the dynamics) at the center of the segment as

$$\begin{aligned} \Delta &= f_c - x \\ &= f_c + 3(x_0 - x_1)/2T + (f_0 + f_1)/4 \end{aligned} \tag{3.5}$$

x_0 and x_1 are varied to enforce $\Delta = 0$. If the cubic polynomial is capable of representing the solution on the given segment, then selecting x_0 and x_1 to drive Δ to zero will produce an accurate approximation to the solution of the state dynamics. The defects for each state evaluated at the center of each segment constitute a set of nonlinear algebraic equations that are a function of the states and controls at each node, the events E, and the design parameters ω. The controls are defined at $S = [0, 1/2, 1]$. The boundary conditions and the path constraints evaluated at both the nodes and centers of the segments provide additional equations (constraints) to be satisfied. All of the independent variables may be collected into a single vector P defined by

$$P^T = [Z^T, E^T, \omega^T] \tag{3.6}$$

Where

$$Z^T = [x_0^T, u_0^T, x_1^T, u_1^T, \ldots\ldots x_{N+1}^T, u_{N+1}^T). \tag{3.7}$$

Collecting all of the nonlinear equations into a single vector equation yields

$$C^T = (\Delta^T, B_{N,}^T H_N^T) \tag{3.8}$$

with

$\Delta^T = (\Delta_{00}, \Delta_{01}, \ldots, \Delta_{\mathrm{ij}} \ldots)$ where $\Delta_{\mathrm{ij}} =$ defect for ith state at jth node
$B_N =$ collection of all boundary conditions
$H_N =$ collection of all path constraints

The performance index J is just a function of P. The trajectory optimization problem stated above can be expressed as: minimize $\Phi(P)$, subject to

$$l \leq \begin{Bmatrix} P \\ AP \\ C(P) \end{Bmatrix} \leq u\,. \tag{3.9}$$

AP is composed of all the linear relationships from Equation (3.8), l and u are the upper and lower bounds for the parameter vector. For equality constraints $l = u$. The upper and lower bounds for the great majority of the nonlinear constraints are usually set to zero, because this forces the solver to choose values for the parameters that satisfy the EOMs. (There may be a small number of additional nonlinear constraints, for example boundary conditions).

System (3.6)–(3.9) constitutes a nonlinear programming problem.

The extension of the preceding analysis to higher order integrators is straightforward. Again, a phase is subdivided into segments. The segments do not need to be of equal length. The rule of thumb, analogous to multistep explicit integrators, is that more segments should be placed where there are rapid changes in the states, controls or constraints.

Within a segment, the values of the states and controls are defined at discrete time points called nodes. For convenience, we define the placement of the nodes relative to the normalized segment lengths. An example set of nodes within a segment is shown in Figure 3.3.

The placement of nodes within a segment can be arbitrary; however, experience has shown benefits to placing the nodes at the Legendre-Gauss-Lobatto (LGL) points. This is accomplished by mapping the segment onto the interval −1 to 1 and using the LGL points in "standard" form. The odd points are called cardinal nodes (τ_1, τ_3, τ_5), while the even points (τ_2, τ_4) are labeled interior nodes. Typically, the number of cardinal nodes per segment is constant within a phase.

The state values specified at the cardinal nodes will be used as parameters for the resulting nonlinear programming problem, while the state values at the interior nodes will be obtained by interpolation. The equations of motion are evaluated to provide time derivative values at the cardinal nodes. Making use of both states values and their time derivatives at the cardinal nodes, Hermite interpolation is used to construct a polynomial representation of the states. This polynomial representation is then evaluated at the interior nodes to compute interpolated values of the states, which in turn are used to compute the state time derivatives at the interior nodes by evaluating the equations of motion. The polynomial representation is also differentiated and evaluated at the interior nodes to compute yet another set of time derivatives. The differences between the slopes as defined by the state representation and the equations of motion at the interior nodes are called the defects. The control functions are represented by values at both the cardinal and interior nodes. This procedure is illustrated in Figure 3.4.

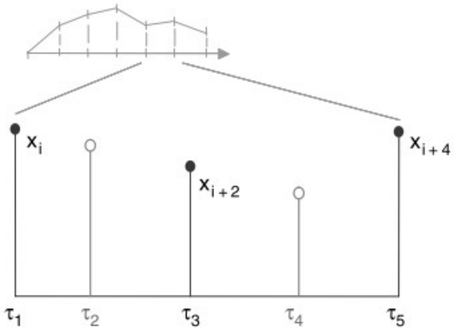

Figure 3.3. Cardinal node segment structure.

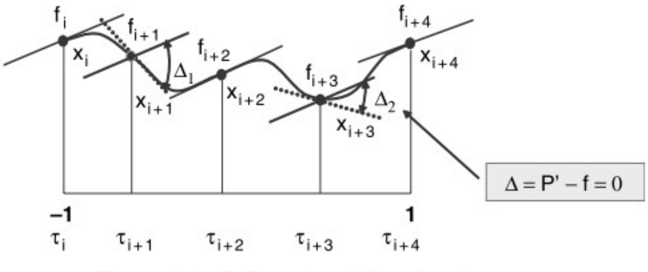

Figure 3.4. Collocation defect development.

This procedure can also be summarized as:
Using a Hermite interpolating polynomial, for each state, we can write

$$x(\tau) = \{u(\tau)\}^T \{x\} + \{v(\tau)\}^T \{f\} = \sum_{i=1}^{(n+1)/2} u_i(\tau) x(\tau_i) + \sum_{i=1}^{(n+1)/2} v_i(\tau) f(\tau_i). \tag{3.10}$$

The state values at the interior nodes can then be computed as

$$\{x_*\} = [E]\{x\} + \frac{T}{2}[F]\{f\}. \tag{3.11}$$

The matrices $[E]$ and $[F]$ are determined from the Hermite polynomial; T is segment length in "dimensional" time. This also allows

$$x'(\tau) = \{u'(\tau)\}^T \{x\} + \{v'(\tau)\}^T \{f\} = \sum_{i=1}^{(n+1)/2} u_i'(\tau) x(\tau_i) + \sum_{i=1}^{(n+1)/2} v_i'(\tau) f(\tau_i) \tag{3.12}$$

Applying our definition of defect, the vector $\{\Delta\}$ of defects at the interior nodes is

$$\{\Delta\} = [A]\{x\} + \frac{T}{2}[B]\{f\} + \frac{T}{2}[C]\{f_*\}. \tag{3.13}$$

with

$\{x\}$	states at the cardinal nodes
$\{f\}$	slopes from the equations of motion at the cardinal nodes
$\{f_*\}$	slopes from the equations of motion at the interior nodes, x_*
T	segment length (needed to convert from "τau" space to "dimensional" time
$[A]$	Matrix of constants
$[B]$	Matrix of constants
$[C]$	Identity Matrix multiplied by -1

The elements of $[A]$ and $[B]$ are just

$$a_{i,j} = u_j'(\tau_i)$$
$$b_{i,j} = v_j'(\tau_i)$$

which are easily built by applying the product rule of differentiation to ACM algorithm 211 [16] (used to compute $u \& v$)

$$u_j(\tau) = \left[\prod_{\substack{i=1 \\ i \neq j}}^{(n+1)/2} \left(\frac{(\tau - \tau_i)}{(\tau_j - \tau_i)} \right)^2 \right] \cdot \left(1 - (\tau - \tau_j) \cdot 2 \cdot \sum_{\substack{i=1 \\ i \neq j}}^{(n+1)/2} \frac{1}{(\tau_j - \tau_i)} \right)$$

$$v_j(\tau) = \left[\prod_{\substack{i=1 \\ i \neq j}}^{(n+1)/2} \left(\frac{(\tau - \tau_i)}{(\tau_j - \tau_i)} \right)^2 \right] \cdot (\tau - \tau_j). \tag{3.14}$$

Notice that the elements of $[A]$, $[B]$, $[C]$, $[D]$, $[E]$, and $[F]$ only depend on the values of τ (the node locations), which are fixed. This means that the matrices need only to be computed once and stored. Combining the segments results in the matrices taking on a banded structure, as shown below for a 2 segment, 3 cardinal node case

$$\begin{Bmatrix} \Delta_1 \\ \Delta_2 \\ \Delta_3 \\ \Delta_4 \end{Bmatrix} = \begin{bmatrix} -1.6654 & 1.4963 & 0.1701 & 0 & 0 \\ -0.1701 & 1.4963 & 1.6654 & 0 & 0 \\ 0 & 0 & -1.6654 & 1.4963 & 0.1701 \\ 0 & 0 & -0.1701 & 1.4963 & 1.6654 \end{bmatrix} \begin{Bmatrix} x_1 \\ x_3 \\ x_5 \\ x_7 \\ x_9 \end{Bmatrix}$$

$$+ \frac{T}{2} \begin{bmatrix} -0.1386 & -0.6530 & -0.0450 & 0 & 0 \\ -0.0450 & -0.6530 & -0.1386 & 0 & 0 \\ 0 & 0 & -0.1386 & -0.6530 & -0.0450 \\ 0 & 0 & -0.0450 & -0.6530 & -0.1386 \end{bmatrix} \begin{Bmatrix} f_1 \\ f_3 \\ f_5 \\ f_7 \\ f_9 \end{Bmatrix}$$

$$+ \frac{T}{2} \begin{bmatrix} -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix} \begin{Bmatrix} f_2 \\ f_4 \\ f_6 \\ f_8 \end{Bmatrix} \tag{3.15}$$

Again we combine the state values at the cardinal nodes, along with the event times and design parameters, in a single array Z. A constraint array is assembled from the boundary conditions, defects, and path constraint. This results in a tractable nonlinear programming problem.

3.2.2 Pseudospectral Methods

Pseudospectral techniques have gained popularity within the last several years [17] [18] [19] [20]. They are very similar to the method of collocation. The major differences are with the manner in which the representative polynomial is constructed and the computation of the defects. When the pseudospectral method is employed, a polynomial representation of the states is formed and a number of constraints are enforced so that the slopes of the polynomials agree with the differential equations at a finite number of points. Values of the states are established at the cardinal and interior nodes. Making use of the state values, Lagrange interpolation is used to construct a polynomial interpolation of the states. This polynomial is differentiated and evaluated at all the nodes to compute interpolated time derivative values of the states. The equations of motion are evaluated to provide the values of the physical time derivatives. The difference between the two sets of time derivatives forms the defects. The procedure is shown in Figure 3.5.

5. Find the volume of the ellipsoid $\frac{x^2}{a^2}+\frac{y^2}{b^2}+\frac{z^2}{c^2}=1$ **Ans.** $\frac{4\pi abc}{3}$

6. Find the volume bounded by the cylinder $x^2+y^2=a^2$ and the planes $y+z=2a$ and $z=0$.
(*M.U. II Semester 2000, 02, 06*) **Ans.** $2\pi a^3$

7. Find the volume bounded by the cylinder $x^2+y^2=a^2$ and the planes $z=0$ and $y+z=b$.
Ans. $\pi a^2 b$

8. Find the volume of the region bounded by $z=x^2+y^2$, $z=0$, $x=-a$, $x=a$ and $y=-a$, $y=a$.
Ans. $\frac{8}{3}a^4$

9. Find the volume enclosed by the cylinder $x^2+y^2=9$ and the planes $x+z=5$ and $z=0$.
Ans. $45\pi-36$

10. Compute the volume of the solid bounded by $x^2+y^2=z$, $z=2x$.(*A.M.I.E., Summer 2000*)
Ans. 2π

11. Find the volume cut from the paraboloid $4z=x^2+y^2$ by plane $z=4$.
(*U.P. I Semester, Dec. 2005*) **Ans.** 32π

12. By using triple integration find the volume cut off from the sphere $x^2+y^2+z^2=16$ by the plane $z=0$ and the cylinder $x^2+y^2=4x$. **Ans.** $\frac{64}{9}(3\pi-4)$

13. The sphere $x^2+y^2+z^2=a^2$ is pierced by the cylinder $x^2+y^2=a^2(x^2-y^2)$.

Prove that the volume of the sphere that lies inside the cylinder is $\frac{8}{3}\left[\frac{\pi}{4}+\frac{5}{3}-\frac{4\sqrt{2}}{3}\right]a^3$.

14. Find the volume of the solid bounded by the surfaces $z=0$, $3z=x^2+y^2$ and $x^2+y^2=9$.
(*A.M.I.E.T.E., Summer 2005*) **Ans.** $\frac{27\pi}{2}$

15. Obtain the volume bounded by the surface $z=c\left(1-\frac{x}{a}\right)\left(1-\frac{y}{b}\right)$ and a quadrant of the elliptic cylinder $\frac{x^2}{a^2}+\frac{y^2}{b^2}=1$, $z>0$ and where a, $b>0$. **Ans.** πabc (*A.M.I.E.T.E., Dec. 2005*)

16. Find the volume of the paraboloid $x^2+y^2=4z$ cut off by the plane $z=4$. **Ans.** 32π

17. Find the volume bounded by the cone $z^2=x^2+y^2$ and the paraboloid $z=x^2+y^2$. **Ans.** $\frac{\pi}{6}$

18. Find the volume enclosed by the cylinders $x^2+y^2=2ax$ and $z^2=2ax$. **Ans.** $\frac{128a^3}{15}$

19. Find the volume of the solid bounded by the plane $z=0$, the paraboloid $z=x^2+y^2+2$ and the cylinder $x^2+y^2=4$. **Ans.** 16π

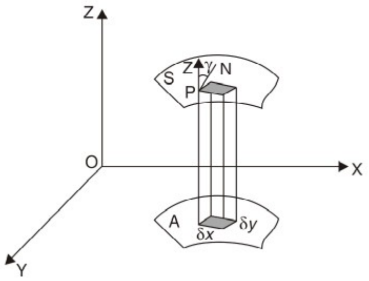
20. The triple integral $\iiint dx\,dy\,dz$ gives
(*a*) Volume of region (*b*) Surface area of region T
(*c*) Area of region *T* (*d*) Density of region *T*. (*A.M.I.E.T.E., Dec. 2006, 2002*) **Ans.** (*a*)

2.16 SURFACE AREA

Let $z=f(x,y)$ be the surface S. Let its projection on the x-y plane be the region A. Consider an element $\delta x.\ \delta y$ in the region A. Erect a cylinder on the element $\delta x.\ \delta y$ having its generator parallel to OZ and meeting the surface S in an element of area δs.

$$\therefore \qquad \delta x\ \delta y=\delta s\cos\gamma,$$

Where γ is the angle between the xy-plane and the tangent plane to S at P, *i.e.,* it is the angle between the Z-axis and the normal to S at P.



Created with Print2PDF. To remove this line, buy a license at: http://www.software602.com/

The direction cosines of the normal to the surface $F(x, y, z) = 0$ are proportional to

$$\frac{\partial F}{\partial x}, \frac{\partial F}{\partial y}, \frac{\partial F}{\partial z}$$

$\therefore$ The direction of the normal to $S\ [F = f(x, y) - z]$ are proportional to $-\frac{\partial z}{\partial x}, -\frac{\partial z}{\partial y}, 1$ and those of the Z-axis are 0, 0 , 1.

$$\text{Direction cosines} = \frac{-\frac{\partial z}{\partial x}}{\sqrt{\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1}}, \frac{-\frac{\partial z}{\partial y}}{\sqrt{\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1}}, \frac{1}{\sqrt{\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1}},$$

Hence
$$\cos\gamma = \frac{1}{\sqrt{\left[\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1\right]}} \quad (\cos\theta = l_1 l_2 + m_1 m_2 + n_1 n_2)$$

$$\delta S = \frac{\delta x\, \delta y}{\cos\gamma} = \sqrt{\left[\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1\right]}\, \delta x\, \delta y\ ; \quad S = \iint_A \sqrt{\left[\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1\right]}\, dx\, dy$$

Example 55. *Find the surface area of the cylinder* $x^2 + z^2 = 4$ *inside the cylinder* $x^2 + y^2 = 4$.

Solution. $x^2 + y^2 = 4$

$$2x + 2z\frac{\partial z}{\partial x} = 0 \text{ or } \frac{\partial z}{\partial x} = -\frac{x}{z}, \ \frac{\partial z}{\partial y} = 0$$

$$\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1 = \frac{x^2}{z^2} + 1 = \frac{x^2 + z^2}{z^2} = \frac{4}{4 - x^2}$$

Hence, the required surface area $= 8\int_0^2 \int_0^{\sqrt{4-x^2}} \sqrt{\left[\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1\right]}\, dx\, dy$

$$= 8\int_0^2 \int_0^{\sqrt{4-x^2}} \frac{2}{\sqrt{4-x^2}}\, dx\, dy = 16\int_0^2 \frac{1}{\sqrt{4-x^2}}\, [y]_0^{\sqrt{4-x^2}}\, dx = 16\int_0^2 \frac{1}{\sqrt{4-x^2}}\, [\sqrt{4-x^2}]\, dx$$

$= 16\int_0^2 dx = 16\,(x)_0^2 = 32$ **Ans.**

Example 56. *Find the surface area of the sphere* $x^2 + y^2 + z^2 = 9$ *lying inside the cylinder* $x^2 + y^2 = 3y$.

Solution.
$$x^2 + y^2 + z^2 = 9$$
$$2x + 2z\frac{\partial z}{\partial x} = 0, \quad \frac{\partial z}{\partial x} = -\frac{x}{z}$$
$$2x + 2z\frac{\partial z}{\partial y} = 0, \quad \frac{\partial z}{\partial y} = -\frac{y}{z}$$

$$\left[\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1\right] = \frac{x^2}{z^2} + \frac{y^2}{z^2} + 1 = \frac{x^2 + y^2 + z^2}{z^2} = \frac{9}{9 - x^2 - y^2} = \frac{9}{9 - r^2} \quad \begin{bmatrix} x = r\cos\theta \\ y = r\sin\theta \end{bmatrix}$$

$$x^2 + y^2 = 3y \text{ or } r^2 = 3r\sin\theta \text{ or } r = 3\sin\theta.$$

Hence, the required surface area

$$= \iint \sqrt{\left[\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1\right]}\, dx\, dy = 4\int_0^{\pi/2}\int_0^{3\sin\theta} \frac{3}{\sqrt{9 - r^2}}\, r\, d\theta\, dr = 12\int_0^{\pi/2} d\theta \int_0^{3\sin\theta} \frac{r\, dr}{\sqrt{9 - r^2}}$$

$$= 12\int_0^{\pi/2} d\theta\, [-\sqrt{9 - r^2}]_0^{3\sin\theta} = 12\int_0^{\pi/2} [-\sqrt{9 - 9\sin^2\theta} + 3]\, d\theta$$

Created with Print2PDF. To remove this line, buy a license at: http://www.software602.com/

$$= 36 \int_0^{\pi/2} (-\cos\theta + 1)\, d\theta = 36\,(-\sin\theta + \theta)_0^{\pi/2} = 36\left(-1 + \frac{\pi}{2}\right) = 18\,(\pi - 2)$$ **Ans.**

Example 57. *Find the surface area of the section of the cylinder $x^2 + y^2 = a^2$ made by the plane $x + y + z = a$.*

Solution.
$$x^2 + y^2 = a^2 \qquad \ldots (1)$$
$$x + y + z = a \qquad \ldots (2)$$

The projection of the surface area on *xy*-plane is a circle
$x^2 + y^2 = a^2$

$$1 + \frac{\partial z}{\partial x} = 0 \quad \text{or} \quad \frac{\partial z}{\partial x} = -1$$
$$1 + \frac{\partial z}{\partial y} = 0 \quad \text{or} \quad \frac{\partial z}{\partial y} = -1$$
$$\sqrt{\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1} = \sqrt{(-1)^2 + (-1)^2 + 1} = \sqrt{3}$$

Hence the required surface area

$$= 4 \int_0^a \int_0^{\sqrt{a^2 - x^2}} \sqrt{\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1}\; dx\, dy = 4 \int_0^a \int_0^{\sqrt{a^2 - x^2}} \sqrt{3}\, dx \cdot dy$$
$$= 4\sqrt{3} \int_0^a [y]_0^{\sqrt{a^2 - x^2}}\, dx = 4\sqrt{3} \int_0^a \sqrt{a^2 - x^2}\, dx$$
$$= 4\sqrt{3}\left[\frac{x}{2}\sqrt{a^2 - x^2} + \frac{a^2}{2}\sin^{-1}\frac{x}{a}\right]_0^a = 4\sqrt{3}\left[0 + \frac{a^2}{2}\,\frac{\pi}{2}\right] = 4\sqrt{3}\left(\frac{a^2\pi}{4}\right) = \sqrt{3}\,\pi\, a^2$$ **Ans.**

Example 58. *Find the area of that part of the surface of the paraboloid of the paraboloid $y^2 + z^2 = 2\,ax$, which lies between the cylinder, $y^2 = ax$ and the plane $x = a$.*

Solution.
$$y^2 + z^2 = 2\,ax \qquad \ldots (1)$$
$$y^2 = ax \qquad \ldots (2)$$
$$x = a \qquad \ldots (3)$$

Differentiating (1), we get

$$2\,z\,\frac{\partial z}{\partial x} = 2\,a, \quad \frac{\partial z}{\partial x} = \frac{a}{z}$$
$$2y + 2\,z\,\frac{\partial z}{\partial y} = 0, \quad \frac{\partial z}{\partial y} = -\frac{y}{z}$$
$$\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1 = \frac{a^2}{z^2} + \frac{y^2}{z^2} + 1 = \frac{a^2 + y^2}{z^2} + 1 \qquad \left[\begin{array}{l} y^2 + z^2 = 2\,ax \\ z^2 = 2\,ax - y^2 \end{array}\right]$$
$$= \frac{a^2 + y^2}{2\,a\,x - y^2} + 1 = \frac{a^2 + y^2 + 2\,a\,x - y^2}{2\,a\,x - y^2} = \frac{a^2 + 2\,a\,x}{2\,a\,x - y^2}$$
$$S = \int_0^a \int_{-\sqrt{ax}}^{\sqrt{ax}} \sqrt{\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1}\; dx\, dy = \int_0^a \int_{-\sqrt{ax}}^{\sqrt{ax}} \sqrt{\frac{a^2 + 2\,ax}{2\,ax - y^2}}\, dx\, dy \qquad \left[\begin{array}{c} y^2 = ax \\ y = \pm\sqrt{ax} \end{array}\right]$$
$$= \sqrt{a} \int_0^a \int_{-\sqrt{ax}}^{\sqrt{ax}} \sqrt{\frac{a + 2\,x}{2\,ax - y^2}}\, dx\, dy = \sqrt{a} \int_0^a \sqrt{a + 2\,x}\, dx \int_{-\sqrt{ax}}^{\sqrt{ax}} \frac{1}{\sqrt{2\,ax + y^2}}\, dy$$

$$= \sqrt{a}\int_0^a \sqrt{a+2x}\,dx\left[\sin^{-1}\frac{y}{\sqrt{2ax}}\right]_{-\sqrt{ax}}^{\sqrt{ax}}$$

$$= \sqrt{a}\int_0^a \sqrt{a+2x}\,dx\left[\sin^{-1}\frac{1}{\sqrt{2}}-\sin^{-1}\left(-\frac{1}{\sqrt{2}}\right)\right] = \sqrt{a}\int_0^a \sqrt{a+2x}\,dx\left[\frac{\pi}{4}-\left(\frac{\pi}{4}\right)\right]$$

$$= \sqrt{a}\,\frac{\pi}{2}\int_0^a \sqrt{a+2x}\,dx = \frac{\pi}{2}\cdot\frac{\sqrt{a}}{2}\cdot\frac{2}{3}[(a+2x)^{3/2}]_0^a$$

$$= \frac{\pi\sqrt{a}}{6}[(3a)^{3/2}-a^{3/2}] = \frac{\pi a^2}{6}[3\sqrt{3}-1] \qquad \textbf{Ans.}$$

EXERCISE 2.11

1. Find the surface area of sphere $x^2 + y^2 + z^2 = 16$. **Ans.** 64π
2. Find the surface area of the portion of the cylinder $x^2 + y^2 = 4y$ lying inside the sphere $x^2 + y^2 + z^2 = 16$. **Ans.** 64.
3. Show that the area of surfaces cz = xy intercepted by the cylinder $x^2 + y^2 = b^2$ is $\iint_A \frac{\sqrt{c^2+x^2+y^2}}{c}\,dx\,dy$, where A is the area of the circle $x^2 + y^2 = b^2$, $z = 0$ **Ans.** $\frac{2}{3}\frac{\pi}{c}\left[(c^2+b^2)^{\frac{1}{2}}-c^2\right]$
4. Find the area of the portion of the sphere $x^2 + y^2 + z^2 = a^2$ lying inside the cylinder $x^2 + y^2 = ax$. **Ans.** $2(\pi - 2)a^2$
5. Find the area of the surface of the cone $z^2 = 3(x^2 + y^2)$ cut out by the paraboloid $z = x^2 + y^2$ using surface integral. **Ans.** 6π

2.17 CALCULATION OF MASS

We have,

Volume = $\iint_V dx\,dy\,dz$ Density = $\rho = f(x, y, z)$

[Density = Mass per unit volume] Mass = Volume × Density

Mass = $\iint_V dx\,dy\,dz$ $\boxed{Mass = \iint_V f(x, y, z)\,dx\,dy\,dz}$

Example 59. Find the mass of a plate which is formed by the co-ordinate planes and the plane $\frac{x}{a}+\frac{y}{b}+\frac{z}{c}=1$, the density is given by $\rho = k\,x\,y\,z$. (*U.P., I Semester, Dec.*, 2003)

Solution. The plate is bounded by the planes $x = 0$, $y = 0$, $z = 0$ and $\frac{x}{a}+\frac{y}{b}+\frac{z}{c}=1$.

$$\text{Mass} = \iiint dx\,dy\,dz\,\rho = \int_0^c\int_0^{b\left(1-\frac{z}{c}\right)}\int_0^{a\left(1-\frac{y}{b}-\frac{z}{c}\right)} dx\,dy\,dz\,(k\,xyz)$$

$$= k\int_0^c z\,dz\int_0^{b\left(1-\frac{z}{c}\right)} y\,dy\int_0^{a\left(1-\frac{y}{b}-\frac{z}{c}\right)} x\,dx = k\int_0^c z\,dz\int_0^{b\left(1-\frac{z}{c}\right)} y\,dy\left(\frac{x^2}{2}\right)_0^{a\left(1-\frac{y}{b}-\frac{z}{c}\right)}$$

$$= k\int_0^c z\,dz\int_0^{b\left(1-\frac{z}{c}\right)} y\,dy\,\frac{a^2}{2}\left(1-\frac{y}{b}-\frac{z}{c}\right)^2 = \frac{k\,a^2}{2}\int_0^c z\,dz\int_0^{b\left(1-\frac{z}{c}\right)} y\left[\left(1-\frac{z}{c}\right)-\frac{y}{b}\right]^2 dy$$

$$= \frac{k\,a^2}{2}\int_0^c z\,dz\int_0^{b\left(1-\frac{z}{c}\right)}\left[y\left(1-\frac{z}{c}\right)^2+\frac{y^3}{b^2}-\frac{2y^2}{b}\left(1-\frac{z}{c}\right)\right]dy$$

Created with Print2PDF. To remove this line, buy a license at: http://www.software602.com/

$$= \frac{k\,a^2}{2}\int_0^c z\,dz\left[\frac{y^2}{2}\left(1-\frac{z}{c}\right)^2+\frac{y^4}{4\,b^2}-\frac{2\,y^3}{3\,b}\left(1-\frac{z}{c}\right)\right]_0^{b\left(1-\frac{z}{c}\right)}$$

$$= \frac{k\,a^2}{2}\int_0^c z\,dz\left[\frac{b^2}{2}\left(1-\frac{z}{c}\right)^4+\frac{b^4}{4\,b^2}\left(1-\frac{z}{c}\right)^4-\frac{2}{3}\cdot\frac{b^3}{b}\left(1-\frac{z}{c}\right)^4\right]$$

$$= \frac{k\,a^2}{2}\int_0^c z\left[\frac{b^2}{2}+\frac{b^2}{4}-\frac{2b^2}{3}\right]\left(1-\frac{z}{c}\right)^4 dz = \frac{k\,a^2}{2}\,\frac{b^2}{12}\int_0^c\left(1-\frac{z}{c}\right)^4 dz \qquad [\text{Put } z = c\sin^2\theta]$$

$$= \frac{k\,a^2\,b^2\,c^2}{12}\int_0^{\frac{\pi}{2}} c\sin^2\theta\,(1-\sin^2\theta)^4\,(2\,c\sin\theta\cos\theta\,d\theta)$$

$$= \frac{k^2\,a^2\,b^2\,c^2}{12}\int_0^{\pi/2}\sin^2\theta\,(\cos^8\theta)\sin\theta\cos\theta\,d\theta = \frac{k^2\,a^2\,b^2\,c^2}{12}\int_0^{\pi/2}\sin^3\theta\cos^9\theta\,d\theta$$

$$= \frac{k^2\,a^2\,b^2\,c^2}{12}\,\frac{\Gamma\left(\frac{3+1}{2}\right)\Gamma\left(\frac{9+1}{2}\right)}{2\,\Gamma\left(\frac{3+9+2}{2}\right)} = \frac{k\,a^2\,b^2\,c^2}{12}\cdot\frac{\Gamma 2\,\Gamma 5}{2\,\Gamma 7} = \frac{k\,a^2\,b^2\,c^2}{12}\,\frac{(1)\,(\Gamma 5)}{2\times 6\times 5\,\Gamma 5} = \frac{k\,a^2\,b^2\,c^2}{720} \quad \textbf{Ans.}$$

2.18 CENTRE OF GRAVITY

$$\bar{x} = \frac{\iiint x\,\rho\,dx\,dy\,dz}{\iiint \rho\,dx\,dy\,dz},\ \bar{y} = \frac{\iiint y\,\rho\,dx\,dy\,dz}{\iiint \rho\,dx\,dy\,dz},\ \bar{z} = \frac{\iiint z\,\rho\,dx\,dy\,dz}{\iiint \rho\,dx\,dy\,dz}$$

Example 60. *Find the co-ordinates of the centre of gravity of the positive octant of the sphere* $x^2 + y^2 + z^2 = a^2$, *density being given* $= k\,xyz$.

Solution. $\bar{x} = \dfrac{\iiint_V x\,\rho\,dx\,dy\,dz}{\iiint_V \rho\,dx\,dy\,dz} = \dfrac{\iiint z\,\rho\,dx\,dy\,dz}{\iiint \rho\,dx\,dy\,dz} = \dfrac{\iiint_V x^2 yz\,dx\,dy\,dz}{\iiint_V xyz\,dx\,dy\,dz}$

Converting into polar co-ordinates, $x = r\sin\theta\cos\phi$, $y = r\sin\theta\sin\phi$, $z = r\cos\theta$,
$dx\,dy\,dz = r^2\sin\theta\,dr\,d\theta\,d\phi$

$$\bar{x} = \frac{\int_0^{\pi/2}\int_0^{\pi/2}\int_0^a (r\sin\theta\cos\phi)^2\,(r\sin\theta\sin\phi)\,(r\cos\theta)\,(r^2\sin\theta\,dr\,d\theta\,d\phi)}{\int_0^{\pi/2}\int_0^{\pi/2}\int_0^a (r\sin\theta\cos\phi)\,(r\sin\theta\sin\phi)\,(r\cos\theta)\,(r^2\sin\theta\,dr\,d\theta\,d\phi)}$$

$$= \frac{\int_0^{\pi/2}\int_0^{\pi/2}\int_0^a r^6\sin^4\theta\cos\theta\sin\phi\cos^2\phi\,dr\,d\theta\,d\phi}{\int_0^{\pi/2}\int_0^{\pi/2}\int_0^a r^5\sin^3\theta\cos\theta\sin\phi\cos\phi\,dr\,d\theta\,d\phi}$$

$$= \frac{\int_0^{\pi/2}\sin\phi\cos^2\phi\,d\phi\int_0^{\pi/2}\sin^4\theta\cos\theta\,d\theta\int_0^a r^6\,dr}{\int_0^{\pi/2}\sin\phi\cos\phi\,d\phi\int_0^{\pi/2}\sin^3\theta\cos\theta\,d\theta\int_0^a r^5\,dr}$$

$$= \frac{\left[-\frac{\cos^3\phi}{3}\right]_0^{\pi/2}\left[\frac{\sin^5\theta}{5}\right]_0^{\pi/2}\left[\frac{r^7}{7}\right]_0^a}{-\left[\frac{\cos^2\phi}{2}\right]_0^{\pi/2}\left[\frac{\sin^4\theta}{4}\right]_0^{\pi/2}\left[\frac{r^6}{6}\right]_0^a} = \frac{\left(\frac{1}{3}\right)\left(\frac{1}{5}\right)\left(\frac{a^7}{7}\right)}{\left(\frac{1}{2}\right)\left(\frac{1}{4}\right)\left(\frac{a^6}{6}\right)} = \frac{16\,a}{35}$$

Similarly, $\bar{y} = \bar{z} = \dfrac{16\,a}{35}$; Hence, C.G. is $\left(\dfrac{16\,a}{35}, \dfrac{16\,a}{35}, \dfrac{16\,a}{35}\right)$ **Ans.**

& < < < < ; $. - 1

We can think of $\mathrm{Tw}(\mathcal{A})$ as being the derived category of $\mathcal{A}$, and can write it as $\mathrm{D}^b(\mathcal{A})$.

Unfortunately, this is still not quite the correct category for us. The derived category $\mathrm{D}^b(X)$ of coherent sheaves on X has another property which $\mathrm{Fuk}(\check{X})$ or $\mathrm{D}^b(\mathrm{Fuk}(\check{X}))$ may not have. Namely, if $\mathcal{F}$ is an object in $\mathrm{D}^b(X)$, and $p : \mathcal{F} \to \mathcal{F}$ a morphism with $p^2 = p$, then one can think of the image of p as another object in $\mathrm{D}^b(X)$. Such a morphism p is called *idempotent*, and $\mathrm{D}^b(X)$ is *split-closed*, essentially saying that $\mathrm{D}^b(X)$ contains all images of idempotent morphisms.

In general, given a linear category, there is a way of constructing a larger category, the *Karoubi completion*, which contains all images of idempotent morphisms. This can be generalized to A_∞-categories, yielding from an A_∞-category $\mathcal{A}$ a split-closed category. We omit the details of this construction—the interested read can consult [**421**], §4. The construction has a similar flavour to the ones we have seen above. In particular, we denote by $\mathrm{D}^\pi(\mathcal{A})$ this process applied to $\mathrm{D}^b(\mathcal{A})$. This can be shown to be a split-closed triangulated A_∞-category. Once one does this, the hoped-for rigorous statement of Homological Mirror Symmetry becomes:

CONJECTURE 8.17. *Let X and $\check{X}$ be a mirror pair of Calabi-Yau manifolds. Then $\mathrm{D}^b_\infty(X)$ and $\mathrm{D}^\pi(\mathrm{Fuk}(\check{X}))$ are quasi-equivalent as A_∞-categories.*

8.4. The elliptic curve

We will now show a limited form of HMS for the elliptic curve. For simplicity, we will not try to compare the full derived and Fukaya categories, though what we do here constitutes most of the work. The case of the elliptic curve has already been studied in detail in [**397, 396**]; we will take a somewhat different approach here inspired by Abouzaid in [**2**] and developed in [**1**] which uses the Čech approach to defining the A_∞ structure on the derived category.

We will do this by building a degeneration of elliptic curves, a family $\mathcal{X} \to D$, where D can be viewed either as the unit disk with coordinate q or, in the category of schemes, $D = \mathrm{Spec}\,\mathbb{C}[[q]]$. This family will be a compactification of the family considered in §6.2.4. The advantage of working with such a family is that the parameter q then corresponds to the Kähler parameter q appearing in the Fukaya category of the mirror, i.e., the variable q in the Novikov ring. In particular, one should view either side as giving a family of categories parametrized by q. Furthermore, by working with an explicit degeneration, the methods introduced here fit well with the philosophy introduced by Gross and Siebert in [**205, 206**]. Although we do not elaborate on that philosophy here, it is helpful in this situation.

We will in fact build the degeneration $\mathcal{X} \to D$ along with a line bundle $\mathcal{L}$ which is ample (positive) when restricted to each fiber. We will then compute all higher multiplication maps involving powers, both positive and negative, of $\mathcal{L}$.

8.4.1. The degeneration: The Tate curve. The method of constructing our degeneration is a special case of a construction of Mumford for degenerations of abelian varieties [**373**]. This degeneration of elliptic curves is usually called the Tate curve. We start with the following data. Pick a degree d for the choice of line bundle, and consider a continuous piecewise linear function $\varphi : \mathbb{R} \to \mathbb{R}$ which has slope i on the interval $[i, i+1]$ for $i \in \mathbb{Z}$. We can choose this to take the value 0 on $[0, 1]$ to be specific; in this case,

$$\varphi(x) = ix - \tfrac{i(i+1)}{2} \text{ for } x \in [i, i+1]$$

and φ satisfies a periodicity condition

$$\varphi(x + d) = \varphi(x) + d \cdot x + \frac{d(d-1)}{2}. \tag{8.12}$$

Let

$$\Delta = \{(x, y) \in \mathbb{R}^2 | y \geq \varphi(x)\}.$$

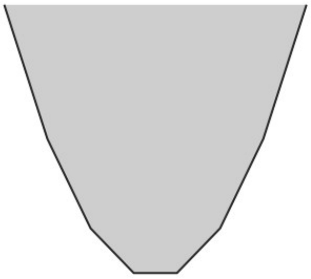

FIGURE 24. The graph of φ. The shaded area is Δ.

Just as a convex polytope determines a projective toric variety, an unbounded polytope can also determine a toric variety. This can be described via the *normal fan* of Δ. For each face $\sigma \subseteq \Delta$, define

$$\check{\sigma} = \{n \in (\mathbb{R}^2)^\vee : n|_\sigma = \text{constant}, \langle n, m\rangle \geq \langle n, m'\rangle \quad \forall m \in \Delta, m' \in \sigma\},$$

the *normal cone* to Δ at σ. We define the normal fan of Δ to be the collection of cones $\{\check{\sigma} | \sigma \subseteq \Delta \text{ a face}\}$. This is a fan living in $(\mathbb{R}^2)^\vee$. It is easy to see that if σ is the interval with endpoints $(i, \varphi(i))$ and $(i+1, \varphi(i+1))$, then $\check{\sigma}$ is the ray generated by $(-i, 1)$. Thus the normal fan Σ of Δ is as depicted in Figure 25. This violates a standard notion of fan in that it contains an infinite number of cones, but we should not be bothered by this: this fan still defines a toric variety X_Σ, covered by an *infinite* number of affine toric charts coming from the cones of Σ. Furthermore, $(0,1) \in \mathbb{R}^2$ takes the value 1 on the primitive generators of the rays of Σ, so if we denote by q the monomial corresponding to $(0,1)$, q is in fact a regular function on X_Σ, defining a map $g : X_\Sigma \to \mathbb{A}^1$.

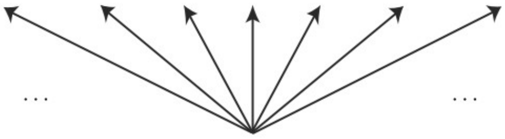

FIGURE 25. The normal fan of Δ.

Since q vanishes to order 1 on each toric divisor of X_Σ (corresponding to a ray of Σ) the fiber $g^{-1}(0)$ consists of an infinite chain of $\mathbb{P}^1$'s. On the other hand, it is not hard to see that any other fiber of g is a copy of $\mathbb{C}^*$.

Like any toric variety, X_Σ has an open cover indexed by the cones in the fan Σ, or equivalently, by the faces of Δ. In particular, we have an open cover $\{U_w | w \text{ is a vertex of } \Delta\}$, where $U_w = \operatorname{Spec} \mathbb{C}[\check{w}^\vee \cap \mathbb{Z}^2]$. This is the open subset of X_Σ corresponding to the cone $\check{w}$ of the fan Σ; alternatively $\check{w}^\vee$ can be viewed as just the tangent wedge to Δ at w, see Figure 26. Similarly, if σ is an edge of Δ, we obtain an open subset U_σ of X_Σ with $U_\sigma = \operatorname{Spec} \mathbb{C}[\check{\sigma}^\vee \cap \mathbb{Z}^2]$.

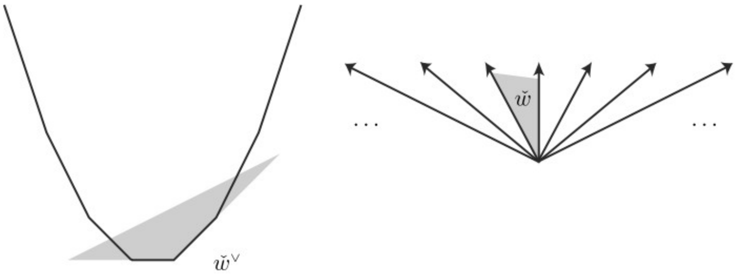

FIGURE 26

Now $\mathbb{Z}$ acts on X_Σ. We can describe this action by describing a $\mathbb{Z}$-action on the fan Σ. The generator of the action is given by the matrix $\left(\begin{smallmatrix} 1 & d \\ 0 & 1 \end{smallmatrix}\right)$ on $(\mathbb{R}^2)^\vee$: this takes a ray $\mathbb{R}_{\geq 0}(i,1)$ to $\mathbb{R}_{\geq 0}(i+d,1)$. This has the effect of acting on the big torus orbit $(\mathbb{C}^*)^2 \subseteq X_\Sigma$, with coordinates z, q corresponding to the standard basis $(1,0), (0,1)$ of $\mathbb{R}^2$, via

$$(z,q) \mapsto (zq^d, q).$$

Hence if we fix a non-zero value of q, the action on the $\mathbb{C}^*$ parametrized by z is $z \mapsto z \cdot q^d$. For $0 < |q| < 1$, the quotient of this fiber by the $\mathbb{Z}$-action is $\mathbb{C}^*/q^{\mathbb{Z}}$. This quotient coincides with

$$\mathbb{C}/\langle 1, \frac{1}{2\pi\sqrt{-1}} \log q\rangle;$$

note that $\exp(2\pi\sqrt{-1}\cdot)$ identifies $\mathbb{C}/\mathbb{Z}$ with $\mathbb{C}^*$. Clearly this is an elliptic curve as long as $|q| \neq 1$.

On the other hand, for $q = 0$, the action on the fiber shifts the infinite chain of $\mathbb{P}^1$'s d places, so the quotient by this $\mathbb{Z}$-action is a cycle of d rational curves, as depicted in Figure 27.

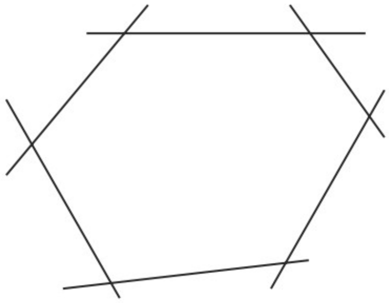

FIGURE 27

We can now take

$$\mathcal{X} = g^{-1}(D)/\mathbb{Z},$$

where D is the open unit disk. Then $g : \mathcal{X} \to D$, induced by q, is a degeneration of elliptic curves to a so-called Kodaira type I_d fiber, i.e., a cycle of d rational curves.

For our purposes, just as in the Fukaya category where we worked with the Novikov ring, a formal power series ring, it is more convenient for us to work with a formal version of this quotient. This is a rather technical point, but it allows us essentially to work entirely with the topology of the singular fiber, and also allows us to take the $\mathbb{Z}$ quotient in a more algebraic category.

Indeed, it is difficult to divide algebraic varieties by groups such as $\mathbb{Z}$. In this situation, we observe first of all that $g^{-1}(0)/\mathbb{Z}$ makes sense as an algebraic variety; as we saw, it is a cycle of d rational curves. On the other hand, let X_Σ^k denote the subscheme of X_Σ defined by the equation $q^{k+1} = 0$, so that X_Σ^k is a "kth order thickening" of $g^{-1}(0)$. Then in fact one can check (the details aren't so important for us) that $X_\Sigma^k/\mathbb{Z}$ also makes sense as a scheme, as a "kth order thickening" of $g^{-1}(0)/\mathbb{Z}$.

We can then construct the "formal scheme"

$$\hat{X}_\Sigma = \varprojlim X^k_\Sigma.$$

See [**222**], II §9, for the definition of a formal scheme. This is a ringed space whose underlying topological space is that of X^k_Σ (these coincide for all k), or equivalently, it has underlying topological space $g^{-1}(0)$. The sheaf of rings on $\hat{X}_\Sigma$ is given on an open set $U \subseteq g^{-1}(0)$ by

$$\Gamma(U, \mathscr{O}_{\hat{X}_\Sigma}) = \varprojlim \Gamma(U, \mathscr{O}_{X^k_\Sigma}).$$

(See, e.g., [**25**] for the definition of inverse limit and more details about completions of rings.) Essentially what this does is it allows us to consider functions in a "formal neighbourhood" of $g^{-1}(0)$ which are formal power series in q. For example, if U_w is the open set of X_Σ defined above, then $\hat{U}_w = g^{-1}(0) \cap U_w$ is topologically an open subset of $g^{-1}(0)$, and

$$\Gamma(\hat{U}_w, \mathscr{O}_{\hat{X}_\Sigma}) = \varprojlim \mathbb{C}[\check{w}^\vee \cap \mathbb{Z}^2]/(q^n) =: \mathbb{C}[\check{w}^\vee \cap \mathbb{Z}^2] \hat{\otimes}_{\mathbb{C}[q]} \mathbb{C}[[q]],$$

where the completed tensor product on the right is defined by the inverse limit. Then

$$\hat{\mathcal{X}} := \hat{X}_\Sigma/\mathbb{Z}$$

makes sense as a formal scheme also, and there is a map of formal schemes $\hat{g} : \hat{\mathcal{X}} \to \hat{\mathbb{A}}^1$ induced by q. Here $\hat{\mathbb{A}}^1$ is the ringed space consisting of the point 0 and the ring $\mathbb{C}[[q]]$. This should be viewed as a formal version of $g : \mathcal{X} \to D$.

We will actually calculate the desired multiplication maps on $\hat{\mathcal{X}}$; all answers will be formal power series in q. However, we first need to construct the desired line bundles on $\hat{\mathcal{X}}$.

To do so, we choose a relatively ample line bundle $\mathcal{L}$ on $\hat{\mathcal{X}}$. In fact, the choice of $\mathcal{L}$ is already present in Δ: a polytope determines not just a toric variety but a line bundle on it. In this case there is a line bundle $\mathcal{L} = \mathscr{O}_\Delta(1)$ on X_Σ which has a basis of sections which is in one-to-one correspondence with integral points of Δ. We can describe $\mathcal{L}$ via its transition maps in the usual way for line bundles on toric varieties, by saying that $\mathcal{L}|_{U_w}$ is trivial, identified naturally with $\mathscr{O}_{U_w} \cdot z^w$. Thus on $U_w \cap U_{w'}$, the transition map from $\mathscr{O}_{U_w}$ to $\mathscr{O}_{U_{w'}}$ is given by multiplication by $z^{w-w'}$. One sees easily that

$$\Delta = \bigcap_{w \text{ a vertex of } \Delta} \check{w}^\vee + w$$

and any integral point of $m \in \Delta$ then gives a well-defined section z^m of $\mathcal{L}$. Note that if $\mathcal{L}$ is restricted to any irreducible component of $g^{-1}(0)$, we get the line bundle $\mathscr{O}_{\mathbb{P}^1}(1)$.

We want $\mathcal{L}$ to induce a line bundle $\hat{\mathcal{L}}$ on $\hat{\mathcal{X}}$. In order to do this, it is not enough to know how $\mathbb{Z}$ acts on $\mathcal{X}$, but how this $\mathbb{Z}$-action lifts to an action on $\mathcal{L}$. For this purpose, it is enough to describe a $\mathbb{Z}$-action on

$$\bigoplus_{n=0}^{\infty} H^0(X_\Sigma, \mathcal{L}^{\otimes n}).$$

This space of sections has a canonical basis given by the integral points of $C(\Delta) \subseteq \mathbb{R}^3$, where

$$C(\Delta) = \overline{\{(rm, r) \mid m \in \Delta, r \in [0, \infty)\}}.$$

Note that the integral points with third coordinate an integer n correspond to elements of a basis for $H^0(X_\Sigma, \mathcal{L}^{\otimes n})$. We want an action which satisfies the following properties:

(1) It is linear on $\mathbb{Z}^3 \subseteq \mathbb{R}^3$, as we want the action of $\mathbb{Z}$ on $\mathcal{L}$ to act by toric automorphisms of the total space of $\mathcal{L}$.
(2) This action preserves the third component, i.e., does not change the degree of a section.
(3) As the action on $\mathcal{L}$ should be compatible with the action on X_Σ, the action on $\mathbb{Z}^2 \times \{0\} \subseteq \mathbb{Z}^3$ should be generated by
$$\begin{pmatrix} 1 & 0 \\ d & 1 \end{pmatrix}$$
(the transpose of the action on $(\mathbb{R}^2)^\vee$).
(4) The action should identify $C(\Delta)$ with itself.

The first three conditions tell us that the generator of the action must be

$$\begin{pmatrix} 1 & 0 & * \\ d & 1 & * \\ 0 & 0 & 1 \end{pmatrix}$$

From the fourth condition, the action must preserve the boundary of $C(\Delta)$, and it follows from the periodicity condition (8.12) that the only choice for this generator is

$$T = \begin{pmatrix} 1 & 0 & d \\ d & 1 & \frac{d(d-1)}{2} \\ 0 & 0 & 1 \end{pmatrix}.$$

For a given $n \geq 0$, we will write this generator as an affine transformation

$$T_n(x, y) := (x + nd, xd + y + \frac{d(d-1)}{2} n),$$

the first two components of $T(x, y, n)$. This describes the action on sections of $\mathcal{L}^{\otimes n}$, a basis being represented by integral points of $n\Delta$.

As before, we can now divide $\mathcal{L}$ out by $\mathbb{Z}$, and this only makes sense on the formal neighbourhood $\hat{X}_\Sigma$ of $g^{-1}(0)$. We then get a line bundle $\hat{\mathcal{L}}$ on $\hat{\mathcal{X}}$.

The easiest way to describe what we have constructed is to write down a $\mathbb{C}[[q]]$-basis of sections for $H^0(\hat{\mathcal{X}}, \hat{\mathcal{L}}^{\otimes n})$. To do so, one writes down a basis of $\mathbb{Z}$-invariant sections of $H^0(X_\Sigma, \mathcal{L}^{\otimes n})$. This basis is as follows: pick any $p \in \frac{1}{n}\mathbb{Z}$. Then set

$$\vartheta_{n,p} := \sum_{s=-\infty}^{\infty} z^{T_n^s(np, n\varphi(p))}.$$

Note that on any given open set U_w, this makes sense formally, i.e.,

$$\vartheta_{n,p} \in (\mathbb{C}[\check{w}^\vee \cap \mathbb{Z}^2]\hat{\otimes}_{\mathbb{C}[q]}\mathbb{C}[[q]]) \cdot z^{nw}.$$

To see why this makes sense, one can check that for any given $k > 0$, all but a finite number of terms in the sum defining $\vartheta_{n,p}$ are zero in $(\mathbb{C}[\check{w}^\vee \cap \mathbb{Z}^2] \otimes_{\mathbb{C}[q]} \mathbb{C}[q]/(q^k)) \cdot z^{nw}$. The functions $\vartheta_{n,p}$ are known as *theta functions*. Note also that

$$\vartheta_{n,p} = \vartheta_{n,p+d}$$

as

$$T_n(np, n\varphi(p)) = (n(p+d), n\varphi(p+d)).$$

It is not difficult to see that the $\vartheta_{n,p}$'s generate the space of $\mathbb{Z}$-invariant sections of $\mathcal{L}^{\otimes n}|_{\hat{X}_\Sigma}$ as a $\mathbb{C}[[q]]$-module. Note however that we need to allow formal power series in q in order for there to exist $\mathbb{Z}$-invariant sections: $\mathcal{L}^{\otimes n}$ on X_Σ has no such sections. This is another way of seeing why we need to pass to the completion before we can take the quotient. Note more generally that if we have any $(x, y) \in \mathbb{Z}^2$ with $(x, y) \in n\Delta$, i.e., $y \geq n\varphi(x/n)$, then

$$\sum_{s=-\infty}^{\infty} z^{T_n^s(x,y)} = q^{y-n\varphi(x/n)}\vartheta_{n,x/n}. \tag{8.13}$$

We define

$$\operatorname{ord}_n(x, y) = y - n\varphi(x/n) \tag{8.14}$$

for any $n \in \mathbb{Z}$, $(x, y) \in \mathbb{Z}^2$. (8.13) is the motivation for this definition.

Note also that elements of this basis of $\mathbb{Z}$-invariant sections are in one-to-one correspondence with points on the integral affine manifold (see §6.1.2) $B = \mathbb{R}/d\mathbb{Z}$ with coordinates in $\frac{1}{n}\mathbb{Z}$, a point which we shall return to in a moment. We write this set of points as $B((1/n)\mathbb{Z})$.

At this point, a reader unhappy with the vague description of the quotient construction we have given may proceed as follows. Consider the $\mathbb{C}[[q]]$-algebra

$$\hat{R} = \bigoplus_{n=0}^{\infty} H^0(\hat{\mathcal{X}}, \hat{\mathcal{L}}^{\otimes n}).$$

One can define this simply by knowing the set of $\mathbb{C}[[q]]$-module generators,

$$\{1\} \cup \{\vartheta_{n,p} | p \in B((1/n)\mathbb{Z}), n \geq 1\},$$

and the multiplication map, i.e., the structure constants of the algebra, something which we will explain shortly. We can then consider the scheme $\operatorname{Proj} \hat{R}$, which is a scheme defined over $\operatorname{Spec} \mathbb{C}[[q]]$ (see for example [**222**], II,

§2). This is a genuine scheme, not a formal scheme. The fact that one can obtain a genuine scheme from a formal scheme in the presence of an ample line bundle is Grothendieck's existence theorem, see EGA III, 5.4.5, [**211**]. So the construction above can be viewed as a special case.

8.4.2. Multiplication of theta functions and triangles. Let us now turn to a geometric interpretation for theta functions and their multiplication. We have just seen an affine manifold B emerge from our description of the basis of theta functions. So it is natural to try to fit what we are doing into the context of Chapter 6.

We will in fact view a fiber of the map $\mathcal{X} \to D$ as $\check{X}(B)$, see §6.2.1. Indeed, the fiber comes along with the restriction of the line bundle $\mathcal{L}$, which is necessarily of degree d. On the other hand, $\check{X}(B)$ comes with a canonical symplectic form ω with $\int_{\check{X}(B)} \omega = d$, so ω represents $c_1(\mathcal{L})$.

The reader may object that this goes against the philosophy of §6.3: namely, one considers line bundles on $X(B)$ and Lagrangians on $\check{X}(B)$. This is indeed the case, but there is a reason for this switch. When we discuss the Fukaya category, we will be able to work, at least in the elliptic curve case, with a fixed almost complex structure, namely, the complex structure $X(B)$. It will be easy to describe holomorphic disks on $X(B)$. By choosing to work on $X(B)$ on the Fukaya side, we are making it easy to describe disks but difficult to describe Lagrangians. Similarly, by working on $\check{X}(B)$ for the derived category side, it is difficult to describe sheaves, but we get a canonically given cohomology class from the symplectic form. As a result, we restrict attention to line bundles with first Chern class represented by integral multiples of ω, and more specifically, powers of $\mathcal{L}$. On $X(B)$, we restrict attention to Lagrangians of a very special sort, namely sections which are induced by multiples of the developing map (§6.1.2), with trivial local system.

Let us be more explicit now and describe, in the spirit of §6.3, the Lagrangians on $X(B)$ which will be mirror dual to the line bundles $\mathcal{L}^{\otimes n}$. First, we need to specify a symplectic form on $X(B)$: by Proposition 6.14, this can be done by specifying a convex multi-valued function on B; the function $K = y^2/2$ will do nicely, with $\omega = dy \wedge dx$. Here we are briefly using the convention of Chapter 6 and writing y as the coordinate on B, and x the fiber coordinate on $X(B)$. Now any real curve contained in $X(B)$ is Lagrangian, so the only role ω plays is in calculating areas of holomorphic disks.

For any $n \in \mathbb{Z}$, let L_n be the image in $X(B)$ of the graph of $x = -ny$, oriented in the direction of increasing y. The minus sign has to do with the choice of sign conventions in defining the Fukaya category. Since x is a periodic coordinate with period 1, and y is a periodic coordinate with period d, this makes sense (see Figure 28). One first notices that if $f : X(B) \to B$

1.2 COMPLEX NUMBERS

A complex number z is an ordered pair (x, y) of real numbers x and y. It is written as $z = (x, y)$ or $z = x + iy$, where $i = \sqrt{-1}$ is known as the imaginary unit. Here, x is called the real part of z and is written as "**Re** (z)", and y is called the imaginary part of z and is written as "**Im** (z)".

If $x = 0$ and $y \neq 0$ then $z = 0 + iy = iy$ which is purely imaginary.

If $x \neq 0$ and $y = 0$ then $z = x + i\,0 = x$ which is real.

Hence, z is **purely imaginary**, if its real part is zero, and is **real** if its imaginary part is zero.

This shows that every real number can be written in the form of a complex number by taking its imaginary part as zero. Hence, the set of real numbers is contained in the set of complex numbers.

Two complex numbers are equal if and only if their corresponding real and imaginary parts are equal.

If $z = x + iy$ is a complex number then its conjugate or complex conjugate is defined as $\overline{z} = x - iy$.

The even power of i is either 1 or –1 and odd power of i is either i or $-i$.

$$i^2 = i.i = -1$$
$$i^3 = i^2.i = -i$$
$$i^4 = (i^2)^2 = (-1)^2 = 1$$
$$i^5 = i.\,i^4 = i, \text{ etc.}$$

1.3 GEOMETRICAL REPRESENTATION OF COMPLEX NUMBERS (ARGAND'S DIAGRAM)

Any complex number $z = x + iy$ can be represented as a point $P(x, y)$ in the xy-plane with reference to the rectangular x and y axes.

The plot of a given complex number $z = x + iy$, as the point $P(x, y)$ in the xy-plane is known as **Argand's diagram** (Fig. 1.1). The x-axis is called the real axis, y-axis is called the imaginary axis, and the xy-plane is called the complex plane.

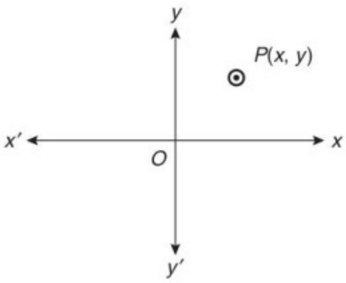

Fig. 1.1

1.4 ALGEBRA OF COMPLEX NUMBERS

Let $z_1 = x_1 + iy_1$ and $z_2 = x_2 + iy_2$ be two complex numbers.

(a) *Addition:* $$z_1 + z_2 = (x_1 + iy_1) + (x_2 + iy_2) = (x_1 + x_2) + i\,(y_1 + y_2)$$

(b) *Subtraction:* $z_1 - z_2 = (x_1 + iy_1) - (x_2 + iy_2)$

$$= (x_1 - x_2) + i\,(y_1 - y_2)$$

(c) *Multiplication:* $z_1 z_2 = (x_1 + iy_1)\,(x_2 + iy_2)$

$$= (x_1 x_2 - y_1 y_2) + i\,(x_2 y_1 + y_2 x_1) \qquad [\because\; i^2 = -1]$$

(d) *Division:*

$$\frac{z_1}{z_2} = \frac{x_1 + iy_1}{x_2 + iy_2}$$

$$= \frac{(x_1 + iy_1)}{(x_2 + iy_2)} \cdot \frac{(x_2 - iy_2)}{(x_2 - iy_2)}$$

$$= \frac{x_1x_2 + y_1y_2}{x_2^2 + y_2^2} + i\left(\frac{y_1x_2 - x_1y_2}{x_2^2 + y_2^2}\right)$$

1.5 DIFFERENT FORMS OF COMPLEX NUMBERS

1.5.1 Cartesian or Rectangular Form

If x and y are real numbers then $z = x + iy$ is called the Cartesian form of the complex number.

1.5.2 Polar Form

The complex number $z = x + iy$ can be represented by the point P whose cartesian co-ordinates are (x, y) (Fig. 1.2). If polar coordinates of the point P are (r, θ) then $x = r\cos\theta$ and $y = r\sin\theta$.

Hence, polar form of z is

$$z = r\cos\theta + ir\sin\theta$$

$$= r(\cos\theta + i\sin\theta)$$

Polar form can also be written as $r \angle \theta$.

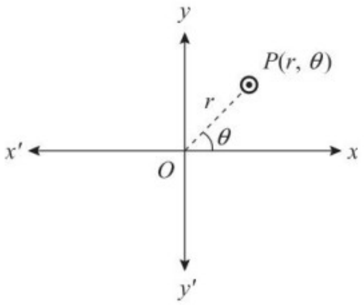

Fig. 1.2

1.5.3 Exponential Form

Polar form of z is

$$z = r(\cos\theta + i\sin\theta)$$

$$\cos\theta + i\sin\theta = e^{i\theta} \qquad \text{[Using Expansion]}$$

Hence, exponential form of z is

$$z = re^{i\theta}$$

Note $e^{i\theta} = \cos\theta + i\sin\theta$, $e^{-i\theta} = \cos\theta - i\sin\theta$.

Hence, $\cos\theta = \frac{1}{2}(e^{i\theta} + e^{-i\theta})$ and $\sin\theta = \frac{1}{2i}(e^{i\theta} - e^{-i\theta})$

1.6 MODULUS AND ARGUMENT (OR AMPLITUDE) OF COMPLEX NUMBERS

Let
$$\begin{aligned} z &= x + iy \\ &= r(\cos\theta + i\sin\theta) \end{aligned}$$

Here 'r' is called the modulus or absolute value of z and is denoted by $|z|$ or mod (z) and θ is called argument or amplitude of z and is denoted by arg (z) or amp (z).

Hence,
$$|z| = r = \sqrt{x^2 + y^2}$$
$$\arg(z) = \theta = \tan^{-1}\left(\frac{y}{x}\right)$$

Note The value of θ lying between $-\pi$ and π is called the **principal value** of argument. The argument of z is the value of θ which lies in the quadrant of point (x, y).

1.7 PROPERTIES OF COMPLEX NUMBERS

Let $z = x + iy$ and $\bar{z} = x - iy$.

(a) $\text{Re}(z) = x = \dfrac{1}{2}(z + \bar{z})$

(b) $\text{Im}(z) = y = \dfrac{1}{2i}(z - \bar{z})$

(c) $(\overline{z_1 + z_2}) = \bar{z}_1 + \bar{z}_2$

(d) $(\overline{z_1 z_2}) = \bar{z}_1 \bar{z}_2$

(e) $\overline{\left(\dfrac{z_1}{z_2}\right)} = \dfrac{\bar{z}_1}{\bar{z}_2}$

(f) $z\bar{z} = |z|^2 = |\bar{z}|^2 \qquad \left[\because |z| = |\bar{z}| = \sqrt{x^2 + y^2}\right]$

(g) $|z_1 z_2| = |z_1|\,|z_2|$

and $\arg(z_1 z_2) = \arg(z_1) + \arg(z_2)$

(h) $\left|\dfrac{z_1}{z_2}\right| = \dfrac{|z_1|}{|z_2|}$

and $\arg\left(\dfrac{z_1}{z_2}\right) = \arg(z_1) - \arg(z_2)$

Example 1

Arg $(z_1, z_2) = $ *Arg* $(z_1) + $ *Arg* (z_2)? *Justify.* **[Summer 2015]**

Solution

Yes, $Arg\,(z_1\, z_2) = Arg\,(z_1) + Arg\,(z_2)$

Let $z_1 = r_1 e^{i\theta_1},\ z_2 = r_2 e^{i\theta_2}$

$$\begin{aligned} z_1 z_2 &= (r_1\, e^{i\theta_1})\,(r_2\, e^{i\theta_2}) \\ &= r_1\, r_2\, e^{i(\theta_1 + \theta_2)} \end{aligned}$$

$$\therefore \qquad \begin{aligned} Arg\,(z_1\, z_2) &= \theta_1 + \theta_2 \\ &= Arg\,(z_1) + Arg(z_2) \end{aligned}$$

Example 2

Find the principal argument Arg z when $z = \dfrac{-2}{1+\sqrt{3}\,i}$. **[Winter 2014]**

Solution

$$\begin{aligned} z &= \frac{-2}{1+\sqrt{3}\,i} \\ &= \frac{-2}{1+\sqrt{3}i} \cdot \frac{\left(1-\sqrt{3}\,i\right)}{\left(1-\sqrt{3}\,i\right)} \\ &= \frac{-2+2\sqrt{3}\,i}{1+3} \\ &= -\frac{1}{2} + i\,\frac{\sqrt{3}}{2} \\ Arg\ z &= \tan^{-1} \frac{\left(\dfrac{\sqrt{3}}{2}\right)}{\left(-\dfrac{1}{2}\right)} \\ &= \tan^{-1}\left(-\sqrt{3}\right) \\ &= \frac{2\pi}{3} \end{aligned}$$

Example 3

Find the modulus and principal value of the arguments of the following complex numbers:

(i) $(4+2i)\left(-3+\sqrt{2}i\right)$

(ii) $\dfrac{2+6\sqrt{3}i}{5+\sqrt{3}i}$

Solution

(i)

$$\begin{aligned}
z &= (4+2i)\left(-3+\sqrt{2}i\right)\\
&= \left(-12+4\sqrt{2}i-6i-2\sqrt{2}\right)\\
&= -\left(12+2\sqrt{2}\right)+i\left(4\sqrt{2}-6\right)\\
|z| &= \sqrt{\left(12+2\sqrt{2}\right)^2+\left(4\sqrt{2}-6\right)^2}\\
&= 2\sqrt{36+2+12\sqrt{2}+8+9-12\sqrt{2}}\\
&= 2\sqrt{55}\\
\arg(z) &= \tan^{-1}\left[\frac{4\sqrt{2}-6}{-\left(12+2\sqrt{2}\right)}\right]\\
&= \tan^{-1}\left(\frac{3-2\sqrt{2}}{6+\sqrt{2}}\right)
\end{aligned}$$

Aliter

$$\begin{aligned}
z &= (4+2i)\left(-3+\sqrt{2}i\right) = z_1 z_2, \text{ say}\\
r &= |z|\\
&= |z_1 z_2|\\
&= |z_1||z_2|\\
&= |4+2i|\left|-3+\sqrt{2}i\right|\\
&= \left(\sqrt{16+4}\right)\left(\sqrt{9+2}\right)\\
&= \sqrt{220}\\
&= 2\sqrt{55}\\
\theta &= \arg(z)\\
&= \arg(z_1 z_2)\\
&= \arg(z_1)+\arg(z_2)\\
&= \arg(4+2i)+\arg\left(-3+\sqrt{2}i\right)
\end{aligned}$$

$$= \tan^{-1}\left(\frac{2}{4}\right) + \tan^{-1}\left(\frac{\sqrt{2}}{-3}\right)$$

$$= \tan^{-1}\left(\frac{1}{2}\right) - \tan^{-1}\left(\frac{\sqrt{2}}{3}\right)$$

$$= \tan^{-1}\left(\frac{\frac{1}{2} - \frac{\sqrt{2}}{3}}{1 + \frac{1}{2} \cdot \frac{\sqrt{2}}{3}}\right)$$

$$= \tan^{-1}\left(\frac{3 - 2\sqrt{2}}{6 + \sqrt{2}}\right)$$

(ii)

$$z = \frac{2 + 6\sqrt{3}i}{5 + \sqrt{3}i}$$

$$= \left(\frac{2 + 6\sqrt{3}i}{5 + \sqrt{3}i}\right)\left(\frac{5 - \sqrt{3}i}{5 - \sqrt{3}i}\right)$$

$$= \frac{28 + 28\sqrt{3}i}{28}$$

$$= 1 + \sqrt{3}i$$

$$|z| = \sqrt{(1)^2 + \left(\sqrt{3}\right)^2} = 2$$

$$\arg(z) = \tan^{-1}\left(\frac{\sqrt{3}}{1}\right) = \frac{\pi}{3}$$

Example 4

Evaluate $\left[(1+i)^{100} + (1-i)^{100}\right]$.

Solution

Let $1 + i = re^{i\theta}$

$$r = |1 + i| = \sqrt{1+1} = \sqrt{2}$$

$$\theta = \tan^{-1}\left(\frac{1}{1}\right) = \tan^{-1} 1 = \frac{\pi}{4}$$

∴ $1 + i = \sqrt{2}e^{i\frac{\pi}{4}}$

and $1 - i = \sqrt{2}e^{-i\frac{\pi}{4}}$

$$\begin{aligned}(1+i)^{100}+(1-i)^{100} &= \left(\sqrt{2}e^{i\frac{\pi}{4}}\right)^{100}+\left(\sqrt{2}e^{-i\frac{\pi}{4}}\right)^{100}\\ &= 2^{50}(e^{25\pi i}+e^{-25\pi i})\\ &= 2^{50}(2\cos 25\pi)\\ &= 2^{51}(-1)\\ &= -2^{51}\end{aligned}$$

Example 5

Express in polar form:

(i) $\left(\frac{2+i}{3-i}\right)^2$ *(ii)* $1+\sin\alpha+i\cos\alpha$

Solution

(i)

$$\begin{aligned}\left(\frac{2+i}{3-i}\right)^2 &= \frac{4+i^2+4i}{9+i^2-6i}\\ &= \frac{3+4i}{8-6i}\\ &= \frac{3+4i}{8-6i}\cdot\frac{8+6i}{8+6i}\\ &= \frac{i}{2}\\ &= 0+i\cdot\frac{1}{2}\end{aligned}$$

Let $$0+i\cdot\frac{1}{2}=r(\cos\theta+i\sin\theta)$$

$$r=\sqrt{0^2+\left(\frac{1}{2}\right)^2}=\frac{1}{2}$$

and $$\theta=\tan^{-1}\left(\frac{\frac{1}{2}}{0}\right)=\tan^{-1}\infty=\frac{\pi}{2}$$

Hence, the polar form is

$$\left(\frac{2+i}{3-i}\right)^2=\frac{1}{2}\left(\cos\frac{\pi}{2}+i\sin\frac{\pi}{2}\right)$$

(ii) $$1+\sin\alpha+i\cos\alpha = 1+\cos\left(\frac{\pi}{2}-\alpha\right)+i\sin\left(\frac{\pi}{2}-\alpha\right)$$

$$= 2\cos^2\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)+2i\sin\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)\cos\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)$$

$$\left[\because\ 1+\cos\theta = 2\cos^2\frac{\theta}{2},\ \sin\theta = 2\sin\frac{\theta}{2}\cos\frac{\theta}{2}\right]$$

$$= 2\cos\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)\left[\cos\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)+i\sin\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)\right]$$

Comparing with the polar form $r(\cos\theta + i\sin\theta)$,

$$r = 2\cos\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)$$

$$\theta = \frac{\pi}{4}-\frac{\alpha}{2}$$

Hence, the polar form is

$$1+\sin\alpha+i\cos\alpha = 2\cos\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)\left[\cos\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)+i\sin\left(\frac{\pi}{4}-\frac{\alpha}{2}\right)\right]$$

Example 6

Find the value of $\sqrt{-5+12i}$.

Solution

Let $$\sqrt{-5+12i} = x+iy$$

$$-5+12i = (x+iy)^2$$

$$-5+12i = (x^2-y^2)+i(2xy)$$

Comparing real and imaginary parts,

$$x^2-y^2 = -5 \qquad \text{... (1)}$$

and $$2xy = 12$$

$$xy = 6$$

Putting $y = \frac{6}{x}$ in Eq. (1),

$$x^2 - \frac{36}{x^2} = -5$$

$$x^4 + 5x^2 - 36 = 0$$

$$(x^2 + 9)(x^2 - 4) = 0$$

$$x^2 = -9, x^2 = 4$$

Since x is real, $x = \pm 2$

and $y = \pm 3$

Hence, $\sqrt{-5+12i} = \pm 2 \pm 3i$

Example 7

If x and y are real, solve the equation $\dfrac{iy}{ix+1} - \dfrac{3y+4i}{3x+y} = 0$.

Solution

$$\frac{iy}{ix+1} - \frac{3y+4i}{3x+y} = 0$$

$$\frac{iy(3x+y)-(3y+4i)(ix+1)}{(ix+1)(3x+y)} = 0$$

$$(-3y+4x)+i(3xy+y^2-3xy-4) = 0+i0$$

$$(-3y+4x)+i(y^2-4) = 0+i0$$

Comparing real and imaginary parts,

$$-3y + 4x = 0$$

and $y^2 - 4 = 0$

$$y = \pm 2$$

$\therefore$ $x = \pm \dfrac{3}{2}$

Hence, the solution is

$$x = \pm \frac{3}{2}, \qquad y = \pm 2$$

Example 8

Solve the equation $z^2 + (2i - 3)z + 5 - i = 0$. **[Summer 2015]**

Solution

$$z^2 + (2i - 3)z + 5 - i = 0$$

1.2.6 Third-Order Nonlinear Optical Processes

We next consider the third-order contribution to the nonlinear polarization

$$\tilde{P}^{(3)}(t) = \epsilon_0 \chi^{(3)} \tilde{E}(t)^3. \tag{1.2.14}$$

For the general case in which the field $\tilde{E}(t)$ is made up of several different frequency components, the expression for $\tilde{P}^{(3)}(t)$ is very complicated. For this reason, we first consider the simple case in which the applied field is monochromatic and is given by*

$$\tilde{E}(t) = \mathcal{E} \cos \omega t. \tag{1.2.15}$$

Then, through use of the identity $\cos^3 \omega t = \frac{1}{4}\cos 3\omega t + \frac{3}{4}\cos \omega t$, we can express the nonlinear polarization as

$$\tilde{P}^{(3)}(t) = \frac{1}{4}\epsilon_0 \chi^{(3)} \mathcal{E}^3 \cos 3\omega t + \frac{3}{4}\epsilon_0 \chi^{(3)} \mathcal{E}^3 \cos \omega t. \tag{1.2.16}$$

The significance of each of the two terms in this expression is described briefly below.

1.2.7 Third-Harmonic Generation

The first term in Eq. (1.2.16) describes a response at frequency 3ω that is created by an applied field at frequency ω. This term leads to the process of third-harmonic generation, which is illustrated in Fig. 1.2.5. According to the photon description of this process, shown in part (b) of the figure, three photons of frequency ω are destroyed and one photon of frequency 3ω is created in this process.

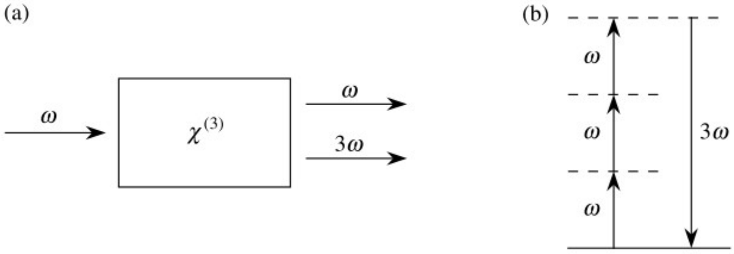

FIGURE 1.2.5: Third-harmonic generation. (a) Geometry of the interaction. (b) Energy-level description.

---

* Here we are describing the field in terms of purely real quantities for the pedagogical value of introducing such a notation.

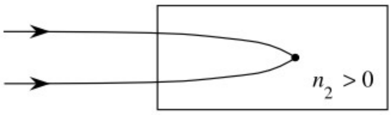

FIGURE 1.2.6: Self-focusing of light.

1.2.8 Intensity-Dependent Refractive Index

The second term in Eq. (1.2.16) describes a nonlinear contribution to the polarization at the same frequency as that of the incident field; this term hence leads to a nonlinear contribution to the refractive index experienced by a wave at frequency ω. We shall see in Section 4.1 that the refractive index in the presence of this type of nonlinearity can be represented as

$$n = n_0 + n_2 I, \tag{1.2.17a}$$

where n_0 is the usual (i.e., linear or low-intensity) refractive index, where

$$n_2 = \frac{3}{4n_0^2\epsilon_0 c}\chi^{(3)} \tag{1.2.17b}$$

is an optical constant that characterizes the strength of the optical nonlinearity, and where $I = \frac{1}{2}n_0\epsilon_0 c\mathcal{E}^2$ is the intensity of the incident wave.

Self-Focusing

One of the processes that can occur as a result of the intensity-dependent refractive index is self-focusing, which is illustrated in Fig. 1.2.6. This process can occur when a beam of light having a nonuniform transverse intensity distribution propagates through a material for which n_2 is positive. Under these conditions, the material effectively acts as a positive lens, which causes the rays to curve toward each other. This process is of great practical importance because the intensity at the focal spot of the self-focused beam is usually sufficiently large to lead to optical damage of the material. The process of self-focusing is described in greater detail in Section 7.1.

1.2.9 Third-Order Interactions (General Case)

Let us next examine the form of the nonlinear polarization

$$\tilde{P}^{(3)}(t) = \epsilon_0\chi^{(3)}\tilde{E}(t)^3 \tag{1.2.18a}$$

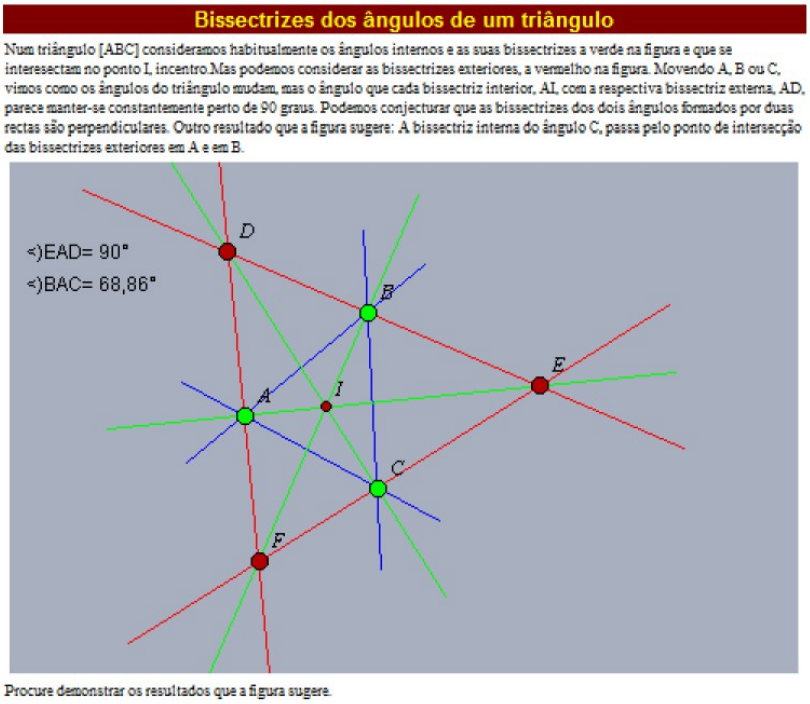
Reconstruir um triângulo de que se conhece um vértice e as rectas que contêm as suas bissectrizes.

Sugestão.
Desenhe um triângulo e as suas bissectrizes (que se intersectam no incentro)dos ângulos internos. Pense em usar a perpendicular à bissectriz tirada pelo vértice do ângulo. Pode confirmar o que se pretende com a nossa construção:

Sugestão: resultado com bissectrizes de um triângulo



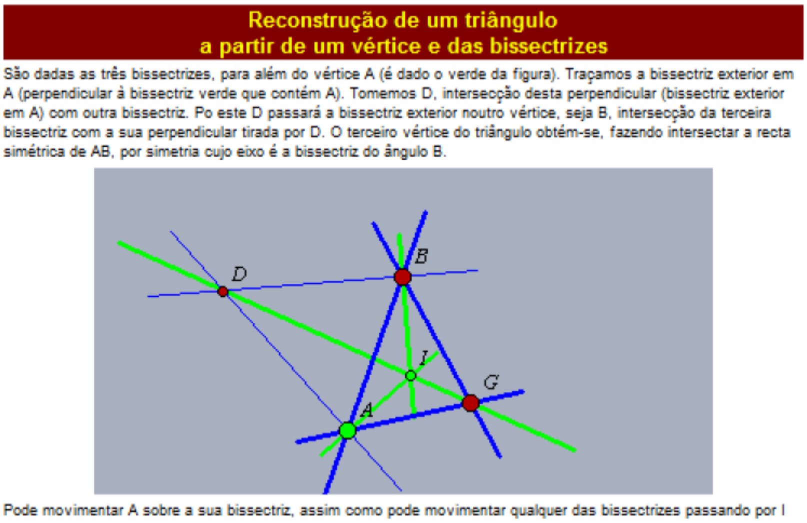
Bissectrizes dos ângulos de um triângulo

Num triângulo [ABC] consideramos habitualmente os ângulos internos e as suas bissectrizes a verde na figura e que se interesectam no ponto I, incentro.Mas podemos considerar as bissectrizes exteriores, a vermelho na figura. Movendo A, B ou C, vimos como os ângulos do triângulo mudam, mas o ângulo que cada bissectriz interior, AI, com a respectiva bissectriz externa, AD, parece manter-se constantemente perto de 90 graus. Podemos conjecturar que as bissectrizes dos dois ângulos formados por duas rectas são perpendiculares. Outro resultado que a figura sugere: A bissectriz interna do ângulo C, passa pelo ponto de intersecção das bissectrizes exteriores em A e em B.

Procure demonstrar os resultados que a figura sugere.

Resposta ao desafio:
Se não tiver reconstruído o triângulo, pode ver a nossa construção com Cinderella.

Construção dinâmica de um triângulo dados um vértice e as três bissectrizes



Reconstrução de um triângulo
a partir de um vértice e das bissectrizes

São dadas as três bissectrizes, para além do vértice A (é dado o verde da figura). Traçamos a bissectriz exterior em A (perpendicular à bissectriz verde que contém A). Tomemos D, intersecção desta perpendicular (bissectriz exterior em A) com outra bissectriz. Po este D passará a bissectriz exterior noutro vértice, seja B, intersecção da terceira bissectriz com a sua perpendicular tirada por D. O terceiro vértice do triângulo obtém-se, fazendo intersectar a recta simétrica de AB, por simetria cujo eixo é a bissectriz do ângulo B.

Pode movimentar A sobre a sua bissectriz, assim como pode movimentar qualquer das bissectrizes passando por I

Antiparallels and Concurrent Euler Lines

Nikolaos Dergiades and Paul Yiu

Abstract. We study the condition for concurrency of the Euler lines of the three triangles each bounded by two sides of a reference triangle and an antiparallel to the third side. For example, if the antiparallels are concurrent at P and the three Euler lines are concurrent at Q, then the loci of P and Q are respectively the tangent to the Jerabek hyperbola at the Lemoine point, and the line parallel to the Brocard axis through the inverse of the deLongchamps point in the circumcircle. We also obtain an interesting cubic as the locus of the point P for which the three Euler lines are concurrent when the antiparallels are constructed through the vertices of the cevian triangle of P.

1. Thébault's theorem on Euler lines

We begin with the following theorem of Victor Thébault [8] on the concurrency of three Euler lines.

Theorem 1 (Thébault)**.** *Let $A'B'C'$ be the orthic triangle of ABC. The Euler lines of the triangles $AB'C'$, $BC'A'$, $CA'B'$ are concurrent at the Jerabek center.*[1]

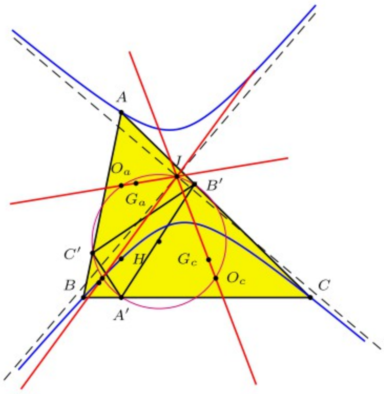

Figure 1. Thébault's theorem on the concurrency of Euler lines

We shall make use of homogeneous barycentric coordinates. With reference to triangle ABC, the vertices of the orthic triangle are the points

$$A' = (0 : S_C : S_B), \qquad B' = (S_C : 0 : S_A), \qquad C' = (S_B : S_A : 0).$$

Publication Date: February 3, 2004. Communicating Editor: Antreas P. Hatzipolakis.

[1] Thébault [8] gave an equivalent characterization of this common point. See also [7].

These are the traces of the orthocenter $H = (S_{BC} : S_{CA} : S_{AB})$.

The centroid of $AB'C'$ is the point

$$(S_{AA} + 2S_{AB} + 2S_{AC} + 3S_{BC} : S_A(S_C + S_A) : S_A(S_A + S_B)).$$

The circumcenter of $A'BC$, being the midpoint of AH, has coordinates

$$(S_{CA} + S_{AB} + 2S_{BC} : S_{AC} : S_{AB}).$$

It is straightforward to verify that these two points lie on the line

$$S_{AA}(S_B - S_C)(x+y+z) = (S_A+S_B)(S_{AB}+S_{BC}-2S_{CA})y - (S_C+S_A)(S_{BC}+S_{CA}-2S_{AB})z, \tag{1}$$

which is therefore the Euler line of triangle $AB'C'$. Furthermore, the line (1) also contains the point

$$J = (S_A(S_B - S_C)^2 : S_B(S_C - S_A)^2 : S_C(S_A - S_B)^2),$$

which is the center of the Jerabek hyperbola.[2] Similar reasoning gives the equations of the Euler lines of triangles $BC'A'$ and $A'B'C$, and shows that these contain the same point J. This completes the proof of Thébault's theorem.

2. Triangles intercepted by antiparallels

Since the sides of the orthic triangles are antiparallel to the respective sides of triangle ABC, we consider the more general situation when the residuals of the orthic triangle are replaced by triangles intercepted by lines ℓ_1, ℓ_2, ℓ_3 antiparallel to the sidelines of the reference triangle, with the following intercepts on the sidelines

	BC	CA	AB
ℓ_1		B_a	C_a
ℓ_2	A_b		C_b
ℓ_3	A_c	B_c	

These lines are parallel to the sidelines of the orthic triangle $A'B'C'$. We shall assume that they are the images of the lines $B'C'$, $C'A'$, $A'B'$ under the homotheties $\mathsf{h}(A, 1-t_1)$, $\mathsf{h}(B, 1-t_2)$, and $\mathsf{h}(C, 1-t_3)$ respectively. The points B_a, C_a etc. have homogeneous barycentric coordinates

$$\begin{aligned} B_a &= (t_1S_A + S_C : 0 : (1-t_1)S_A), & C_a &= (t_1S_A + S_B : (1-t_1)S_A : 0), \\ C_b &= ((1-t_2)S_B : t_2S_B + S_A : 0), & A_b &= (0 : t_2S_B + S_C : (1-t_2)S_B), \\ A_c &= (0 : (1-t_3)S_C : t_3S_C + S_B), & B_c &= ((1-t_3)S_C : 0 : t_3S_C + S_A). \end{aligned}$$

---

[2] The point J appears as X_{125} in [4].

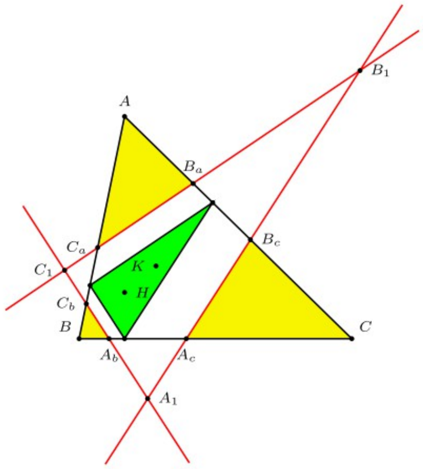

Figure 2. Triangles intercepted by antiparallels

2.1. *The Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$.* Denote by $\mathbf{T}_1$ the triangle AB_aC_a intercepted by ℓ_1; similarly $\mathbf{T}_2$ and $\mathbf{T}_3$. These are oppositely similar to ABC. We shall study the condition of the concurrency of their Euler lines.

Proposition 2. *With reference to triangle ABC, the barycentric equations of the Euler lines of $\mathbf{T}_i$, $i = 1, 2, 3$, are*

$$\begin{aligned}(1-t_1)S_{AA}(S_B-S_C)(x+y+z) &= c^2(S_{AB}+S_{BC}-2S_{CA})y - b^2(S_{BC}+S_{CA}-2S_{AB})z,\\(1-t_2)S_{BB}(S_C-S_A)(x+y+z) &= a^2(S_{BC}+S_{CA}-2S_{AB})z - c^2(S_{CA}+S_{AB}-2S_{BC})x,\\(1-t_3)S_{CC}(S_A-S_B)(x+y+z) &= b^2(S_{CA}+S_{AB}-2S_{BC})x - a^2(S_{AB}+S_{BC}-2S_{CA})y.\end{aligned}$$

Proof. It is enough to establish the equation of the Euler line $\mathcal{L}_1$ of $\mathbf{T}_1$. This is the image of the Euler line $\mathcal{L}_1'$ of triangle $AB'C'$ under the homothety $\mathsf{h}(A, 1-t_1)$. A point $(x : y : z)$ on $\mathcal{L}_1$ corresponds to the point $((1-t_1)x - t_1(y+z) : y : z)$ on $\mathcal{L}_1'$. The equation of $\mathcal{L}_1$ can now by obtained from (1). □

From the equations of these Euler lines, we easily obtain the condition for their concurrency.

Theorem 3. *The three Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, are concurrent if and only if*

$$t_1a^2(S_B-S_C)S_{AA} + t_2b^2(S_C-S_A)S_{BB} + t_3c^2(S_A-S_B)S_{CC} = 0. \qquad (2)$$

Proof. From the equations of $\mathcal{L}_i$, $i = 1, 2, 3$, given in Proposition 2, it is clear that the condition for concurrency is

$$(1-t_1)a^2(S_B-S_C)S_{AA} + (1-t_2)b^2(S_C-S_A)S_{BB} + (1-t_3)c^2(S_A-S_B)S_{CC} = 0.$$

This simplifies into (2) above. □

2.2. *Antiparallels with given common point of $\mathcal{L}_i$, $i = 1, 2, 3$.* We shall assume triangle ABC scalene, *i.e.*, its angles are unequal and none of them is a right angle. For such triangles, the Euler lines of the residuals of the orthic triangle and the corresponding altitudes intersect at finite points.

Theorem 4. *Given a point Q in the plane of a scalene triangle ABC, there is a unqiue triple of antiparallels ℓ_i, $i = 1, 2, 3$, for which the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, are concurrent at Q.*

Proof. Construct the parallel through Q to the Euler line of $AB'C'$ to intersect the line AH at O_a. The circle through A with center O_a intersects AC and AB at B_a and C_a respectively. The line B_aC_a is parallel to $B'C'$. It follows that its Euler line is parallel to that of $AB'C'$. This is the line O_aQ. Similar constructions give the other two antiparallels with corresponding Euler lines passing through Q. □

We make a useful observation here. From the equations of the Euler lines given in Proposition 2 above, the intersection of any two of them have coordinates expressible in linear functions of t_1, t_2, t_3. It follows that if t_1, t_2, t_3 are linear functions of a parameter t, and the three Euler lines are concurrent, then as t varies, the common point traverses a straight line. In particular, $t_1 = t_2 = t_3 = t$, the Euler lines are concurrent by Theorem 3. The locus of the intersection of the Euler lines is a straight line. Since this intersection is the Jerabek center when $t = 0$ (Thébault's theorem), and the orthocenter when $t = -1$,[3] this is the line

$$\mathcal{L}_\text{c} : \qquad \sum_{\text{cyclic}} S_{AA}(S_B - S_C)(S_{CA} + S_{AB} - 2S_{BC})x = 0.$$

We give a summary of some of the interesting loci of common points of Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, when the lines ℓ_i, $i = 1, 2, 3$, are subjected to some further conditions. In what follows, $\mathbf{T}$ denotes the triangle bounded by the lines ℓ_i, $i = 1, 2, 3$.

Line	Construction	Condition	Reference
$\mathcal{L}_\text{c}$	HJ	$\mathbf{T}$ homothetic to orthic triangle at X_{25}	
$\mathcal{L}_\text{q}$	Remark below	ℓ_i, $i = 1, 2, 3$, concurrent	§3.2
$\mathcal{L}_\text{t}$	KX_{74}	ℓ_i are the antiparallels of a Tucker hexagon	§6
$\mathcal{L}_\text{f}$	X_5X_{184}	$\mathcal{L}_i$ intersect on Euler line of $\mathbf{T}$	§7.2
$\mathcal{L}_\text{r}$	GX_{110}	$\mathbf{T}$ and ABC perspective	§8.3

Remark. $\mathcal{L}_\text{q}$ can be constructed as the line parallel to the Brocard axis through the intersection of the inverse of the deLongchamps point in the circumcircle.

---

[3] For $t = 1$, this intersection is the point X_{74} on the circumcircle, the isogonal conjugate of the infinite point of the Euler line.

3. Concurrent antiparallels

In this section we consider the case when the antiparallels ℓ_1, ℓ_2, ℓ_3 all pass through a point $P = (u : v : w)$. In this case,

$$\begin{aligned}
B_a &= ((S_C + S_A)u - (S_B - S_C)v : 0 : (S_A + S_B)v + (S_C + S_A)w),\\
C_a &= ((S_A + S_B)u + (S_B - S_C)w : (S_A + S_B)v + (S_C + S_A)w : 0),\\
C_b &= ((S_B + S_C)w + (S_A + S_B)u : (S_A + S_B)v - (S_C - S_A)w : 0),\\
A_b &= (0 : (S_B + S_C)v + (S_C - S_A)u : (S_B + S_C)w + (S_A + S_B)u),\\
A_c &= (0 : (S_C + S_A)u + (S_B + S_C)v : (S_B + S_C)w - (S_A - S_B)u),\\
B_c &= ((S_C + S_A)u + (S_B + S_C)v : 0 : (S_C + S_A)w + (S_A - S_B)v).
\end{aligned}$$

For example, when $P = K$, these are the vertices of the second cosine circle.

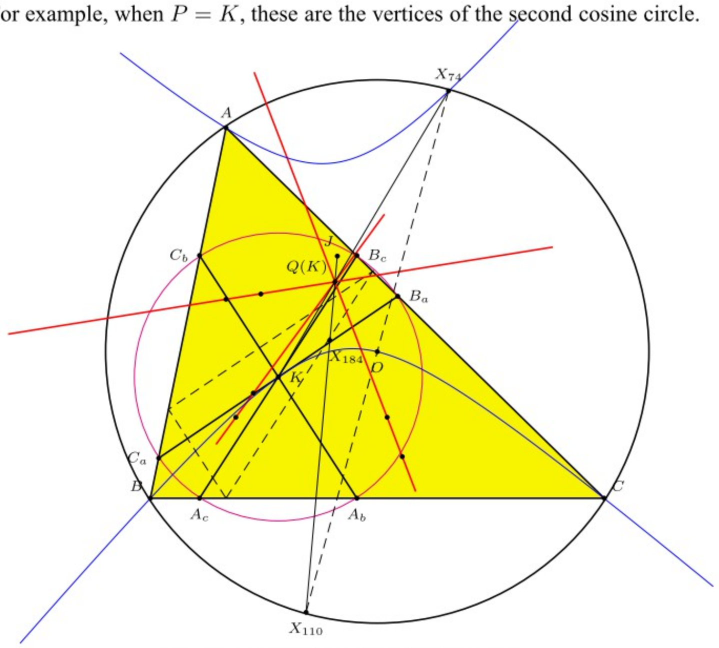

Figure 3. $Q(K)$ and the second Lemoine circle

Proposition 5. *The Euler lines of triangles* $\mathbf{T}_i$, $i = 1, 2, 3$, *are concurrent if and only if* P *lies on the line*

$$\mathcal{L}_{\rm p}: \qquad \frac{S_A(S_B - S_C)}{a^2}x + \frac{S_B(S_C - S_A)}{b^2}y + \frac{S_C(S_A - S_B)}{c^2}z = 0.$$

When P *traverses* $\mathcal{L}_{\rm p}$, *the intersection* Q *of the Euler lines traverses the line*

$$\mathcal{L}_{\rm q}: \qquad \sum_{\text{cyclic}} \frac{(b^2 - c^2)(a^2(S_{AA} + S_{BC}) - 4S_{ABC})}{a^2}x = 0.$$

For a point P on the line $\mathcal{L}_{\rm p}$, we denote by $Q(P)$ the corresponding point on $\mathcal{L}_{\rm q}$.

Proposition 6. *For points* P_1, P_2, P_3 *on* $\mathcal{L}_{\rm p}$, $Q(P_1)$, $Q(P_2)$, $Q(P_3)$ *are points on* $\mathcal{L}_{\rm q}$ *satisfying*

$$Q(P_1)Q(P_2) : Q(P_2)Q(P_3) = P_1P_2 : P_2P_3.$$

3.1. *The line* $\mathcal{L}_{\rm p}$. The line $\mathcal{L}_{\rm p}$ contains K and is the tangent to the Jerabek hyperbola at K. See Figure 4. It also contains, among others, the following points.

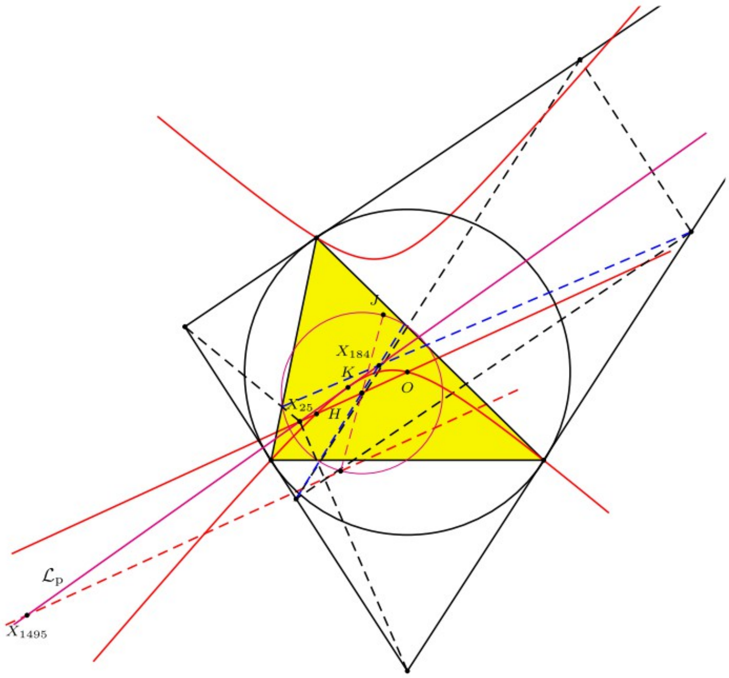

Figure 4. The line $\mathcal{L}_{\rm p}$

(1) $X_{25} = \left(\frac{a^2}{S_A} : \frac{b^2}{S_B} : \frac{c^2}{S_C}\right)$ which is on the Euler line of ABC, and is the homothetic center of the orthic and the tangential triangles,[4]

(2) $X_{184} = (a^4S_A : b^4S_B : c^4S_C)$ which is the homothetic center of the orthic triangle and the medial tangential triangle,[5]

---

[4] See also §4.1.

[5] For other interesting properties of X_{184}, see [6], where it is named the procircumcenter of triangle ABC.

(3) $X_{1495} = (a^2(S_{CA}+S_{AB}-2S_{BC}) : \cdots : \cdots)$ which lies on the parallel to the Euler line through the antipode of the Jerabek center on the nine-point circle. [6]

3.2. *The line* $\mathcal{L}_{\mathrm{q}}$. The line $\mathcal{L}_{\mathrm{q}}$ is parallel to the Brocard axis. See Figure 5. It contains the following points.

(1) $Q(K) = (a^2S_A(b^2c^2(S_{BB}-S_{BC}+S_{CC})-2a^2S_{ABC}) : \cdots : \cdots)$. It can be constructed as the intersection of the lines joining K to X_{74}, and J to X_{110}. See Figure 3 and §6 below. The line $\mathcal{L}_{\mathrm{q}}$ can therefore be constructed as the parallel through this point to the Brocard axis.

(2) $Q(X_{1495}) = (a^2S_A(a^2S^2 - 6S_{ABC}) : \cdots : \cdots)$, which is on the line joining O to X_{184} (on $\mathcal{L}_{\mathrm{p}}$).

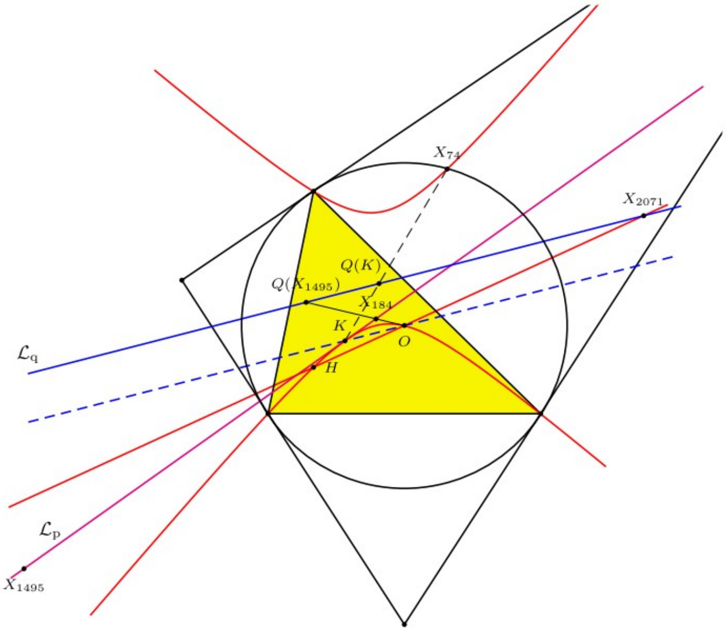

Figure 5. The line $\mathcal{L}_{\mathrm{q}}$

The line $\mathcal{L}_{\mathrm{q}}$ intersects the Euler line of ABC at the point

$$X_{2071} = (a^2(a^2S_{AAA} + S_{AA}(S_{BB} - 3S_{BC} + S_{CC}) - S_{BBCC}) : \cdots : \cdots),$$

---

[6] This is the point X_{113}.

which is the inverse of the de Longchamps point in the circumcircle. This corresponds to the antiparallels through

$$P_{2071}=(a^4((a^2S_{AAA}+S_{AA}(S_{BB}-3S_{BC}+S_{CC})-S_{BBCC}):\cdots:\cdots)$$

on the line $\mathcal{L}_{\text{p}}$. This point can be constructed by a simple application of Theorem 4 or Proposition 6. (See also Remark 2 following Theorem 12).

3.3. *The intersection of* $\mathcal{L}_{\text{p}}$ *and* $\mathcal{L}_{\text{q}}$. The lines $\mathcal{L}_{\text{p}}$ and $\mathcal{L}_{\text{q}}$ intersect at the point

$$M=(a^2S_A(S_{AB}+S_{AC}+S_{BB}-4S_{BC}+S_{CC}):\cdots:\cdots).$$

(1) $Q(M)$ is the point on $\mathcal{L}_{\text{q}}$ with coordinates

$$(a^2S_A(S_{AA}(S_{BB}+S_{CC})+a^2S_A(S_{BB}-3S_{BC}+S_{CC})+S_{BC}(S_B-S_C)^2):\cdots:\cdots).$$

(2) The point P on $\mathcal{L}_{\text{p}}$ for which $Q(P)=M$ has coordinates

$$(a^2(a^2(2S_{AA}-S_{BC})+2S_A(S_{BB}-3S_{BC}+S_{CC})):\cdots:\cdots).$$

4. The triangle $\mathbf{T}$ bounded by the antiparallels

We assume the line ℓ_i, $i=1,2,3$, nonconcurrent so that they bound a nondegenerate triangle $\mathbf{T}=A_1B_1C_1$. Since these lines have equations

$$\begin{aligned}
-t_1S_A(x+y+z) &= -S_Ax+S_By+S_Cz,\\
-t_2S_B(x+y+z) &= \ \ S_Ax-S_By+S_Cz,\\
-t_3S_C(x+y+z) &= \ \ S_Ax+S_By-S_Cz,
\end{aligned}$$

the vertices of $\mathbf{T}$ are the points

$$\begin{aligned}
A_1 =&(-a^2(t_2S_B+t_3S_C):2S_{CA}+t_2b^2S_B+t_3S_C(S_C-S_A)\\
&:2S_{AB}+t_2S_B(S_B-S_A)+t_3c^2S_C),\\
B_1 =&(2S_{BC}+t_3S_C(S_C-S_B)+t_1a^2S_A:-b^2(t_3S_C+t_1S_A)\\
&:2S_{AB}+t_3c^2S_C+t_1S_A(S_A-S_B))\\
C_1 =&(2S_{BC}+t_1a^2S_A+t_2S_B(S_B-S_C):2S_{CA}+t_1S_A(S_A-S_C)+t_2b^2S_B\\
&:-c^2(t_1S_A+t_2S_B)).
\end{aligned}$$

4.1. *Homothety with the orthic triangle* . The triangle $\mathbf{T}=A_1B_1C_1$ is homothetic to the orthic triangle $A'B'C'$. The center of homothety is the point

$$P(\mathbf{T})=\left(\frac{t_2S_B+t_3S_C}{S_A}:\frac{t_3S_C+t_1S_A}{S_B}:\frac{t_1S_A+t_2S_B}{S_C}\right), \tag{3}$$

and the ratio of homothety is

$$1+\frac{t_1a^2S_{AA}+t_2b^2S_{BB}+t_3c^2S_{CC}}{2S_{ABC}}.$$

Proposition 7. *If the Euler lines* $\mathcal{L}_i$, $i=1,2,3$, *are concurrent, the homothetic center* $P(\mathbf{T})$ *of* $\mathbf{T}$ *and the orthic triangle lies on the line* $\mathcal{L}_{\text{p}}$.

Proof. If we write $P(\mathbf{T}) = (x : y : z)$. From (3), we obtain

$$t_1 = \frac{-xS_A + yS_B + zS_C}{2S_A}, \quad t_2 = \frac{-yS_B + zS_C + xS_A}{2S_B}, \quad t_3 = \frac{-zS_C + xS_A + yS_B}{2S_C}.$$

Substitution in (2) yields the equation of the line $\mathcal{L}_{\text{p}}$. □

For example, if $t_1 = t_2 = t_3 = t$, $P(\mathbf{T}) = X_{25} = \left(\frac{a^2}{S_A} : \frac{b^2}{S_B} : \frac{c^2}{S_C}\right)$.[7] If the ratio of homothety is 0, triangle $\mathbf{T}$ degenerates into the point X_{25} on $\mathcal{L}_{\text{p}}$. The intersection of $\mathcal{L}_{\text{c}}$ and $\mathcal{L}_{\text{q}}$ is the point

$$\begin{aligned} Q(X_{25}) =& (a^2S_A(b^4S_B^4 + c^4S_C^4 + a^2S_{AAA}(S_B - S_C)^2 \\ & - S_{ABC}(4a^2S_{BC} + 3S_A(S_B - S_C)^2)) : \cdots : \cdots). \end{aligned}$$

Remark. The line $\mathcal{L}_{\text{p}}$ is also the locus of the centroid of $\mathbf{T}$ for which the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, concur.

4.2. *Common point of $\mathcal{L}_i$, $i = 1, 2, 3$, on the Brocard axis.* We consider the case when the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, intersect on the Brocard axis. A typical point on the Brocard axis, dividing the segment OK in the ratio $t : 1 - t$, has coordinates

$$(a^2(S_A(S_A + S_B + S_C) + (S_{BC} - S_{AA})t) : \cdots : \cdots).$$

This point lies on the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, if and only if we choose

$$\begin{aligned} t_1 =& \frac{-(S_A + S_B + S_C)(S^2 - S_{AA}) + b^2c^2(S_B + S_C - 2S_A)t}{2S_{AA}(S_A + S_B + S_C)}, \\ t_2 =& \frac{-(S_A + S_B + S_C)(S^2 - S_{BB}) + c^2a^2(S_C + S_A - 2S_B)t}{2S_{BB}(S_A + S_B + S_C)}, \\ t_3 =& \frac{-(S_A + S_B + S_C)(S^2 - S_{CC}) + a^2b^2(S_A + S_B - 2S_C)t}{2S_{CC}(S_A + S_B + S_C)}. \end{aligned}$$

The corresponding triangle $\mathbf{T}$ is homothetic to the orthic triangle at the point

$$(a^2(-(S_A + S_B + S_C) \cdot a^2S_A + t(-(2S_A + S_B + S_C)S_{BC} + b^2S_{CA} + c^2S_{AB}) : \cdots : \cdots),$$

which divides the segment $X_{184}K$ in the ratio $2t : 1 - 2t$. The ratio of homothety is $-\frac{a^2b^2c^2}{4S_{ABC}}$. These triangles are all directly congruent to the medial tangential triangle of ABC. We summarize this in the following proposition.

Proposition 8. *Corresponding to the family of triangles directly congruent to the medial tangential triangle, homothetic to orthic triangle at points on the line $\mathcal{L}_{\text{p}}$, the common points of the Euler lines of $\mathcal{L}_i$, $i = 1, 2, 3$, all lie on the Brocard axis.*

---

[7] See also §3.1(1). The tangential triangle is $\mathbf{T}$ with $t = 1$.

5. Perspectivity of $\mathbf{T}$ with ABC

Proposition 9. *The triangles* $\mathbf{T}$ *and* ABC *are perspective if and only if*

$$\sum_{\text{cyclic}}(S_B - S_C)(t_1S_{AA} - t_2t_3S_{BC}) = 0. \tag{4}$$

Proof. From the coordinates of the vertices of $\mathbf{T}$, it is straightforward to check that $\mathbf{T}$ and ABC are perspective if and only if

$$t_1a^2S_{AA} + t_2b^2S_{BB} + t_3c^2S_{CC} + 2S_{ABC} = 0$$

or (4) holds. Since the area of triangle $\mathbf{T}$ is

$$\frac{(t_1a^2S_{AA} + t_2b^2S_{BB} + t_3c^2S_{CC} + 2S_{ABC})^2}{a^2b^2c^2S_{ABC}}$$

times that of triangle ABC, we assume $t_1a^2S_{AA}+t_2b^2S_{BB}+t_3c^2S_{CC}+2S_{ABC} \neq 0$ and (4) is the necessary and sufficient condition for perspectivity. $\square$

Theorem 10. *If the triangle* $\mathbf{T}$ *is nondegenerate and is perspective to* ABC*, then the perspector lies on the Jerabek hyperbola of* ABC*.*

Proof. If triangles $A_1B_1C_1$ and ABC are perspective at $P = (x : y : z)$, then

$$A_1 = (u + x : y : z), \quad B_1 = (x : v + y : z), \quad C_1 = (x : y : w + z)$$

for some u, v, w. Since the line B_1C_1 is parallel to $B'C'$, which has infinite point $(S_B - S_C : -(S_C + S_A) : S_A + S_B)$, we have

$$\begin{vmatrix} S_B - S_C & -(S_C + S_A) & S_A + S_B \\ x & y + v & z \\ x & y & z + w \end{vmatrix} = 0,$$

and similarly for the other two lines. These can be rearranged as

$$\begin{aligned}
\frac{(S_C + S_A)x - (S_B - S_C)y}{v} - \frac{(S_B - S_C)z + (S_A + S_B)x}{w} &= S_B - S_C, \\
\frac{(S_A + S_B)y - (S_C - S_A)z}{w} - \frac{(S_C - S_A)x + (S_B + S_C)y}{u} &= S_C - S_A, \\
\frac{(S_B + S_C)z - (S_A - S_B)x}{u} - \frac{(S_A - S_B)y + (S_C + S_A)z}{v} &= S_A - S_B.
\end{aligned}$$

Multiplying these equations respectively by

$$S_A(S_B + S_C)yz, \qquad S_B(S_C + S_A)zx, \qquad S_C(S_A + S_B)xy$$

and adding up, we obtain

$$\left(1 + \frac{x}{u} + \frac{y}{v} + \frac{z}{w}\right)\sum_{\text{cyclic}} S_A(S_{BB} - S_{CC})yz = 0.$$

Since the area of triangle $\mathbf{T}$ is

$$uvw\left(1 + \frac{x}{u} + \frac{y}{v} + \frac{z}{w}\right)$$

times that of triangle ABC, we must have $1+\frac{x}{u}+\frac{y}{v}+\frac{z}{w}\neq 0$. It follows that

$$\sum_{\text{cyclic}} S_A(S_{BB}-S_{CC})yz=0.$$

This means that P lies on the Jerabek hyperbola. □

We shall identify the locus of the common points of Euler lines in §8.3 below. In the meantime, we give a construction for the point Q from the perspector on the Jerabek hypebola.

Construction. Given a point P on the Jerabek hyperbola, construct parallels to $A'B'$ and $A'C'$ through an arbitrary point A_1' on the line AP. Let M_1 be the intersection of the Euler lines of the triangles formed by these antiparallels and the sidelines of ABC. With another point A_1'' obtain a point M_2 by the same construction. Similarly, working with two points B_1' and B_1'' on BP, we construct another line M_3M_4. The intersection of M_1M_2 and M_3M_4 is the common point Q of the Euler lines corresponding the antiparallels that bound a triangle perspective to ABC at P.

6. The Tucker hexagons and the line $\mathcal{L}_t$

It is well known that if the antiparallels, together with the sidelines of triangle ABC, bound a Tucker hexagon, the vertices lie on a circle whose center is on the Brocard axis. If this center divides the segment OK in the ratio $t:1-t$, the antiparallels pass through the points dividing the symmedians in the same ratio. The vertices of the Tucker hexagon are

$$\begin{aligned} B_a &= (S_C+(1-t)c^2:0:tc^2), & C_a &= (S_B+(1-t)b^2:tb^2:0),\\ C_b &= (ta^2:S_A+(1-t)a^2:0), & A_b &= (0:S_C+(1-t)c^2:tc^2),\\ A_c &= (0:tb^2:S_B+(1-t)b^2), & B_c &= (ta^2:0:S_A+(1-t)a^2). \end{aligned}$$

In this case,

$$1-t_1=\frac{t\cdot b^2c^2}{S_A(S_A+S_B+S_C)},\quad 1-t_2=\frac{t\cdot c^2a^2}{S_B(S_A+S_B+S_C)},\quad 1-t_3=\frac{t\cdot a^2b^2}{S_C(S_A+S_B+S_C)}.$$

It is clear that the Euler lines $\mathcal{L}_i$, $i=1,2,3$, are concurrent. As t varies, this common point traverses a straight line $\mathcal{L}_t$. We show that this is the line joining K to $Q(K)$.

(1) For $t=1$, this Tucker circle is the second Lemoine circle with center K, the triangle $\mathbf{T}$ degenerates into the point K. The common point of the Euler lines is therefore the point $Q(K)$. See §3.2 and Figure 3.

(2) For $t=\frac{3}{2}$, the vertices of the Tucker hexagon are

$$\begin{aligned} B_a &= (a^2+b^2-2c^2:0:3c^2), & C_a &= (c^2+a^2-2b^2:3b^2:0),\\ C_b &= (3a^2:b^2+c^2-2a^2:0), & A_b &= (0:a^2+b^2-2c^2:3c^2),\\ A_c &= (0:3b^2:c^2+a^2-2b^2), & B_c &= (3a^2:0:b^2+c^2-2a^2). \end{aligned}$$

The triangles $\mathbf{T}_i$, $i = 1, 2, 3$, have a common centroid K, which is therefore the common point of their Euler lines. The corresponding Tucker center is the point X_{576} (which divides OK in the ratio $3 : -1$).

From these, we obtain the equation of the line

$$\mathcal{L}_{\text{t}} : \qquad \sum_{\text{cyclic}} b^2c^2S_A(S_B - S_C)(S_{CA} + S_{AB} - 2S_{BC})x = 0.$$

Remarks. (1) The triangle $\mathbf{T}$ is perspective to ABC at K. See, for example, [5].

(2) The line $\mathcal{L}_{\text{t}}$ also contains X_{74} which we may regard as corresponding to $t = 0$.

For more about Tucker hexagons, see §8.2.

7. Concurrency of four or more Euler lines

7.1. *Common point of $\mathcal{L}_i$, $i = 1, 2, 3$, on the Euler line of ABC.* We consider the case when the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, intersect on the Euler line of ABC. A typical point on the Euler line axis divides the segment OH in the ratio $t : 1 - t$, has coordinates

$$(a^2S_A - (S_{CA} + S_{AB} - 2S_{BC})t) : \cdots : \cdots).$$

This lies on the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, if and only if we choose

$$\begin{aligned} t_1 =& \frac{-(S^2 - S_{AA}) + (S^2 - 3S_{AA})t}{2S_{AA}}, \\ t_2 =& \frac{-(S^2 - S_{BB}) + (S^2 - 3S_{BB})t}{2S_{BB}}, \\ t_3 =& \frac{-(S^2 - S_{CC}) + (S^2 - 3S_{CC})t}{2S_{CC}}. \end{aligned}$$

Independently of t, the corresponding triangle $\mathbf{T}$ is always homothetic to the medial tangential triangle at the point P_{2071} on the line $\mathcal{L}_{\text{p}}$ for which $Q(P_{2071}) = X_{2071}$, the intersection of $\mathcal{L}_{\text{q}}$ with the Euler line. See the end of §3.2 above. The ratio of homothety is $1 + t - \frac{8S_{ABC}}{a^2b^2c^2}t$. We summarize this in the following proposition.

Proposition 11. *Let P_{2071} be the point on $\mathcal{L}_{\text{p}}$ such that $Q(P_{2071}) = X_{2071}$. The Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, corresponding to the sidelines of triangles homothetic at P_{2071} to the medial tangential triangle intersect on the Euler line of ABC.*

7.2. *The line $\mathcal{L}_{\text{f}}$.* The Euler line of triangle $\mathbf{T}$ is the line

$$\begin{aligned} &(x + y + z) \sum_{\text{cyclic}} t_1a^2S_{AA}(S_B - S_C)(S^2 + S_{BC})(S^2 - S_{AA}) \\ =&2S_{ABC} \sum_{\text{cyclic}} (S^2 + S_{CA})(S^2 + S_{AB})x. \end{aligned} \tag{5}$$

Theorem 12. *The Euler lines of the four triangles* $\mathbf{T}$ *and* $\mathbf{T}_i$*,* $i = 1, 2, 3$*, are concurrent if and only if*

$$\begin{aligned} t_1 &= -\frac{16S^2 \cdot S_{ABC} + t(a^2b^4c^4 - 4S_{ABC}(3S^2 - S_{AA}))}{4S_{AA}(a^2b^2c^2 + 4S_{ABC})}, \\ t_2 &= -\frac{16S^2 \cdot S_{ABC} + t(a^4b^2c^4 - 4S_{ABC}(3S^2 - S_{BB}))}{4S_{BB}(a^2b^2c^2 + 4S_{ABC})}, \\ t_3 &= -\frac{16S^2 \cdot S_{ABC} + t(a^4b^4c^2 - 4S_{ABC}(3S^2 - S_{CC}))}{4S_{CC}(a^2b^2c^2 + 4S_{ABC})}, \end{aligned}$$

with $t \neq \frac{-24a^2b^2c^2S_{ABC}}{(a^2b^2c^2-8S_{ABC})(3(S_A+S_B+S_C)S^2+S_{ABC})}$*. The locus of the common point of the four Euler lines is the line* $\mathcal{L}_\mathrm{f}$ *joining the nine-point center of* ABC *to* X_{184}*, with the intersection with* $\mathcal{L}_\mathrm{q}$ *deleted.*

Proof. The equation of the Euler line $\mathcal{L}_i$, $i = 1, 2, 3$, can be rewritten as

$$\begin{aligned} & t_1S_A(S_B - S_C)(x + y + z) + S_{AA}(S_B - S_C)x \\ & +(S_{AB}(S_B - S_C) - (S_{AA} - S_{BB})S_C)y + (S_{AC}(S_B - S_C) + (S_{AA} - S_{CC})S_B)z = 0, \quad (6) \\ & t_2S_A(S_B - S_C)(x + y + z) + S_{BB}(S_C - S_A)y \\ & +(S_{BA}(S_C - S_A) + (S_{BB} - S_{AA})S_C)x + (S_{BC}(S_C - S_A) - (S_{BB} - S_{CC})S_A)z = 0, \quad (7) \\ & t_3S_C(S_A - S_B)(x + y + z) + S_{CC}(S_A - S_B)z \\ & +(S_{CA}(S_A - S_B) - (S_{CC} - S_{AA})S_B)x + (S_{CB}(S_A - S_B) + (S_{CC} - S_{BB})S_A)y = 0. \quad (8) \end{aligned}$$

Multiplying (4), (5), (6) respectively by

$$a^2S_A(S^2+S_{BC})(S^2-S_{AA}), \quad b^2S_B(S^2+S_{CA})(S^2-S_{BB}), \quad c^2S_C(S^2+S_{AB})(S^2-S_{CC}),$$

and adding, we obtain by Theorem 10 the equation of the line

$$\mathcal{L}_\mathrm{f}: \qquad \sum_{\text{cyclic}} (S_B - S_C)(S^2(2S_{AA} - S_{BC}) + S_{ABC} \cdot S_A)x = 0$$

which contains the common point of the Euler lines of $\mathbf{T}_i$, $i = 1, 2, 3$, if it also lies on the Euler line $\mathcal{L}$ of $\mathbf{T}$. The line $\mathcal{L}_\mathrm{f}$ contains the nine-point center X_5 and $X_{184} = (a^4S_A : b^4S_B : c^4S_C)$. Let Q_t be the point which divides the segment $X_{184}X_5$ in the ratio $t : 1 - t$. It has coordinates

$$\begin{aligned} &((1 - t)4S^2 \cdot a^4S_A + t(a^2b^2c^2 + 4S_{ABC})(S_{CA} + S_{AB} + 2S_{BC}) \\ &: (1 - t)4S^2 \cdot b^4S_B + t(a^2b^2c^2 + 4S_{ABC})(2S_{CA} + S_{AB} + S_{BC}) \\ &: (1 - t)4S^2 \cdot c^4S_C + t(a^2b^2c^2 + 4S_{ABC})(S_{CA} + 2S_{AB} + S_{BC})). \end{aligned}$$

The point Q_t lies on the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, respectively if we choose t_1, t_2, t_3 given above.

If Q lies on $\mathcal{L}_{\rm q}$, then $Q_t = Q(P)$ for some point P on $\mathcal{L}_{\rm p}$.[8] In this case, the triangle $\mathbf{T}$ degenerates into the point $P \neq Q$ and its Euler line is not defined. It should be excluded from $\mathcal{L}_{\rm f}$. The corresponding value of t is as given in the statement above. □

Here are some interesting points on $\mathcal{L}_{\rm f}$.

(1) For $t = 0$, $\mathbf{T}$ is perspective with ABC at X_{74}, and the common point of the four Euler lines is X_{184}. The antiparallels are drawn through the intercepts of the trilinear polars of $X_{186} = \left(\frac{a^2}{S_A(S^2-3S_{AA})} : \cdots : \cdots\right)$, the inversive image of the orthocenter in the circumcircle.

(2) For $t = 1$, this common point is the nine-point of triangle ABC. The triangle $\mathbf{T}$ is homothetic to the orthic triangle at X_{51} and to the medial tangential triangle at the point P_{2071} in §3.2.

(3) $t = -\frac{a^2b^2c^2}{4S_{ABC}}$ gives X_{156}, the nine-point center of the tangential triangle.

In these two cases, we have the concurrency of five Euler lines.

(4) The line $\mathcal{L}_{\rm f}$ intersects the Brocard axis at X_{569}. This corresponds to $t = \frac{2a^2b^2c^2}{3a^2b^2c^2+4S_{ABC}}$.

Proposition 13. *The triangle* $\mathbf{T}$ *is perspective with* ABC *and its Euler line contains the common point of the Euler lines of* $\mathbf{T}_i$, $i = 1, 2, 3$ *precisely in the following three cases.*

(1) $t = 0$, *with perspector* X_{74} *and common point of Euler line* X_{184}.

(2) $t = \frac{-12a^2b^2c^2S_{ABC}}{a^4b^4c^4-12a^2b^2c^2S_{ABC}-16(S_{ABC})^2}$, *with perspector* K.

Remarks. (1) In the first case,

$$t_1 = \frac{k}{S_{AA}}, \qquad t_2 = \frac{k}{S_{BB}}, \qquad t_3 = \frac{k}{S_{CC}}$$

for $k = -\frac{4S^2 \cdot S_{ABC}}{a^2b^2c^2+4S_{ABC}}$. The antiparallels pass through the intercepts of the trilinear polar of X_{186}, the inversive image of H in the circumcircle.

(2) In the second case, the antiparallels bound a Tucker hexagon. The center of the Tucker circle divides OK in the ratio $t : 1-t$, where

$$t = \frac{S^2(S_A+S_B+S_C)(a^2b^2c^2-16S_{ABC})}{a^4b^4c^4-12a^2b^2c^2S_{ABC}-16(S_{ABC})^2}.$$

It follows that the common point of the Euler lines is the intersection of the lines $\mathcal{L}_{\rm f} = X_5X_{184}$ and $\mathcal{L}_{\rm t}$.

8. Common points of $\mathcal{L}_i$, $i = 1, 2, 3$, when $\mathbf{T}$ is perspective

If the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, are concurrent, then, according to (2) we may put

$$t_1 = \frac{k(\lambda+S_A)}{a^2S_{AA}}, \qquad t_2 = \frac{k(\lambda+S_B)}{b^2S_{BB}}, \qquad t_3 = \frac{k(\lambda+S_C)}{c^2S_{CC}}$$

---

[8] This point is the intersection of $\mathcal{L}_{\rm p}$ with the line joining the Jerabek center J to X_{323}, the reflection in X_{110} of the inversive image of the centroid in the circumcircle.

for some λ and k. If, also, the $\mathbf{T}$ is perspective, (4) gives

$$k(k\lambda+S_{ABC})(\lambda+S_A+S_B+S_C)(k(3\lambda+S_A+S_B+S_C)+2S_{ABC})=0.$$

If $k=0$, $\mathbf{T}$ is the orthic triangle. We consider the remaining three cases below.

8.1. *The case* $k(S_A+S_B+S_C+3\lambda)+2S_{ABC}=0$. In this case,

$$\begin{aligned}t_1&=-\frac{2S_{ABC}+k(S_B+S_C-2S_A)}{3a^2S_{AA}},\\ t_2&=-\frac{2S_{ABC}+k(S_C+S_A-2S_B)}{3b^2S_{BB}},\\ t_3&=-\frac{2S_{ABC}+k(S_A+S_B-2S_C)}{3c^2S_{CC}}.\end{aligned}$$

The antiparallels are concurrent.

8.2. *The case* $k\lambda+S_{ABC}=0$. In this case,

$$t_1=\frac{k-S_{BC}}{a^2S_A},\qquad t_2=\frac{k-S_{CA}}{b^2S_B},\qquad t_3=\frac{k-S_{AB}}{c^2S_C}.$$

In this case, the perspector is the Lemoine point K. The antiparallels bound a Tucker hexagon. The locus of the common point of Euler lines is the line $\mathcal{L}_t$. Here are some more interesting points on this line.

(1) For $k=0$, we have

$$t_1=-\frac{S_{BC}}{S_A(S_B+S_C)},\qquad t_2=-\frac{S_{CA}}{S_B(S_C+S_A)},\qquad t_3=-\frac{S_{AB}}{S_C(S_A+S_B)}.$$

This gives the Tucker hexagon with vertices

$$\begin{aligned}B_a&=(S_{CC}:0:S^2), & C_a&=(S_{BB}:S^2:0),\\ C_b&=(S^2:S_{AA}:0), & A_b&=(0:S_{CC}:S^2),\\ A_c&=(0:S^2:S_{BB}), & B_c&=(S^2:0:S_{AA}).\end{aligned}$$

These are the pedals of A', B', C' on the sidelines. The Tucker circle is the Taylor circle. The triangle $\mathbf{T}$ is the medial triangle of the orthic triangle. The corresponding Euler lines intersect at X_{974}, which is the intersection of $\mathcal{L}_t=KX_{74}$ with X_5X_{125}. See [2].

(2) For $k=\frac{S_{ABC}}{S_A+S_B+S_C}$, we have

$$t_1=-\frac{S_{BC}}{S_A(S_A+S_B+S_C)},\qquad t_2=-\frac{S_{CA}}{S_B(S_A+S_B+S_C)},\qquad t_3=-\frac{S_{AB}}{S_C(S_A+S_B+S_C)}.$$

The Tucker circle is the second Lemoine circle, considered in §6.

(3) The line $\mathcal{L}_t$ intersects the Euler line at

$$X_{378}=\left(\frac{a^2(S^2+3S_{AA})}{S_A}:\cdots:\cdots\right).$$

The corresponding Tucker circle has center

$$(S^2(S_B+S_C)(S_C-S_A)(S_A-S_B)+3(S_A+S_B)(S_B+S_C)(S_C+S_A)S_{BC}:\cdots:\cdots)$$

which is the intersection of the Brocard axis and the line joining the orthocenter to X_{110}.

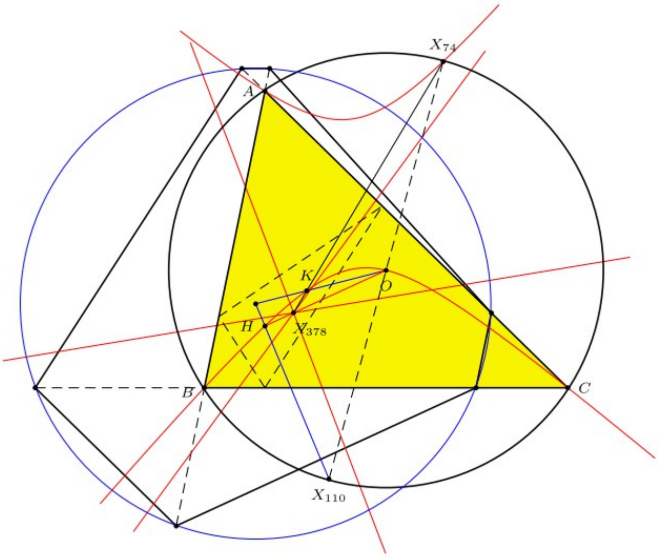

Figure 6. Intersection of 4 Euler lines at X_{378}

8.3. *The case* $\lambda = -(S_A+S_B+S_C)$. In this case, we have

$$t_1 = -\frac{k}{S_{AA}}, \qquad t_2 = -\frac{k}{S_{BB}}, \qquad t_3 = -\frac{k}{S_{CC}}.$$

In this case, the perspector is the point

$$\left(\frac{1}{2S_{ABC}\cdot S_A - k(b^2c^2-2S_{BC})}:\cdots:\cdots\right)$$

on the Jerabek hyperbola. If the point on the Jerabek hyperbola is the isogonal conjugate of the point which divides OH in the ratio $t:1-t$, then

$$k = \frac{4tS^2\cdot S_{ABC}}{a^2b^2c^2(1+t)+4t\cdot S_{ABC}}.$$

The locus of the intersection of the Euler lines $\mathcal{L}_i$, $i=1,2,3$, is clearly a line. Since this intersection is the Jerabek center for $k=0$ (Thébault's theorem) and the centroid for $k = \frac{S^2}{3}$, this is the line

$$\mathcal{L}_{\mathrm{r}} : \qquad \sum_{\text{cyclic}} (S_B - S_C)(S_{BC} - S_{AA})x = 0.$$

This line also contains, among other points, X_{110} and X_{184}. We summarize the general situation in the following theorem.

Theorem 14. *Let P be a point on the Euler line other than the centroid G. The antiparallels through the intercepts of the trilinear polar of P bound a triangle perspective with ABC (at a point on the Jerabek hyperbola). The Euler lines of the triangles $\mathbf{T}_i$, $i = 1, 2, 3$, are concurrent (at a point Q on the line L_{r} joining the centroid G to X_{110}).*

Here are some interesting examples with P easily constructed on the Euler line.

P	Perspector	Q
H	H	X_{125}
O	$X_{64} = X_{20}^*$	X_{110}
X_{30}	X_{2071}^*	G
X_{186}	X_{74}	X_{184}
X_{403}	$X_{265} = X186^*$	X_{1899}
X_{23}	$X_{1177} = X_{858}^*$	X_{182}
X_{858}		X_{1352}
X_{1316}		X_{98}

Remarks. (1) X_{186} is the inversive image of H in the circumcircle.
(2) X_{403} is the midpoint between H and X_{186}.
(3) X_{23} is the inversive image of G in the circumcircle.
(4) X_{858} is the inferior of X_{23}.
(5) X_{182} is the midpoint of OK, the center of the Brocard circle.
(6) X_{1352} is the reflection of K in the nine-point center.
(7) X_{1316} is the intersection of the Euler line and the Brocard circle apart from O.

9. Two loci: a line and a cubic

We conclude this paper with a brief discussion on two locus problems.

9.1. *Antiparallels through the vertices of a pedal triangle.* Suppose the antiparallels ℓ_i, $i = 1, 2, 3$, are constructed through the vertices of the pedal triangle of a finite point P. Then the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, are concurrent if and only if P lies on the line

$$\sum_{\text{cyclic}} S_A(S_B - S_C)(S_{AA} - S_{BC})x = 0.$$

This is the line containing H and the Tarry point X_{98}. For $P = H$, the common point of the Euler line is

$$X_{185} = (a^2 S_A(S_A(S_{BB} + S_{CC}) + a^2 S_{BC}) : \cdots : \cdots).$$

9.2. *Antiparallels through the vertices of a cevian triangle.* If, instead, the antiparallels ℓ_i, $i = 1, 2, 3$, are constructed through the vertices of the cevian triangle of P, then the locus of P for which the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, are concurrent is the cubic

$$\mathcal{K}: \quad \frac{S_A + S_B + S_C}{S_{ABC}} xyz + \sum_{\text{cyclic}} \frac{x}{S_A(S_B - S_C)} \left(\frac{S_A + S_B}{S_C} y^2 - \frac{S_C + S_A}{S_B} z^2 \right) = 0.$$

This can also be written in the form

$$\begin{aligned}&(\sum_{\text{cyclic}} (S_B + S_C)yz)(\sum_{\text{cyclic}} S_A(S_B - S_C)(S_B + S_C - S_A)x)\\ =&(\sum_{\text{cyclic}} S_A(S_B - S_C)x)(\sum_{\text{cyclic}} S_A(S_B + S_C)yz).\end{aligned}$$

From this, we obtain the following points on $\mathcal{K}$:

- the orthocenter H (as the intersection of the Euler line and the line $\sum_{\text{cyclic}} S_A(S_B - S_C)(S_B + S_C - S_A)x) = 0$),
- the Euler reflection point X_{110} (as the "fourth" intersection of the circumcircle and the circumconic $\sum_{\text{cyclic}} S_A(S_B + S_C)yz = 0$ with center K),
- the intersections of the Euler line with the circumcircle, the points X_{1113} and X_{1114}.

Corresponding to $P = X_{110}$, the Euler lines $\mathcal{L}_i$, $i = 1, 2, 3$, intersect at the circumcenter O. On the other hand, X_{1113} and X_{1114} are the points

$$(a^2 S_A + \lambda(S_{CA} + S_{AB} - 2S_{BC}) : \cdots : \cdots)$$

for $\lambda = -\frac{abc}{\sqrt{a^2b^2c^2 - 8S_{ABC}}}$ and $\lambda = \frac{abc}{\sqrt{a^2b^2c^2 - 8S_{ABC}}}$ respectively. The antiparallels through the traces of each of these points correspond to

$$t_1 = t_2 = t_3 = \frac{\lambda - 1}{\lambda + 1}.$$

This means that the corresponding intersections of Euler lines lie on the line $\mathcal{L}_c = HJ$ in §2.2.

9.3. *The cubic* $\mathcal{K}$. The infinite points of the cubic $\mathcal{K}$ can be found by rewriting the equation of $\mathcal{K}$ in the form

$$\begin{aligned}&(\sum_{\text{cyclic}} S_A(S_B - S_C)(S_B + S_C)yz)(\sum_{\text{cyclic}} (S_B + S_C)x)\\ =&(x + y + z)(\sum_{\text{cyclic}} (S_B + S_C)(S_B - S_C)(S_A(S_A + S_B + S_C) - S_{BC})yz)\end{aligned}$$

They are the infinite points of the Jerabek hyperbola and the line $(S_B + S_C)x + (S_C + S_A)y + (S_A + S_B)z = 0$. The latter is $X_{523} = (S_B - S_C : S_C - S_A : S_A - S_B)$. The asymptotes of $\mathcal{K}$ are

- the parallels to the asymptotes of Jerabek hyperbola through the antipode the Jerabek center on the nine-point circle, *i.e.*,

$$X_{113} = ((S_{CA} + S_{AB} - 2S_{BC})(b^2 S_{BB} + c^2 S_{CC} - a^2 S_{AA} - 2S_{ABC}) : \cdots : \cdots),$$

- the perpendicular to the Euler line (of ABC) at the circumcenter O, intersecting $\mathcal{K}$ again at

$$Z = \left(\frac{S_{CA} + S_{AB} - 2S_{BC}}{b^2 S_{BB} + c^2 S_{CC} - a^2 S_{AA} - 2S_{ABC}} : \cdots : \cdots \right),$$

  which also lies on the line joining H to X_{110}. See Figure 7. [9]

Figure 7. The cubic $\mathcal{K}$

---

[9] We thank Bernard Gibert for providing the sketch of $\mathcal{K}$ in Figure 7.

Remark. The asymptotes of $\mathcal{K}$ and the Jerabek hyperbola bound a rectangle inscribed in the nine-point circle. Two of the vertices and $J = X_{125}$ and its antipode X_{113}. The other two are the points X_{1312} and X_{1313} on the Euler line.

Another 5-step Division of a Segment in the Golden Section

Kurt Hofstetter

Abstract. We give one more 5-step division of a segment into golden section, using ruler and compass only.

Inasmuch as we have given in [1, 2] 5-step constructions of the golden section we present here another very simple method using ruler and compass only. It is fascinating to discover how simple the golden section appears. For two points P and Q, we denote by $P(Q)$ the circle with P as center and PQ as radius.

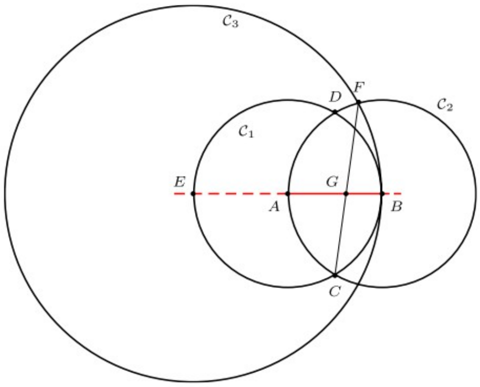

Figure 1

Construction. Given a segment AB, construct

(1) $\mathcal{C}_1 = A(B)$,
(2) $\mathcal{C}_2 = B(A)$, intersecting $\mathcal{C}_1$ at C and D,
(3) the line AB to intersect $\mathcal{C}_1$ at E (apart from B),
(4) $\mathcal{C}_3 = E(B)$ to intersect $\mathcal{C}_2$ at F (so that C and F are on opposite sides of AB),
(5) the segment CF to intersect AB at G.

The point G divides the segment AB in the golden section.

Publication Date: February 10, 2004. Communicating Editor: Paul Yiu.

Proof. Suppose AB has unit length. It is enough to show that $AG = \frac{1}{2}(\sqrt{5}-1)$.

Extend BA to intersect $\mathcal{C}_3$ at H. Let CD intersect AB at I, and let J be the orthogonal projection of F on AB. In the right triangle HFB, $BH = 4$, $BF = 1$. Since $BF^2 = BJ \times BH$, $BJ = \frac{1}{4}$. Therefore, $IJ = \frac{1}{4}$. It also follows that $JF = \frac{1}{4}\sqrt{15}$.

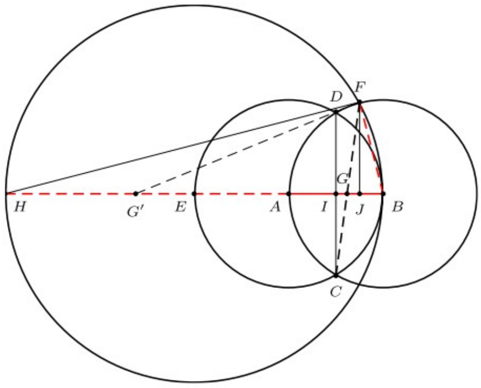

Figure 2

Now, $\frac{IG}{GJ} = \frac{IC}{JF} = \frac{\frac{1}{2}\sqrt{3}}{\frac{1}{4}\sqrt{15}} = \frac{2}{\sqrt{5}}$. It follows that $IG = \frac{2}{\sqrt{5}+2} \cdot IJ = \frac{\sqrt{5}-2}{2}$, and $AG = \frac{1}{2} + IG = \frac{\sqrt{5}-1}{2}$. This shows that G divides AB in the golden section. $\square$

Remark. If FD is extended to intersect AH at G', then G' is such that $G'A : AB = \frac{1}{2}(\sqrt{5}+1) : 1$.

After the publication of [2], Dick Klingens and Marcello Tarquini have kindly written to point out that the same construction had appeared in [3, p.51] and [4, S.37] almost one century ago.

& ;< 6< < $. - B -

Theorem 6.3.7. *Let P be a polytope in $\mathbb{R}^n$ that is combinatorially equivalent to an n-dimensional hypercube, let $G(P) := (V_P, E_P)$ denote its 1-skeleton graph, and let D_P denote the set of diagonals of P. Then,*

$$\sum_{xy \in E_P} (\| x - y \|_2)^2 \geq \sum_{xy \in D_P} (\| x - y \|_2)^2,$$

with equality if and only if P is an n-parallelotope.

Proof. The proof is by induction on n. It relies essentially on the following identity:

$$\sum_{i,j=1}^{n} (\| x_i - y_j \|_2)^2 - \sum_{1 \leq i < i' \leq n} (\| x_i - x_{i'} \|_2)^2 + (\| y_i - y_{i'} \|_2)^2 = n^2 (\| p - q \|_2)^2$$

for any points $x_1, \ldots, x_n, y_1, \ldots, y_n$ and setting $p := \frac{1}{n} \sum_{i=1}^{n} x_i$, $q := \frac{1}{n} \sum_{i=1}^{n} y_i$. See Deza and Maehara [1994] for details. ∎

6.4 An Example: The Spherical Distance Space

We describe here a classical example of ℓ_1-embeddable distance space, namely, the spherical distance space. This is the distance space defined on a sphere S, taking as distance between two points $x, y \in S$ the quantity

$$(6.4.1) \qquad r \cdot \arccos \left(\frac{(x - c)^T (x - y)}{r^2} \right),$$

where c denotes the center of S and r its radius. The quantity (6.4.1) is known as the *spherical distance* (or *great circle metric*) between x and y. (This is the geodesic distance on the sphere S between the points x and y, which coincides with the angle between the two vectors from c to x and from c to y.) We may clearly suppose that the sphere S is centered at the origin and, up to scaling of the distances, that it has radius 1. Let S_m denote the m-dimensional unit sphere, i.e.,

$$S_m := \{x \in \mathbb{R}^{m+1} \mid \sum_{i=1}^{m+1} x_i^2 = 1\}.$$

We let $\mathcal{S}_m$ denote the distance space (S_m, d_S), where d_S is the distance defined by (6.4.1), i.e.,

$$(6.4.2) \qquad d_S(x, y) := \arccos(x^T y) \text{ for all } x, y \in S_m.$$

Similarly, we let $\mathcal{S}_{m,r}$ denote the distance space $(S_{m,r}, d_S)$, where $S_{m,r}$ is the m-dimensional sphere centered at the origin with radius r and d_S is defined by (6.4.1). So, $\mathcal{S}_m = \mathcal{S}_{m,1}$. The distance space $\mathcal{S}_{m,r}$ is called a *spherical distance space.* We refer to Blumenthal [1953] for a detailed study of the metric properties of these distance spaces. We mention here some properties that are most relevant to our treatment.

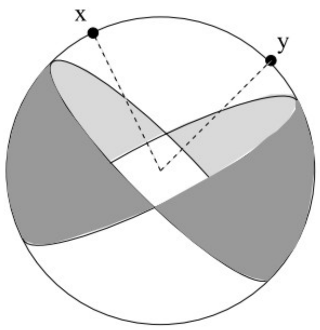

Figure 6.4.3: $H(x)\triangle H(y)$ is the shaded region

A first basic property of spherical distance spaces is that they are ℓ_1-embeddable. For this, let us consider for a point $x \in S_m$ the *hemisphere* $H(x)$ containing x; that is, $H(x)$ consists of the points $y \in S_m$ such that $d_S(x,y) \leq \frac{\pi}{2}$ or, equivalently, $x^Ty \geq 0$. We also consider the measure μ on S_m defined by

$$\mu(A) := \frac{\mathrm{vol}(A)}{\mathrm{vol}(S_m)} \quad \text{for } A \subseteq S_m.$$

(Here, $\mathrm{vol}(A)$ denotes the m-dimensional volume of A.) Hence, S_m equipped with the measure μ is a probability space. Then,

$$\text{(6.4.4)} \qquad \mu(H(x)\triangle H(y)) = \frac{1}{\pi}\arccos(x^Ty) \quad \left(= \frac{1}{\pi}d_S(x,y)\right) \quad \text{for } x,y \in S_m.$$

This relation can be easily verified; it was first observed by Kelly [1970b]. For an illustration in the case $m = 2$, see Figure 6.4.3. The result from Theorem 6.4.5[6] [7] below follows as an immediate consequence, using Proposition 4.2.1.

Theorem 6.4.5. *Given* $u_1, \ldots, u_n \in S_m$, *the vector* $(\frac{1}{\pi}\arccos(u_i^Tu_j))_{1\leq i<j\leq n}$ *belongs to the cut polytope* $\mathrm{CUT}_n^{\square}$. *Therefore, the spherical distance space* $\mathcal{S}_{m,r}$

---

[6] In other words, Theorem 6.4.5 indicates how to derive inequalities valid for the pairwise angles among a set of n unit vectors; namely, by considering valid inequalities for the cut polytope $\mathrm{CUT}_n^{\square}$. This fact will be reminded in Section 31.2.

[7] There is no analogue of Theorem 6.4.5 for the closely related elliptic distance spaces. The *elliptic distance space* $\mathcal{E}\ell_m$ is obtained from the spherical distance space $\mathcal{S}_m$ by identifying antipodal points; thus taking $\min(d_S(x,y), \pi - d_S(x,y))$ as distance between $x,y \in S_m$. The elliptic distance space $\mathcal{E}\ell_m$ is a semimetric space (Blumenthal [1953]) but it is not hypermetric (in fact, not 5-gonal (Kelly [1970b])). One more divergence between spherical and elliptic distance spaces lies in the determination of their congruence orders. As we see in Theorem 6.4.8 the order of congruence of the spherical distance space $\mathcal{S}_m$ can be easily determined; on the other hand the order of congruence of the elliptic distance space $\mathcal{E}\ell_m$ is known only in dimension $m \leq 2$ (see Seidel [1975] and precise references therein).

is isometrically ℓ_1*-embeddable for every* $r > 0$, $m \geq 1$. ∎

In fact, isometric subspaces of spherical distance spaces and of Euclidean distance spaces are very closely related notions, as the results below indicate.

Let d be a distance on the set $V_n := \{1, \ldots, n\}$. Consider the symmetric matrix[8] $A = (a_{ij})_{i,j=1}^n$ defined by

$$a_{ij} := \cos(d_{ij}) \quad \text{for } i, j = 1, \ldots, n.$$

Hence, the diagonal entries of A are all equal to 1. Moreover, let $\tilde{d}$ denote the distance on the set $V_n \cup \{x_0\}$ (x_0 is a new element not belonging to V_n) defined by

$$\begin{array}{ll} \tilde{d}(x_0, i) = 1 & \text{for } i \in V_n, \\ \tilde{d}(i, j) = 2 - 2\cos(d(i,j)) = 4\sin^2(\frac{d(i,j)}{2}) & \text{for } i, j \in V_n. \end{array}$$

Proposition 6.4.6. *Let* $m \geq 1$ *be an integer and* d, $\tilde{d}$, *and* A *be defined as above. The following assertions are equivalent.*

(i) *The distance space* (V_n, d) *is an isometric subspace of the* m*-dimensional spherical distance space* $\mathcal{S}_m$.

(ii) $d_{ij} \in [0, \pi]$ *for all* $i, j \in V_n$ *and the matrix* A *is positive semidefinite with* rank $A \leq m + 1$.

(iii) $d_{ij} \in [0, \pi]$ *for all* $i, j \in V_n$ *and the distance space* $(V_n \cup \{x_0\}, \tilde{d})$ *can be isometrically embedded into* ℓ_2^{m+1}.

Proof. The equivalence (i) $\Longleftrightarrow$ (ii) is clear. Indeed, (V_n, d) is an isometric subspace of $\mathcal{S}_m$ if and only if there exist $u_1, \ldots, u_n \in S_m$ such that $\cos(d(i,j)) = u_i^T u_j$ for all $i, j \in V_n$; that is, if the matrix A is positive semidefinite with rank $\leq m + 1$. The equivalence (ii) $\Longleftrightarrow$ (iii) follows from Corollary 6.2.5 and the fact that A coincides with the matrix $P_{x_0}(V_n \cup \{x_0\}, \tilde{d})$. ∎

Corollary 6.4.7. *A distance space* (V_n, d) *embeds isometrically in* $\mathcal{S}_{m,r}$ *(for some* $m \geq 1$*) if and only if* $d_{ij} \in [0, \pi r]$ *for all* $i, j \in V_n$ *and the matrix* $A := (\cos(\frac{d_{ij}}{r}))_{i,j=1}^n$ *is positive semidefinite. Then, the smallest* m *such that* (V_n, d) *embeds into* $\mathcal{S}_{m,r}$ *is* $m =$ rank $A - 1$. ∎

Using Proposition 6.4.6, one can derive a compactness result for spherical distance spaces analogue to the compactness result for Euclidean spaces from Theorem 6.2.13; this result can be found in Blumenthal [1953].

Theorem 6.4.8. *Given* $m \geq 1$, *a distance space* (X, d) *can be isometrically embedded into the* m*-dimensional spherical distance space* $\mathcal{S}_m$ *if and only if the*

---

[8] We will study in detail in Section 31.3 the set of positive semidefinite matrices with all diagonal entries equal to 1. We will use, in particular, Theorem 6.4.5.

same holds for every subspace (Y, d) *where* $Y \subseteq X$ *with* $|Y| = m + 3$. ▮

In particular, the order of congruence of the spherical distance space $\mathcal{S}_n$ is equal to $m + 3$. To see it, consider the distance space (X, d), where $|X| \geq m + 3$ and $d_{ij} := \arccos(-\frac{1}{m+1})$ for all $i \neq j \in X$. Then, (X, d) does not embed in $\mathcal{S}_m$ (because the matrix $(\cos(d_{ij}))_{i,j \in X}$ is not positive semidefinite). On the other hand, every subspace (Y, d) with $|Y| = m + 2$ embeds in $\mathcal{S}_m$ (as $(\cos(d_{ij}))_{i,j \in Y}$ is positive semidefinite with rank $m + 1$).

There are further intimate links between the spherical and Euclidean distances. In fact, as Schoenberg [1935] observed, every set of affinely independent vectors equipped with the Euclidean distance can be isometrically embedded into some spherical distance space. And, if the vectors are not independent, their Euclidean distances can be realized asymptotically as limits of spherical distances. This permits to derive the well-known implication: "ℓ_2-embeddable $\Longrightarrow \ell_1$-embeddable".

Proposition 6.4.9. *Let* $u_0, u_1, \ldots, u_n \in \mathbb{R}^n$ *be affinely independent. Then, the distance space* $(\{u_0, u_1, \ldots, u_n\}, d_{\ell_2})$ *is an isometric subspace of* $\mathcal{S}_{n,r}$ *for some* r *large enough.*

Proof. We can suppose without loss of generality that $u_0 := 0$. By assumption, the matrix $P = (p_{ij} := u_i^T u_j)_{i,j=1}^n$ is positive definite. Let $A(r)$ be the $(n + 1) \times (n + 1)$ symmetric matrix with entries $a_{ij} := \cos(\frac{d_{ij}}{r})$ for $i, j = 0, 1, \ldots, n$. In view of Corollary 6.4.7, it suffices to show that $A(r) \succ 0$ for r large enough. In what follows, we write $A \sim B$ for two matrices A and B if $A \succ 0 \Longleftrightarrow B \succ 0$. Clearly, $A(r) \sim B(r)$, where the 00-th entry of $B(r)$ is $b_{00} := 1$, its $0i$-th entry is $b_{0i} := a_{0i} - 1$ (for $i = 1, \ldots, n$) and its ij-th entry is $b_{ij} := a_{ij} - a_{0i} - a_{0j} + 1$ (for $i, j = 1, \ldots, n$) (to see it, subtract the row indexed by 0 in $A(r)$ to every other row and, then, the column indexed by 0 to every other column). We now use the fact that $\cos x = 1 - \frac{1}{2}x^2 + o(x^4)$ when $x \longrightarrow 0$. Hence, each entry of $B(r)$ can be expressed as $b_{0i} = -\frac{1}{2r^2}p_{ii} + o(\frac{1}{r^4})$, $b_{ij} = \frac{1}{r^2}p_{ij} + o(\frac{1}{r^4})$. Therefore, after suitably scaling $B(r)$, we obtain that $A(r) \sim B(r) \sim C(r)$, where the 0-th entry of $C(r)$ is $4r^2$, its $0i$-th entry is $p_{ii} + o(\frac{1}{r^2})$, and its ij-th entry is $p_{ij} + o(\frac{1}{r^2})$. One can now easily verify that $C(r) \succ 0$ for any r large enough. (Note here that it suffices to check that the $n+1$ principal subdeterminants of $C(r)$ disposed along the diagonal are positive, which holds for r large enough by the assumption that $P \succ 0$.) ▮

Remark 6.4.10. Proposition 6.4.9 extends to an arbitrary set of vectors in the case when they all lie on a common line. But, it does not extend to an arbitrary set of vectors in dimension ≥ 2. As counterexample, take for $u_1, \ldots, u_{n+1}$ the vertices of an equilateral simplex and for u_0 the barycentrum of the simplex. Then, the distance space $(\{u_0, u_1, \ldots, u_{n+1}\}, d_{\ell_2})$ does not embed in any spherical distance space. ▮

Let us now indicate how the Euclidean distance can be approximated by spherical distances[9]. For this, let $u_1, \ldots, u_n \in \mathbb{R}^m$. We are interested in evaluating their mutual Euclidean distances. So, set $d_{ij} := \| u_i - u_j \|_2$ for $i, j = 1, \ldots, n$. We show how to express d as a limit of distances $d^{(r)}$ (when $r \longrightarrow \infty$) where each $d^{(r)}$ can be isometrically embedded in $\mathcal{S}_{m,r}$. The idea for this is intuitively very simple. Namely, for $r > 0$ consider the sphere $S^{(r)}$ in the space $\mathbb{R}^{m+1}$ with center $c := (0, \ldots, 0, r)$ and radius r. One can visualize $S^{(r)}$ as a sphere lying on top of $\mathbb{R}^m$, being viewed as the hyperplane $x_{m+1} = 0$ in $\mathbb{R}^{m+1}$. Every vector $u \in \mathbb{R}^m$ with $\| u \|_2 \leq r$ can be 'lifted' to a point $u^{(r)} \in S^{(r)}$, by setting

$$u^{(r)} := \left(u, r - \sqrt{r^2 - (\| u \|_2)^2} \right).$$

Let $r \geq \max_{i=1}^n \| u_i \|_2$. For $i = 1, \ldots, n$, let $u_i^{(r)} \in S^{(r)}$ be the 'lifting' of u_i as defined above. Set

$$d^{(r)}(i,j) := r \cdot \arccos\left(\frac{(u_i - c)^T (u_j - c)}{r^2} \right) \quad \text{for } i, j = 1, \ldots, n.$$

So, $d^{(r)}(i,j)$ represents the spherical distance between $u_i^{(r)}$ and $u_j^{(r)}$ on the sphere $S^{(r)}$. Clearly, this length converges to the Euclidean distance $\| u_i - u_j \|_2$ as r tends to infinity, i.e.,

$$\lim_{r \longrightarrow \infty} d^{(r)}(i,j) = \| u_i - u_j \|_2 \, . \tag{6.4.11}$$

In a precise way, one can estimate $d^{(r)}(i,j)$ for large r as follows:

$$\begin{aligned} d^{(r)}(i,j) &= r \cdot \arccos\left(\tfrac{\sqrt{r^2 - (\|u_i\|_2)^2} \sqrt{r^2 - (\|u_j\|_2)^2} + u_i^T u_j}{r^2} \right) \\ &= r \cdot \arccos\left(\sqrt{1 - \tfrac{(\|u_i\|_2)^2}{r^2}} \sqrt{1 - \tfrac{(\|u_j\|_2)^2}{r^2}} + \tfrac{u_i^T u_j}{r^2} \right) \\ &\approx r \cdot \arccos\left(1 - \tfrac{(\|u_i - u_j\|_2)^2}{2r^2} \right) \approx \| u_i - u_j \|_2 \, . \end{aligned}$$

(Here, we use the fact that $\sqrt{1-x} \approx 1 - \frac{1}{2}x$ and $\arccos(1 - x^2) \approx \sqrt{2}x$ as $x \longrightarrow 0$.) ∎

Proposition 6.4.12. *For a distance space (X, d),*

d is isometrically ℓ_2-embeddable $\Longrightarrow$ d is isometrically ℓ_1-embeddable.

Proof. This follows from the above observations, (6.4.11) and Theorem 6.4.5. ∎

Exercise 11.10. Prove that the complexity of Algorithm 11.17 (Stratifying Cylindrical Decision) $(s\,d)^{O(1)^k}$, where s is a bound on the number of elements of $\mathcal{P}$ and d is a bound on the degrees of the polynomials in $\mathcal{P}$. When $\mathrm{D}=\mathbb{Z}$, and the bitsizes of the coefficients of $\mathcal{P}$ are bounded by τ, prove the bitsizes of the intermediate computations and the output are bounded by $\tau d^{O(1)^{k-1}}$.

Using cylindrical decomposition, it is possible to design algorithms for computing various topological informations.

Remark 11.19.

a) It is possible to compute a semi-algebraic description of the semi-algebraically connected components of a $\mathcal{P}$-semi-algebraic set with complexity $(s\quad d)^{O(1)^k}$ as follows, using the proofs of Theorem 5.21 and Theorem 5.38 and the complexity analysis of Algorithm 11.17 (Stratifying Cylindrical Decomposition) (Exercise 11.10). Hint: Consider a $\mathcal{P}$-semi-algebraic set, compute a stratifying family adapted to $\mathcal{P}$ and a description of the cells associated to the corresponding Stratifying Cylindrical Decomposition. Determine the adjacency relations between cells from the list of non-empty sign conditions, using Proposition 5.39 (Generalized Thom's Lemma). Use these adjacencies to describe the connected components of S. We do not give details since we are going to see in Chapters 15 and 16 much better algorithms for the description of connected components of semi-algebraic sets.

b) A triangulation of a closed and bounded semi-algebraic set, as well as its homology groups, can be computed with complexity $(s\,d)^{O(1)^k}$, using the proof of Theorem 5.43, the definition of the homology groups of bounded and closed semi-algebraic sets in Chapter 6, and the complexity analysis of Algorithm 11.17 (Stratifying Cylindrical Decomposition) (Exercise 11.10). We do not give details either, even though we currently have no better algorithm for computing the homology groups.

c) A bound on the finite number of topological types of algebraic sets defined by polynomials of degree d follows from Algorithm 11.17 (Stratifying Cylindrical Decomposition). The bound is polynomial in d and doubly exponential in the number $\binom{d+k}{k}$ of monomials of degree d in k variables. Again, we do not give details for this quantitative version of Theorem 5.47. □

11.6 Topology of Curves

In this section, D is an ordered integral domain contained in a real closed field R and $\mathrm{C}=\mathrm{R}[i]$.

The simplest situation where the Cylindrical Decomposition Algorithm can be performed is the case of one single non-zero polynomial bivariate polynomial $P(X,Y)\in\mathrm{D}[X,Y]$.

The zero set of this polynomial is an algebraic subset $\mathrm{Zer}(P, \mathrm{R}^2) \subset \mathrm{R}^2$ contained in the plane R^2 and distinct from R^2.

Since an algebraic set is semi-algebraic, there are three possible cases:

- $\mathrm{Zer}(P, \mathrm{R}^2)$ is an algebraic set of dimension 1, which is called a **curve**.
- $\mathrm{Zer}(P, \mathrm{R}^2)$ is an algebraic set of dimension 0, i.e. a finite set of points.
- $\mathrm{Zer}(P, \mathrm{R}^2)$ is empty.

Typical examples of these three situations are the unit circle defined by $X^2 + Y^2 - 1 = 0$, the origin defined by $X^2 + Y^2 = 0$, and the empty set defined by $X^2 + Y^2 + 1 = 0$.

Let us consider a polynomial $P(X, Y)$ in two variables, monic and separable, of degree d as a polynomial in Y. By separable we mean in this section that any gcd of P and $\partial P / \partial Y$ is an element of $\mathrm{R}(X)$. This is not a big loss of generality since it is always possible to make a polynomial monic by a change of variables of the form $X + a\,Y$, $a \in \mathbb{Z}$, by Lemma 4.73. Replacing P by a separable polynomial can be done using Algorithm 10.1 (Gcd and gcd-free part), and does not modify the zero set. The zero set of this polynomial is an algebraic set $\mathrm{Zer}(P, \mathrm{R}^2)$ contained in the plane.

The cylindrifying family of polynomials associated to P consists of the subdiscriminants of P with respect to Y (see page 102 and Proposition 4.27), which are polynomials in the variable X, denoted by $\mathrm{sDisc}_j(X)$ for j from 0 to $d - 1$ (since P is monic in Y, sDisc_d and sDisc_{d-1} are constant). Denote by sDisc the list sDisc_d, ...sDisc_0. Note that $\mathrm{Disc}(X) = \mathrm{sDisc}_0(X)$ is the discriminant, and is not identically 0 since P is separable (see Equation (4.4) and Corollary 4.2). On intervals between the roots of $\mathrm{Disc}_0(X)$, the number of roots of $P(x, Y)$ in R is fixed (this is a special case of Theorem 5.16). The number of roots of $P(x, Y)$ can be determined by the signs of the other signed subresultant coefficients and is equal to PmV(sDisc) according to Theorem 4.33. Note that on an interval between two roots of $\mathrm{Disc}(X)$ in R, the signs of the subdiscriminants may change but PmV(sDisc) is fixed.

A cylindrical decomposition of the plane adapted to P can thus be obtained as follows: the cells of R are the roots of $\mathrm{Disc}(X)$ in R and the intervals they determine. Above each root of $\mathrm{Disc}(X)$ in R, $\mathrm{Zer}(P, \mathrm{R}^2)$ contains a finite number of points. These points and intervals between them are cells of R^2. Above each interval determined by the roots of $\mathrm{Disc}(X)$, there are 1 dimensional cells, called **curve segments**, which are graphs of functions from the interval to R, and 2 dimensional cells which are bands between these graphs. Finally, $\mathrm{Zer}(P, \mathrm{R}^2)$ is the union of the points and curve segments of this cylindrical decomposition and consists of a finite number of points projecting on the roots of $\mathrm{Disc}(X)$ and a finite number of curve segments homeomorphic to segments of R and projecting on intervals determined by the roots of $\mathrm{Disc}(X)$. If above every interval determined by the roots of $\mathrm{Disc}(X)$ there are no curve segments, $\mathrm{Zer}(P, \mathrm{R}^2)$ is at most a finite number of points. or empty. If moreover above every root of $\mathrm{Disc}(X)$ there are no points $\mathrm{Zer}(P, \mathrm{R}^2)$ is empty.

The purpose of the algorithm we are going to present is to compute exactly the topology of the curve $\mathrm{Zer}(P, \mathrm{R}^2)$, i.e. to determine a planar graph homeomorphic to $\mathrm{Zer}(P, \mathrm{R}^2)$. After performing, if necessary, a linear change of coordinates, this will be done by indicating adjacencies between points of the curve $\mathrm{Zer}(P, \mathrm{R}^2)$ above roots of $\mathrm{Disc}(X)$ and curve segments on intervals between these roots. In this study, the notions of critical points of the projection and of curves in generic position will be useful.

The **critical points** of the projection of $\mathrm{Zer}(P, \mathrm{C}^2)$ to the X-axis are the points $(x, y) \in \mathrm{Zer}(P, \mathrm{C}^2)$ such that y is a multiple root of $P(x, Y)$.

The critical points of the projection of $\mathrm{Zer}(P, \mathrm{C}^2)$ to the X-axis are of two kinds

- **singular points** of $\mathrm{Zer}(P, \mathrm{C}^2)$, i.e. points of $\mathrm{Zer}(P, \mathrm{C}^2)$ where
$$\partial P / \partial X(x, y) = \partial P / \partial Y(x, y) = 0,$$
- **ordinary critical points** points where the tangent to $\mathrm{Zer}(P, \mathrm{C}^2)$ is well defined and parallel to the Y-axis, i.e. points $(x, y) \in \mathrm{C}^2$ where
$$\partial P / \partial Y(x, y) = 0, \partial P / \partial X(x, y) \neq 0.$$

In both cases, the first coordinate of a critical point of the projection of $\mathrm{Zer}(P, \mathrm{C}^2)$ to the X-axis is a root of the discriminant $\mathrm{Disc}(X)$ of P considered as a polynomial in Y.

Computing the topology will be particularly easy for a curve in generic position, which is the notion we define now. Indeed, the critical points of the projection of $\mathrm{Zer}(P, \mathrm{C}^2)$ on the X_1-axis are easy to characterize in this case.

Let P be polynomial of degree d in $\mathrm{R}[X, Y]$ that is separable. The set $\mathrm{Zer}(P, \mathrm{C}^2)$ is in **generic position** if the following two conditions are satisfied:

- $\deg(P) = \deg_Y(P)$,
- for every $x \in \mathrm{C}$, $\gcd(P(x, Y), \partial P / \partial Y(x, Y))$ is either a constant or a polynomial of degree j with exactly one root of multiplicity j. In other words, there is at most one critical point (x, y) of the projection of $\mathrm{Zer}(P, \mathrm{C}^2)$ to the X_1-axis above any $x \in \mathrm{C}$.

Note that above an element x_1 of R which is a root of $\mathrm{Disc}(X)$, the unique root of $\gcd(P(x, Y), \partial P / \partial Y(x_{,Y}))$ is necessarily in R. So there is exactly a critical point with coordinates in R above each root of $\mathrm{Disc}(X)$ in R.

Example 11.20. If $P = (X^2 - Y + 1)(X^2 + Y^2 - 2Y)$, the set $\mathrm{Zer}(P, \mathrm{C}^2)$ is not in generic position since there are two critical points of the projection on X above the point 0, namely $(0, 0)$ and $(0, 1)$. □

The output of the algorithm computing the topology of a curve in generic position will be the following:

- the number r of roots of $\mathrm{Disc}(X)$ in R. We denote these roots by $x_1 < \cdots < x_r$, and by $x_0 = -\infty, x_{r+1} = +\infty$.

- the number m_i of roots of $P(x,\, Y)$ in R when x varies on $(x_i,\, x_{i+1})$, for $i = 0, \ldots, r$.
- the number n_i of roots of $P(x, Y)$ in R. We denote these roots by $y_{i,j}$, for $j = 1, \ldots, n_i$.
- a number $c_i \le n_i$ such that if $C_i = (x_i, z_i)$ is the unique critical point of the projection of $\mathrm{Zer}(P, \mathrm{C}^2)$ on the X-axis above x_i, $z_i = y_{i,c_i}$.

  More precisely, the output is

$$[m_0, [n_1, c_1], \ldots, m_{r-1}, [n_r, c_r], m_r]].$$

It is clear that a graph homeomorphic to $\mathrm{Zer}(P, \mathrm{R}^2) \subset \mathrm{R}^2$ can be drawn using the output since if $m_i \geq n_i$ (resp. $m_i \geq n_{i+1}$), C_i belong to the closure of $m_i - n_i$ (resp. $m_i - n_{i+1}$) curve segments above (x_i, x_{i+1}) getting glued at C_i (resp. C_{i+1}) and if $m_i = n_i - 1$ (resp. $m_i = n_{i+1} - 1$) the point C_i does not belong to the closure of a curve segment above (x_i, x_{i+1}).

The critical points of the projection of $\mathrm{Zer}(P,\, \mathrm{C}^2)$ on the X-axis in the generic position case are easy to determine.

We denote

$$\begin{aligned} \mathrm{sDiscP}_j(X, Y) &= \mathrm{sResP}_j(P(X, Y), \partial P / \partial Y(X, Y)) \\ \mathrm{sDisc}_j(X) &= \mathrm{sRes}_j(P(X, Y), \partial P / \partial Y(X, Y)) \end{aligned}$$

(P is considered as a polynomial in Y).

Proposition 11.21. *Let P be a polynomial of degree d in $\mathrm{R}[X, Y]$, separable and in generic position. If (x, y) is a critical point of the projection of $\mathrm{Zer}(P,\, \mathrm{C}^2)$ on the X-axis, and j is the multiplicity of y as a root of $P(x, Y)$ (considered as a polynomial in X_2), then*

$$\mathrm{Disc}(x) = \mathrm{sDisc}_1(x) = 0, \ldots, \mathrm{sDisc}_{j-1}(x) = 0, \mathrm{sDisc}_j(x) \neq 0,$$

and

$$y = -\frac{1}{j} \frac{\mathrm{sDisc}_{j,j-1}(x)}{\mathrm{sDisc}_j(x)},$$

where $sDisc_{j,j-1}(X)$ is the coefficient of Y^{j-1} in $\mathrm{sDiscP}_j(X, Y)$.

Proof: Since $(x, y) \in \mathrm{R}^2$ is a critical point of the projection of $\mathrm{Zer}(P, \mathrm{C}^2)$ on the X-axis, $j > 0$. Since P is in generic position, $\mathrm{sDiscP}_j(x, Y)$ is a degree j polynomial with only one root, y, which implies that

$$\mathrm{sDiscP}_j(x, Y) = \mathrm{sDisc}_j(x)(Y - y)^j, \tag{11.4}$$

and

$$y = -\frac{1}{j} \frac{\mathrm{sDisc}_{j,j-1}(x)}{\mathrm{sDisc}_j(x)},$$

identifying coefficients of degree $j - 1$ on both sides of (11.4). □

We can also count the number of points of the curve above the critical points using the following result.

Proposition 11.22. *Let* $P(X,Y)\in \mathrm{D}[X,Y]$ *be a degree* d *separable polynomial such that* $\mathrm{lcof}_Y(P)\in \mathrm{D}$ *and* $x\in \mathrm{R}$. *Let*

$$R(X,Y,Z)=(Y-Z)\,\partial P/\partial Y(X,Y)-d\,P(X,Y).$$

We denote

$$T_j(X,Z)=\mathrm{sRes}_j(P(X,Y),R(X,Y,Z))$$

(considered as polynomials in Y*) and* $T(X,Z)$ *the list* $T_j(X,Z)$, j *from* 0 *to* $d-1$. *Let* $r=\mathrm{PmV}(\mathrm{sDisc}(x))$.

a)

$$\#\{y\in \mathrm{R}\mid P(x,y)=0\}=r$$

b) If $P(x,z)\neq 0$,

$$\#\{y\in \mathrm{R}\mid P(x,y)=0\ \wedge\ z<y\}=(r+\mathrm{PmV}(T(x,z)))/2.$$

c) If $P(x,z)=0$,

$$\#\{y\in \mathrm{R}\mid P(x,y)=0\ \wedge\ z<y\}=(r+\mathrm{PmV}(T(x,z))-1)/2.$$

Proof: We denote

$$\begin{aligned}
Z_x &= \{y\in \mathrm{R}\mid P(x,y)=0\},\\
\mathrm{TaQ}(1,Z_x) &= \#(Z_x)\\
&= \#(\{y\in \mathrm{R}\mid P(x,y)=0\})\\
\mathrm{TaQ}(Y-z,Z_x) &= \#(\{y\in \mathrm{R}\mid P(x,y)=0\wedge y>z\})\\
&- \#(\{y\in \mathrm{R}\mid P(x,y)=0\wedge y<z\}),\\
\mathrm{TaQ}((Y-z)^2,Z_x) &= \#\{y\in \mathrm{R}\mid P(x,y)=0\wedge y\neq z\}.
\end{aligned}$$

a) follows from Theorem 4.33. b) and c) follow from Equation (2.6) (see page 65) applied to $P(x,Y)$ and $Y-z$:

$$\begin{bmatrix} 1 & 1 & 1\\ 0 & 1 & -1\\ 0 & 1 & 1\end{bmatrix}\cdot\begin{bmatrix} c(Y=z,P(x,Y)=0)\\ c(Y>z,P(x,Y)=0)\\ c(Y<z,P(x,Y)=0)\end{bmatrix}=\begin{bmatrix}\mathrm{TaQ}(1,P(x,Y))\\ \mathrm{TaQ}(Y-z,P(x,Y))\\ \mathrm{TaQ}((Y-z)^2,P(x,Y))\end{bmatrix}.$$

If $P(x,z)\neq 0$, we have $c(Y-z=0,P(x,Y)=0)=0$. Thus

$$c(Y>z,P(x,Y)=0)=(\mathrm{TaQ}(1,P(x,Y))+\mathrm{TaQ}(Y-z,P(x,Y)))/2.$$

If $P(x,z)=0$, we have $c(Y-z=0,P(x,Y)=0)=1$. Thus

$$c(Y>z,P(x,Y))=(\mathrm{TaQ}(1,P(x,Y))+\mathrm{TaQ}(Y-z,P(x,Y))-1)/2. \qquad \square$$

Next we show that it is always possible to perform a linear change of variables such that in the new coordinates the curve is in generic position. The idea is to maximize the number of distinct roots of the discriminant, which are the X-coordinates of the critical points.

Let P be a separable polynomial in $\mathrm{D}[X,\ Y]$, U a new variable and $Q(U,X,Y)$ the polynomial defined by:

$$Q(U,X,Y)=P(X+UY,Y).$$

If $a\in\mathbb{Z}$, let $\mathrm{Zer}(P_a,\mathrm{R}^2)$ denote the curve defined by the polynomial

$$P_a(X,Y)=Q(a,X,Y)=0.$$

We denote

$$\begin{aligned}\mathrm{sDiscP}_j(U,X,Y) &= \mathrm{sResP}_j(Q(U,X,Y),\partial Q/\partial Y(U,X,Y))\\ \mathrm{sDisc}_j(U,X) &= \mathrm{sRes}_j(Q(U,X,Y),\partial Q/\partial Y(U,X,Y))\end{aligned}$$

Note that $\mathrm{Disc}(U,\ X)$=$\mathrm{sDisc}_0(U,\ X)$ is the discriminant of $Q(U,\ X,\ Y)$ with respect to the variable Y. We denote by $\mathrm{sDisc}(U,\ X)$ the list of the subdiscriminants $\mathrm{sDisc}_j(U,X)$. Let $\Delta(U)$ be the non-zero subdiscriminant of smallest possible index of $\mathrm{Disc}(U,X)$ with respect to the variable X.

Proposition 11.23. *Let a be an integer number such that*

$$\deg_{X_2}(Q(a,X,Y))=\deg(Q(a,X,Y)) \quad \textit{and} \quad \Delta(a)\neq 0.$$

Then P_a is in generic position.

Proof: Suppose that $\deg_{X_2}(P_a(X,\ Y))=\deg(P_a(X,\ Y))$ and P_a is not in generic position. Let δ be a new variable and consider the field $\mathrm{C}\langle\delta\rangle$ of algebraic Puiseux series in δ. We are going to prove the following property (P): the number of distinct roots of $\mathrm{Disc}(a+\delta,X)$ in $\mathrm{C}\langle\delta\rangle$, which is the discriminant of $P_{a+\delta}(X,\ Y)$ with respect to the variable Y, is bigger than the number of distinct roots of $\mathrm{Disc}(a,\ X)$ in C, which is the discriminant of $P_a(X,Y)$ with respect to the variable Y. Thus, by definition of Δ, $\Delta(a)=0$, and the statement is proved.

The end of the proof is devoted to proving property (P).

We first study the number of critical points of the projection of $\mathrm{Zer}(P_\delta,\mathrm{C}^2)$ on the X-axis close to a critical point of the projection of $\mathrm{Zer}(P,\mathrm{C}^2)$ to the X-axis.

- If (x,y) is a singular point of $\mathrm{Zer}(P_a,\mathrm{C}^2)$, $(x+\delta y,y)$ is a singular point of $\mathrm{Zer}(P_{a+\delta},\mathrm{C}^2)$.
- If (x,y) is an ordinary critical point of the projection of $\mathrm{Zer}(P_a,\mathrm{C}^2)$ on the X_1-axis, $(x+\delta y)$ is not a critical point of the projection of $\mathrm{Zer}(P_{a+\delta},\mathrm{C}^2)$ on the X_1-axis. However we are going to prove that there is an ordinary critical point of the projection of $\mathrm{Zer}(P_{a+\delta},\mathrm{C}^2)$ on the X_1-axis of the form $(x+\delta y+u,y+v)$, $o(u)>1,o(v)>0$.

If (x,y) is an ordinary critical point of the projection of $\mathrm{Zer}(P_a,\mathrm{C}^2)$ on the X-axis, there exists r such that

$$\begin{gathered}P_a(x,y)=0,\partial P_a/\partial X(x,y)=b\neq 0,\\ \partial P_a/\partial Y(x,y)=\cdots=\partial^{r-1}P_a/\partial Y^{r-1}(x,y)=0,\partial^r P_a/\partial Y^r(x,y)=r!\,c\neq 0.\end{gathered}$$

Writing Taylor's formula for P_a in the neighborhood of (x, y), we have

$$P_a(X, Y) = b(X - x) + c(Y - y)^r + A(X, Y),$$

with $A(X, Y)$ a linear combination of monomials multiple of $(X - y)$ or $(Y - y)^r$. We consider a new variable ε and a point of $\mathrm{Zer}(P_a, \mathrm{C}\langle\varepsilon\rangle^2)$ with coordinates $x + \xi, y + \varepsilon$, infinitesimally close to x, y. In other words we consider a solution ξ of

$$b\xi + c\varepsilon^r + A(x + \xi, y + \varepsilon) = 0 \tag{11.5}$$

which is infinitesimal. Using the proof of Theorem 2.91, there is a solution of Equation (11.5) of the form $\xi = -(c/b)\varepsilon^r + w$, $0(w) > r$. Moreover

$$\begin{array}{rcl} \partial P_a/\partial X(x + \xi, y + \varepsilon) & = & b + w_1, o(w_1) > 1, \\ \partial P_a/\partial Y(x + \xi, y + \varepsilon) & = & c\, r\, \varepsilon^{r-1} + w_2, o(w_2) > r - 1. \end{array}$$

Thus, if $(\partial P_a/\partial X(x + \xi', y + \varepsilon'), \partial P_a/\partial Y(x + \xi', y + \varepsilon'))\}$ is proportional to $(1, \delta)$, with ε' and ξ' infinitesimal in $\mathrm{C}\langle\delta\rangle$, we have

$$\begin{array}{rcl} \varepsilon' & = & d\delta^{1/(r-1)} + w_3 \\ \xi' & = & -(1/r)\, d\, \delta^{r/(r-1)} + w_4 \end{array}$$

with $d^{r-1} = b/c\ r$, $o(w_3) > 1/(r - 1)$, $o(w_4) > r/(r - 1)$. Thus there is a point $(x + \xi', y + \varepsilon')$ of $\mathrm{Zer}(P_a, \mathrm{C}\langle\delta\rangle^2)$ with gradient proportional to $(1, \delta)$, and $o(\varepsilon') > 0, o(\xi') > 1$. In other words, $(x + \delta y + \xi' + \delta\varepsilon', y + \varepsilon')$ is a critical point of the projection of $\mathrm{Zer}(P_{a+\delta}, \mathrm{C}\langle\delta\rangle^2)$ on the X-axis.

Suppose that (x, y_1) and (x, y_2) are two distinct critical point of the projection of $\mathrm{Zer}(P_a, \mathrm{C}^2)$ to the X_1-axis. According to the preceding discussion, there are two critical point of the projection of $\mathrm{Zer}(P_{a+\delta}, \mathrm{C}^2)$ to the X-axis, with first coordinates $x + \delta\, y_1 + u_1$ and $x + \delta\, y_2 + u_2$, with $o(u_1) > 1, o(u_2) > 1$.Note that $x + \delta\, y_1 + u_1$ and $x + \delta\, y_2 + u_2$ are distinct, since $y_1 - y_2$ is not infinitesimal. We have proved that the number of distinct roots of $\mathrm{Disc}(a + \delta, X)$ in $\mathrm{C}\langle\delta\rangle$ is strictly bigger that the number of distinct roots of $\mathrm{Disc}(a, X)$ in C. □

The Topology of a Curve Algorithm can now be described. We perform the computation as if the curve was in generic position. If it is not, the algorithm detects it and then a new linear change of coordinates is performed.

Algorithm 11.18. **[Topology of a Curve]**

- **Structure:** an ordered integral domain D contained in a real closed field R (resp. the field of real numbers $\mathbb{R}$).
- **Input:** a separable polynomial P in $\mathrm{D}[X, Y]$ of degree d.
- **Output:** the topology of the curve $\mathrm{Zer}(P, \mathrm{R}^2)$, described by
  - An integer a such that $P_a(X, Y) = P(X + a\,Y, Y)$ is in general position.
  - The number r of roots of $\mathrm{Disc}(a,\ X)$ in R. We denote these roots by $x_1 < \cdots < x_r$, and by $x_0 = -\infty, x_{r+1} = +\infty$.
  - The number m_i of roots of $P_a(x, Y)$ in R when x varies on (x_i, x_{i+1}), $i = 0, \ldots, r$.

  - The number n_i of roots of $P_a(x_i, Y)$ in R. We denote these roots by $y_{i,j}$, $j = 1, \ldots, n_i$.
  - An index $c_i \leq n_i$ such that if $C_i = (x_i, z_i)$ is the unique critical point of the projection of $\mathrm{Zer}(P_a, \mathrm{C}^2)$ on the X_1-axis above x_i, $z_i = y_{i,c_i}$.

  More precisely, the output is $[a, [m_0, [n_1, c_1], \ldots, m_{r-1}, [n_r, c_r], m_r]]$.
- **Complexity:** $O(d^{11} \log_2(d))$, where d is a bound on the degrees of P.
- **Procedure:**
  - Take $a := 0$.
  - $(\star)$ Define $P_a(X, Y) := P(X + a\,X, Y)$.
  - If P_a is not quasi-monic with respect to Y, the curve is not in generic position. Take $a := a + 1$, go to $(\star)$.
  - Otherwise, compute the subdiscriminants $\mathrm{sDisc}(a,\ X)$ of $P_a(X,\ Y)$ (considered as a polynomial in Y). Characterize the roots $x_1, \ldots, x_r$ of $\mathrm{Disc}(a, X)$ using Algorithm 10.14 (Thom encoding) (resp. Algorithm 10.4 (Real Root Isolation)).
  - For every $1 \leq i \leq r$, determine $j(i)$ such that

    $$\mathrm{Disc}_0(a, x_i) = 0, \ldots, \mathrm{sDisc}_{j(i)-1}(a, x_i) = 0, \mathrm{sDisc}_{j(i)}(a, x_i) \neq 0,$$

    and compute the sign ε_i of $\mathrm{sDisc}_{j(i)}(a, x_i)$ using Algorithm 10.15 (Sign at the Roots in a real closed field) (resp. Algorithm 10.6 (Sign at a Real Root)).
  - Define

    $$z_i = -\frac{1}{j(i)} \frac{\mathrm{sDisc}_{j(i), j(i)-1}(a, x_i)}{\mathrm{sDisc}_{j(i)}(a, x_i)}.$$

  - Check whether, for every $i = 1, \ldots, r$, z_i is a root of multiplicity $j(i)$ of $\mathrm{sDisc}_{j(i)}(x_i, Y)$ using Algorithm 10.15 (Sign at the Roots in a real closed field) (resp. Algorithm 10.6 (Sign at a Real Root)).
  - If there exists i such that z_i is not a root of multiplicity $j(i)$ of $\mathrm{sDisc}_{j(i)}(a,\ x_i,\ Y)$, the curve is not in generic position. Take $a := a + 1$, go to $(\star)$.
  - If for every i, z_i is a root of multiplicity $j(i)$ of $\mathrm{sDisc}_{j(i)}(a, x_i, Y)$, the curve is in generic position.
  - For every $0 \leq i \leq r$ choose an intermediate point $t_i \in (x_i, x_{i+1})$ (with the convention $x_0 = -\infty, x_{r+1} = +\infty$) using Algorithm 10.18 (Intermediate Points) and Remark 10.77, and compute the number m_i of roots of $P_a(t_i,\ Y)$ evaluating the signs of the signed subresultant coefficients at t_i using Algorithm 10.11 (Sign Determination) (resp. choose an intermediate rational point $t_i \in (x_i, x_{i+1})$ using the isolating intervals for the x_i and compute the number m_i of roots of $P_a(t_i, Y)$ using Algorithm 10.4 (Real Root Isolation)).
  - Compute, for every $i \leqslant r$,

    $$\begin{aligned} S &= \varepsilon_i\,(j(i)\,\mathrm{sDisc}_{j(i)}(a, X)\,Y + \mathrm{sDisc}_{j(i), j(i)-1}(X)\,(\partial P_a / \partial Y)) \\ R &= S - \varepsilon_i\, j(i)\, d\ \mathrm{sDisc}_{j(i)}(a, X)\ P_a \end{aligned}$$

and the list

$$T_i(X) \;=\; \mathrm{sRes}(P_a, R).$$

- Evaluate the signs of the elements of $T_i(X)$ at x_i to determine the number of real roots of the polynomial $P_a(x_i, Y)$ which are strictly bigger than z_i using Proposition 11.22 and Algorithm 10.15 (Sign at the Roots in a real closed field) (resp. Algorithm 10.6 (Sign at a Real Root)).
- Decide whether $\mathrm{Zer}(P, \mathrm{R}^2)$ is empty or a finite number of points.

Proof of correctness: By Lemma 4.74, there are only a finite number of values of a such that $\deg_{X_2}(Q(a, X, Y)) \neq \deg(Q(a, X, Y))$. Moreover there are only a finite number of zeros of $\Delta(X)$. So by Proposition 11.23, there are only a finite number of values of a such that the curve is not in generic position. The correctness of the algorithm follows from Proposition 11.21, and the correctness of Algorithm 10.14 (Thom encoding) (resp. Algorithm 10.4 (Real Root Isolation)), Algorithm 10.15 (Sign at the Roots in a real closed field) (resp. Algorithm 10.6 (Sign at a Real Root)), Algorithm 10.18 (Intermediate Points), and Algorithm 10.11 (Sign Determination). □

Complexity analysis: We estimate the complexity of the computation in a general real closed field.

Let d be the degree of $P(X, Y)$ a separable polynomial in $\mathrm{D}[X, Y]$.

The degree of $\mathrm{Disc}(U, X)$ is $O(d^2)$, and the degree of δ is $O(d^4)$. So there are at most $O(d^4)$ values of a to try.

For each value of a, we compute the subdiscriminant sequence of $P_a(X, Y)$ (considered as polynomial in Y): this requires $O(d^2)$ arithmetic operations in $\mathrm{D}[X]$ by Algorithm 8.21 (Signed subresultant). The degrees of the polynomials in X produced in the intermediate computations of the algorithm are bounded by $2\, d^2$ by Proposition 8.45. The complexity in D for this computation is $O(d^6)$.

The Thom encoding of the roots of $\mathrm{Disc}(a,\ X)$ takes $O(d^8\ \log_2(d))$ arithmetic operations using the complexity analysis of Algorithm 10.14 (Thom encoding). Checking whether $Q(X,\ Y)$ is in generic position takes also $O(d^8 \log_2(d))$ arithmetic operations using the complexity analysis of Algorithm 10.15 (Sign at the Roots in a real closed field), since there are at most $O(d^2)$ calls to this algorithm with polynomials of degree d^2.

Since there are at most $O(d^4)$ values of a to try, the complexity to reach generic position is $O(d^{11} \log_2(d))$.

The choice of the intermediate points, the determination of all m_i, the determination of $j(i)$ and ε_i takes again $O(d^8 \log_2(d))$ arithmetic operations using the complexity analysis of Algorithm 10.18 (Intermediate Points) and Algorithm 10.15 (Sign at the Roots in a real closed field).

The computation of one list T_i by Algorithm 8.21 (Signed subresultant) requires $O(d^2)$ arithmetic operations in $\mathrm{D}[X]$. The degree of the polynomials in X produced in the intermediate computations of the algorithm are bounded by $O(d^4)$ by Proposition 8.45. The complexity in D for the computation of the list $\bar{T}$ is $O(d^{10})$.

So the total complexity for computing the various T_i is $O(d^{11})$.

The only remaining computations are the determination of the signs taken by the polynomials of T_i evaluated at the roots of $\mathrm{Disc}(a,\, X)$. The degrees of the polynomials involved are $O(d^4)$ and and their number is $O(d^2)$. This takes $O(d^{10})$ operations using the complexity analysis of Algorithm 10.15 (Sign at the Roots in a real closed field).

So the total complexity for determining the topology of $\mathrm{Zer}(P,\ \mathrm{R}^2)$ is $O(d^{11}\log_2(d))$.

If $\mathrm{D} = \mathbb{Z}$ and the coefficients of P are of bitsizes bounded by τ, the coefficients of $P_a(X,Y)$ are $\tau + O(d)\,\nu$ where ν is the bitsize of d, since there are at most $O(d^4)$ values of a to try. For each value of a, the bitsizes of the integers produced in the intermediate computations of the subresultantnt sequence of $P_a(X,Y)$ are bounded by $O(d\,(\tau + d\nu))$ by the complexity analysis of Algorithm 8.21 (Signed subresultant).

The univariate sign determinations performed in the last steps of the algorithm produce integers of bitsizes $O(d^2\,(\tau + d\,\nu)\log_2(d)))$, according to the complexity analysis of Algorithm 10.14 (Thom encoding), Algorithm 10.15 (Sign at the Roots in a real closed field), Algorithm 10.18 (Intermediate Points). So the maximum bitsizes of the integers in the computation determining the topology of $\mathrm{Zer}(P, \mathrm{R}^2)$ is $O(d^2\,(\tau + d\,\nu)\log_2(d)))$. □

Example 11.24. Let us consider the real algebraic curve defined by the monic polynomial

$$P = 2\,Y^3 + (3\,X - 3)\,Y^2 + (3\,X^2 - 3\,X)\,Y + X^3.$$

The discriminant of P (considered as polynomial in Y) is

$$-\,27X^2(X^4 + 6X^2 - 3).$$

whose real roots are given by

$$x_1 = -\sqrt{-\,3 + 2\sqrt{3}}, \qquad x_2 = 0, \qquad x_3 = \sqrt{-\,3 + 2\sqrt{3}}.$$

Using the signed subresultant sequence, we determine that above each $x_{1,i}$, for $i = 1, \ldots, 3$, $P(x_i, Y)$ has two real roots, and only one of these roots is double. Thus the curve is already in generic position. The multiplicity of the unique critical point (x_i, z_i) as a root of $P(x_i, Y)$ is 2, and is given by the equation

$$z_i = -\frac{x_i(x_i^2 + 2x_i - 1)}{2\,x_i^2 - 2}.$$

We also determine that before x_1 and after x_3, $P(x, Y)$ has only one real root, while between x_1 and x_2, and between x_2 and x_3 $P(x, Y)$ has three real roots.

For $i = 1, 3$, there is one root of $P(x_i, Y)$ under z_i, while for $i = 2$ there is one root of $P(x_i, Y)$ above z_i.

Finally, the topology of the curve is given by the following graph

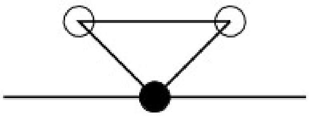

Fig. 11.3. Topology of the curve

where the points represent the critical points of the projection on the X-axis. The white points are critical points of the projection on the X-axis, while the black one is singular.

The topology can be described by 0 which is the value of a (the curve was given in generic position) and the list

$$[1, [2, 2], 3, [2, 1], 3, [2, 2], 1]$$

which can be read as follows: there are three roots of $\mathrm{Disc}(a, X)$, the number of branches above (x_0, x_1) is 1, the number of points above x_1 is 2 and the index of the critical point is 2, the number of branches above (x_1, x_2) is 3, the number of points above x_2 is 2 and the index of the critical point is 1, the number of branches above (x_2, x_3) is 3, the number of points above x_3 is 2, and the index of the critical point is 2, the number of branches above (x_3, x_4) is 1. □

11.7 Restricted Elimination

A variant of Algorithm 11.1 (Elimination) will be useful in the last chapters of the book. In this variant, we are interested at the signs of a family of polynomials at the roots of a polynomial, rather that at all the sign conditions of a family of polynomials.

We need some preliminary work.

We first prove a result similar to Theorem 5.12 and Proposition 5.13 which is adapted to the situation we are interested in studying.

Proposition 11.25. *Let P and Q be in $\mathrm{R}[X_1, \ldots X_k]$, and let S be a semi-algebraically connected semi-algebraic subset of R^{k-1} such that P is not identically 0 on S, and such that $\deg(P(x', X_k))$, the number of distinct roots of P in C, and $\deg(\gcd(P(x', X_k), Q(x', X_k)))$ are constant over S. Then there are ℓ continuous semi-algebraic functions $\xi_1 < \cdots < \xi_\ell$: $S \to \mathrm{R}$ such that, for every $x' \in S$, the set of real roots of $P(x', X_k)$ is exactly $\{\xi_1(x'), \ldots, \xi_\ell(x')\}$. Moreover, for $i = 1, \ldots, \ell$, the multiplicity of the root $\xi_i(x')$ is constant for $x' \in S$ and so is the sign of $Q(\xi_i(x'))$.*

Introduction

In this article we shall give an overview of some recent developments in the theory of complex algebraic surfaces of general type.

After the *rough* or *Enriques-Kodaira* classification of complex (algebraic) surfaces, dividing compact complex surfaces in four classes according to their Kodaira dimension $-\infty$, 0, 1, 2, the first three classes nowadays are quite well understood, whereas even after decades of very active research on the third class, the class of surfaces *of general type*, there is still a huge number of very hard questions left open. Of course, we made some selection, which is based on the research interest of the authors and we claim in no way completeness of our treatment. We apologize in advance for omitting various very interesting and active areas in the theory of surfaces of general type as well as for not being able to mention all the results and developments which are important in the topics we have chosen.

Complex surfaces of general type come up with certain (topological, birational) invariants, topological as for example the topological Euler number e and the self intersection number of the canonical divisor K^2 of a minimal surface, which are linked by several (in-) equalities. In the first chapter we will summarize the classically known inequalities, which force surfaces of general type in a certain region of the plane having K^2 and e as coordinates, and we shall briefly comment on the so-called *geography* problem, whether,

---

[⋆] The present work was performed in the realm of the SCHWERPUNKT "Globale Methoden in der komplexen Geometrie", and was also supported by a VIGONI-DAAD Program. A first draft of this article took origin from the lectures by the second author at the G.A.C. Luminy Meeting, october 2005: thanks to the organizers!

given numerical invariants lying in the admissible range, i.e., fulfilling the required inequalities, does there exist a surfaces having these invariants. We shall however more broadly consider the three classical invariants K^2, p_g, q, which determine the other invariants $\chi := 1 - q + p_g, e = 12\chi - K^2$.

An important new inequality, which Severi tried without success to establish, and which has been attacked for many years with partial results by several authors, asserts that a surface of maximal Albanese dimension satisfies the inequality $K^2 \geq 4\chi$. We will report on Pardini's surprisingly simple proof of this so-called Severi's conjecture (cf. [Par05]).

The study of the pluricanonical maps is an essential technique in the classification of surface of general type. The main results concerning the m-canonical maps with $m \geq 3$ go back to an earlier period and we refer to [Cat87b] for a report on them.

We will report in the second chapter on recent developments concerning the bicanonical map; we would like to mention Ciliberto's survey (cf. [Cil97]) on this topic for the state of art ten years ago. Here instead, we combine a discussion of this topic with the closely intertwined problem of classification of surfaces with low values of the numerical invariants.

In the third chapter we report on surfaces of general type with geometric genus p_g equal to four, a class of surfaces whose investigation was started by Federigo Enriques (cf. chapter VIII of his book 'Le superficie algebriche', [Enr49]).

By Gieseker's theorem we know that for fixed K^2 and χ there exists a quasi projective coarse moduli space $\mathcal{M}_{K^2,\chi}$ for the birational equivalence classes of surfaces of general type. It is a very challenging problem to understand the geometry of these moduli spaces even for low values of the invariants. The case $p_g = 4$ is studied via the behaviour of the canonical map. While it is still possible to divide the moduli space into various locally closed strata according to the behaviour of the canonical map, it is very hard to decide how these strata patch together.

Using certain presentations of Gorenstein rings of codimension 4 introduced by M. Reid and D. Dicks, which arrange the defining equations as Pfaffians of certain matrices with many symmetries in such a way that these equations behave well under deformation, it is possible to exhibit explicit deformations, which allow to "connect" certain irreducible components of the moduli space.

Inspired by a construction of A. Beauville of a surface with $K^2 = 8$, $p_g = q = 0$, the second author defined Beauville surfaces as surfaces which are rigid and which admit an unramified covering which is isomorphic to a product of curves of genus at least 2. In this case the moduli space of surfaces orientedly homeomorphic to a given surface consists either of a unique real point, or of a pair of complex conjugate points corresponding to complex conjugate surfaces.

These surfaces, and the more general surfaces isogenous to a product, not only provide cheap counterexamples to the Friedman-Morgan speculation (which will be treated more extensively in the sixth section of this article), but provide also a wide class of surfaces quite manageable in order to test conjectures, and offer also counterexamples to various problems. The ease with which one can handle these surfaces is based on the fact that these surfaces are determined by "discrete" combinatorial data.

Beauville surfaces, their relations to group theory and to Grothendieck's theory of 'Dessins d'enfants' will be discussed in the fourth chapter.

It is a very difficult and very intriguing problem to decide whether two algebraic surfaces, which are not deformation equivalent, are in fact diffeomorphic.

The theory of Lefschetz fibrations provides an algebraic tool to prove that two surfaces are diffeomorphic. By a theorem of Kas (which holds also in the symplectic context) two Lefschetz fibrations are diffeomorphic if and only if their corresponding factorizations of the identity in the mapping class group are equivalent under the equivalence relation generated by Hurwitz moves and by simultaneous conjugation. We outline the theory, which was used with success in [CW04] in chapter five, which we end with a brief report on the status of two very old conjectures by Chisini concerning cuspidal curves and algebraic braids.

As already mentioned before, one of the fundamental problems in the theory of surfaces of general type is to understand their moduli spaces, in particular the connected components which parametrize the deformation equivalence classes of minimal surfaces of general type. By a classical result of Ehresmann, two deformation equivalent algebraic varieties are diffeomorphic. The other direction, i.e., whether two diffeomorphic minimal surfaces of general type are indeed in the same connected component of the moduli space, was an open problem since the eighties. We discuss in the last chapter the various counterexamples to the Friedman-Morgan speculation, who expected a positive answer to the question (unlike the second author, cf. [Kat83]).

Moreover, we briefly report on another equivalence relation introduced by the second author, the so-called quasi étale-deformation (Q.E.D.) equivalence relation, i.e., the equivalence relation generated by birational equivalence, by quasi étale morphisms and by deformation equivalence. For curves and surfaces of special type two varieties are Q.E.D. equivalent if and only if they have the same Kodaira dimension, whereas there are infinitely many surfaces of general type, which are pairwise not Q.E.D. equivalent.

1 Old and New Inequalities

1.1 Invariants of Surfaces

Let X be a compact complex manifold and let Ω^n_X be its canonical bundle, i.e., the line bundle of holomorphic $n-$forms (usually denoted by ω_X, since it is a dualizing sheaf in the sense of Serre duality). A corresponding canonical divisor is usually denoted by K_X.

To X one associates its *canonical ring*

$$R(X) := \oplus_{m \geq 0} H^0(\omega_X^{\otimes m}).$$

The trascendency degree over $\mathbb{C}$ of this ring leads to

- the *Kodaira dimension* $\kappa(X) := tr(R(X)) - 1$,

if $R(X) \neq \mathbb{C}$, otherwise $\kappa(X) := -\infty$. The Kodaira dimension is invariant under deformation (by Siu's theorem [Siu02], generalizing Iitaka's theorem for surfaces) and can assume the values $-\infty, 0, \dots, n = \dim X$.

Definition 1. *X is said to be* of general type *if the Kodaira dimension is maximal, $\kappa(X) = \dim X$.*

We are interested in the case of *surfaces*, i.e., of manifolds of dimension 2, of general type.

The three principal invariants under deformations for the study of these surfaces are

- the self intersection of the canonical class K_S^2 of a minimal model,
- the geometric genus $p_g := h^0(\omega_X)$ and
- the irregularity $q := h^1(\mathcal{O}_S) = h^0(\Omega^1_S)$.

The equality $h^1(\mathcal{O}_S) = h^0(\Omega^1_S)$ follows by Hodge theory since every algebraic surface is projective.

The invariants we have introduced, with the exception of K_S^2, are not only deformation invariants but also birational invariants.

Definition 2. *A smooth surface S is called* minimal *(or* a minimal model*) iff it does not contain any exceptional curve E of the first kind (i.e. $E \cong \mathbb{P}^1$, $E^2 = -1$).*

Every surface can be obtained by a minimal one (its "minimal model") after a finite sequence of blowing ups of smooth points; this model is moreover unique if $\kappa(S) \geq 0$ (see III.4.4, III.4.5 and III.4.6 of [BHPV04]). Thus, every birational class of surfaces of general type contains exactly one minimal surface, and one classifies surfaces of general type by studying their minimal models. To each minimal surface of general type we will associate its numerical

- type (K_S^2, p_g, q),

a triple of integers given by the three invariants introduced above.

In fact these determine all other classical invariants, as

- the Euler-Poincaré characteristic of the trivial sheaf $\chi(\mathcal{O}_S) = 1 - q + p_g$;
- the topological Euler characteristic $e(S) = c_2(S) = 12\chi(\mathcal{O}_S) - K_S^2$;
- the plurigenera $P_m(S) := h^0(\omega_X^{\otimes m}) = \chi(\mathcal{O}_S) + \binom{m}{2} K_S^2$.

The epression for c_2 is a classical theorem of M. Noether, and the expression for the plurigenera follows by Riemann-Roch and by Mumford's vanishing theorem.

By the theorems on pluricanonical maps (cf. [Bom73]), minimal surfaces S of general type with fixed invariants are birationally mapped to normal surfaces X in a fixed projective space of dimension $P_5(S) - 1$. X is uniquely determined, is called the *canonical model* of S, and is obtained contracting to points all the (-2)-curves of S (curves $E \cong \mathbb{P}^1$, with $E^2 = -2$).

Let us recall Gieseker's theorem

Theorem 1 (Gieseker [Gie77]). *There exists a quasi-projective coarse moduli scheme for canonical models of surfaces of general type S with fixed K_S^2 and $c_2(S)$.*

In particular, we can consider the subscheme $\mathcal{M}_{K_S^2, p_g, q}$ corresponding to minimal surfaces of general type of type (K_S^2, p_g, q). By the above theorem, it is a quasi projective scheme, in particular, it has finitely many irreducible components.

It is a dream ever since to completely describe $\mathcal{M}_{K_S^2, p_g, q}$ for as many types as possible.

1.2 Classical Inequalities and Geography

Obviously the first question is: for which values of (K_S^2, p_g, q) is $\mathcal{M}_{K_S^2, p_g, q}$ non empty?

For example, it is clear that $p_g(S)$ and $q(S)$ are always nonnegative, since they are dimensions of vector spaces.

In fact much more is known. In the following table we collect the well known classical inequalities holding among the invariants of minimal surfaces of general type:

$$\begin{array}{lll}
 & K_S^2 \geq 1 & \qquad\qquad\qquad \chi \geq 1 \\
(N) & K_S^2 \geq 2p_g - 4 & \text{or the weaker } K_S^2 \geq 2\chi(\mathcal{O}_S) - 6 \\
(D) & \text{if } q > 0,\ K_S^2 \geq 2p_g & \text{or the weaker if } q > 0,\ K_S^2 \geq 2\chi(\mathcal{O}_S) \\
(MY) & K_S^2 \leq 9\chi &
\end{array}$$

We have labeled by (N)= Noether, (D) = Debarre, (MY) = Miyaoka-Yau the rows, corresponding to the names of the inequalities ([Deb82], [Deb83], [Miy77], [Yau78], see also [BHPV04], chap. 7).

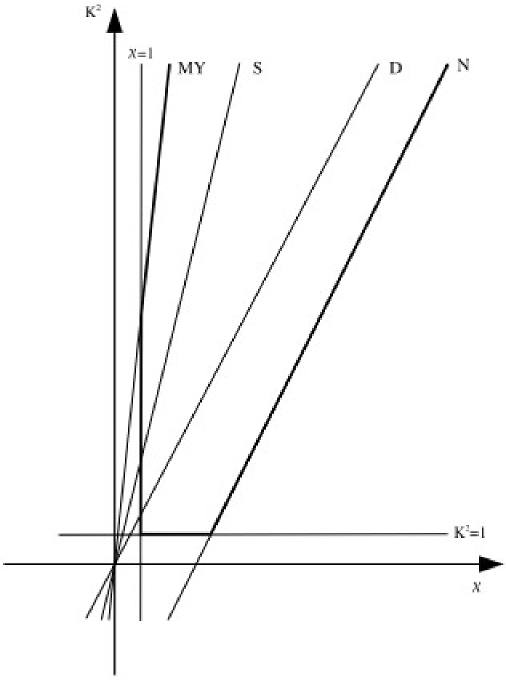

Fig. 1. The geography of minimal surfaces of general type

In figure 1 we have drawn the limit lines (i.e., where equality holds) of the various inequalities in the (χ, K_S^2)-plane.

The above listed inequalities show that the pair of invariants χ, K_S^2 of a minimal surface of general type gives a point with integral coordinates in the convex region limited by the "bold" piecewise linear curve. Moreover, if $q > 0$ this point cannot be at the "right" of the line D.

We drew one more line in our picture, labeled by S. This is the Severi line $K^2 = 4\chi$, i.e., the equality case of the Severi inequality $K^2 \geq 4\chi \Leftrightarrow K^2 \geq \frac{1}{2}e$, which will be discussed in detail at the end of this section.

1.3 Surfaces Fibred over a Curve

An important method for the study of surfaces of general type is to consider relatively minimal fibrations of surfaces over curves $f : S \to B$.

Definition 3. *A* fibration $f : S \to B$ *is a surjective morphism with connected fibres. We are interested in the case of fibrations* of surfaces to curves*, meaning that in this paper* S *and* B *will always be smooth compact complex manifolds of respective dimensions* 2 *and* 1.

The fibration is said to be relatively minimal *if* f *does not contract any rational curve of self intersection* -1 *to a point.*

One denotes

- by b the genus of the base curve B;
- by g the genus of a general fibre.

To avoid confusion, let us point out that a fibration is called rational or irrational according to the genus b of the base being 0 or > 0. On the other hand, the genus of the fibration is the genus g of the fibre. For example, if we say f is a genus 2 rational fibration, we intend that $g = 2$ and $b = 0$.

The classical way of saying: a genus b pencil of curves of genus g is however still the most convenient way to describe a fibration.

To a relatively minimal fibration f one associates

- its relative canonical bundle $\omega_{S|B} := \omega_S \otimes f^*(\omega_B^\vee)$ and
- the sheaves $(\forall n \geq 0)$ $V_n := f_*(\omega_{S|B}^{\otimes n})$.

The sheaves V_n are vector bundles (i.e., locally free sheaves) with very nice properties.

Theorem 2 (Fujita [Fuj78a], [Fuj78b]). *The vector bundles V_n are* semipositive, *i.e., every locally free quotient of it has nonnegative degree.*

To be more precise, V_1 is a direct sum of an ample vector bundle with $q(S) - b$ copies of the trivial bundle and with some undecomposable stable degree 0 vector bundle without global sections. Zucconi [Zuc97] proved moreover that if one of those stable bundles has rank 1, then it is a torsion line bundle.

For $n \geq 2$ we have:

Theorem 3 (Esnault-Viehweg [EV90]). *$\forall n \geq 2$ the vector bundle V_n is ample unless f has constant moduli, which means that all the smooth fibres are isomorphic.*

Since $R^1 f_* \omega_{S|B} = \mathcal{O}_B$ by relative duality, and $R^1 f_* \omega_{S|B}^{\otimes n} = 0 \ \forall n \geq 2$ by the assumption of relative minimality, one can compute the Euler characteristic of V_n by Riemann-Roch, and consequently its degree.

We introduce the following invariants of the fibration f:

- the self intersection of the relative canonical divisor

$$K_f^2 := \omega_{S|B} \cdot \omega_{S|B} = K_S^2 - 8(g-1)(b-1),$$

- the Euler characteristic of the relative canonical divisor

$$\chi_f = \chi(\omega_{S|B}) = \chi(\mathcal{O}_S) - (g-1)(b-1),$$

- its slope $\lambda(f) := K_f^2 / \chi_f$.

The slope is clearly defined only for $\chi_f \neq 0$, or equivalently (as we will see soon) if the fibration is not a holomorphic bundle.

The above mentioned computation gives

$$\deg V_n = \chi_f + \frac{n(n-1)}{2} K_f^2$$

and since by Fujita's theorem these numbers are nonnegative this gives the two inequalities $K_f^2 \geq 0$ and $\chi_f \geq 0$ respectively known as Arakelov's inequality (cf. [Ara71]) and Beauville's inequality (cf. [Bea82]).

In fact, we have the following list of inequalities

$$\begin{array}{ll} (A) & K_f^2 \geq 0 \ , \ i.e., \ K_S^2 \geq 8(g-1)(b-1), \\ (B) & \chi_f \geq 0 \ , \ i.e., \ \chi(\mathcal{O}_S) \geq (g-1)(b-1), \\ (ZS) & c_2(S) \geq 4(b-1)(g-1), \\ (NN) & q \leq b+g, \\ (X) & 4 - \frac{4}{g} \leq \lambda(f) \leq 12. \end{array}$$

Here the meaning of the labeling is the following: (A) = Arakelov's inequality, (B) = Beauville' inequality, (X) = Xiao's inequality (also known as slope inequality), (NN) = no name's inequality, (ZS) = Zeuthen-Segre. A proof of those inequalities can be found in [Bea82] with the exception of the slope inequality, proved in [Xia87] (see also [CH88] in the semistable case).

The equality cases of the first 4 inequalities are well described:

- if equality holds in (A), f has constant moduli;
- equality holds in (B) $\Leftrightarrow$ f has constant moduli and is smooth;
- for $g \geq 2$, equality holds in (ZS) $\Leftrightarrow$ f is smooth;
- $q = b + g \Leftrightarrow f$ is birationally equivalent to the projection of a product $B \times F$ to the first factor.

In particular, we see that the slope is defined whenever the fibration is not a holomorphic bundle, since the denominator χ_f vanishes iff equality holds in Beauville's inequality.

An important consequence is the following

Theorem 4 (Beauville). *If X is a minimal surface of general type, then $p_g \geq 2q - 4$. Moreover, if $p_g = 2q - 4$, then S is a product of a curve of genus 2 with a curve of genus $q - 2$.*

Note for later use (see next section) the following

Corollary 1. *If $p_g = q$ (i.e., if $\chi(\mathcal{O}_S) = 1$), then $p_g = q \leq 4$. Moreover, minimal surfaces of general type with $p_g = q = 4$ are exactly the products of two genus 2 curves.*

Proof of theorem 4. The standard wedge product on 1−forms induces a natural map

$$\wedge : \Lambda^2 H^0(\Omega^1_S) \to H^0(\Omega^2_S)$$

Recall that $q = \dim H^0(\Omega^1_S)$, $p_g = \dim H^0(\Omega^2_S)$. Let us assume $p_g \leq 2q - 4$.

By a dimension count, if $p_g \leq 2q - 4$, the projective linear subspace of $\mathbb{P}(\Lambda^2 H^0(\Omega^1_S))$ corresponding to the kernel of the above map must intersect the Plücker embedding of the Grasmannian $G_2(H^0(\Omega^1_S))$ (which has dimension $2q - 4$), and therefore there are two linearly independent $1-$forms ω_1 and ω_2 such that the following holomorphic two form is identically zero: $\omega_1 \wedge \omega_2 \equiv 0$.

By the theorem of Castelnuovo-De Franchis there is a fibration $f : S \to B$ with base of genus $b \geq 2$, and two holomorphic $1-$forms $\alpha_1,\ \alpha_2 \in H^0(\Omega^1_B)$ such that $f^*\alpha_i = \omega_i$. Since S is of general type, also $g \geq 2$.

Then

$$\chi_f \geq 0 \Rightarrow \chi(\mathcal{O}_S) \geq (b-1)(g-1) = (b-2)(g-2) + b + g - 3 \geq q - 3.$$

So we have $1 - q + p_g \geq q - 3 \Leftrightarrow p_g \geq 2q - 4$.

If $p_g = 2q - 4$, all inequalities are equalities and then, since $q = b + g$ and $(b-2)(g-2) = 0$, S is a product of two curves of genus at least 2, and one of the two must have genus exactly 2.

□

1.4 Severi's Inequality

We recall that the Albanese variety $Alb(X)$ of a compact Kähler manifold X is the cokernel of the natural map

$$\int : H_1(X, \mathbb{Z}) \to H^0(\Omega^1(X))^\vee$$

defined by integrating $1-$forms on 1-cycles.

The Albanese morphism

$$\alpha : X \to Alb(X)$$

is defined (up to translations in $Alb(X)$) by fixing a point $p_0 \in X$, and by associating to each point $p \in X$ the class in $Alb(X)$ of $\int_{p_0}^{p}$, where the integral is taken along any path between p_0 and p.

Recall that, if X is projective (as any surface of general type), $Alb(X)$ is an abelian variety (of dimension q).

The Albanese morphism is a powerful tool for studying *irregular* surfaces ($q > 0$) and in particular:

Definition 4. *A variety X is called of* maximal Albanese dimension *if the image of the Albanese morphism has the same dimension as X.*

This is the general case for surfaces, since otherwise the Albanese morphism is a fibration onto a smooth curve of genus q. We see then that for surfaces maximal Albanese dimension is equivalent to the non existence of a genus q pencil.

We can now state the theorem known as *Severi's inequality*

Special Families of Curves, of Abelian Varieties, and of Certain Minimal Manifolds over Curves

Introduction

Let $f : X \to Y$ be a surjective morphism from an $n+1$ dimensional complex projective manifold X to a curve Y. In this article we want to present some recent results about the structure of f, in particular about its discriminant locus S, i.e. the set of points s in Y with $f^{-1}(s)$ singular. So

$$f : V = f^{-1}(U) \longrightarrow U = Y \setminus S$$

will always be smooth. We will usually require $\Delta = f^*S$ to be a normal crossing divisor.

If $Y = \mathbb{P}^1$ and if X is a curve of genus $g(X) > 0$ the Hurwitz formula implies that $\#S \geq 3$. In the extremal case $\#S = 3$, X is obviously defined over a number field. G.V. Belyĭ has shown in [Be79] that the existence of f with $\#S = 3$ characterizes curves defined over a number field.

As conjectured by F. Catanese and M. Schneider, the first part can be generalized for $n > 0$.

Theorem 0.1 ([VZ01]). *Let X be a complex projective manifold of Kodaira dimension $\kappa(X) \geq 0$ and let $f : X \to \mathbb{P}^1$ be a surjective morphism. Then f has at least 3 singular fibres.*

It is more reasonable to assume that the general fibre F of f is connected, or as we will say, that $f : X \to Y$ is a family of n-dimensional manifolds, and to use the Hurwitz formula for the Stein factorization to get hold of the general

---

* This work has been supported by the "DFG-Schwerpunktprogramm Globale Methoden in der Komplexen Geometrie", and by the DFG-Leibniz program.

case. Y will be again a curve of arbitrary genus. Putting together results due to Parshin-Arakelov, Migliorini, Kovács, Bedulev-Viehweg, Oguiso-Viehweg and Viehweg-Zuo (see [VZ01] and the references given there) one has:

Theorem 0.2. *Let $f : X \to Y$ be a non-isotrivial family of n-folds, with general fibre F. Assume either*

a. $\kappa(F) = \dim(F)$, or
b. ω_F semiample.

Then $\deg(\Omega^1_Y(\log S)) = 2g(Y) - 2 + \#S > 0$.

Here f is isotrivial, if over some finite covering $Y' \to Y$ the pullback $X \times_Y Y'$ is birational to $F \times Y'$.

As a byproduct, the proof of 0.2 in [VZ01] (see also [Kov02]) gives some explicit lower bounds for the degree of $\deg(\Omega^1_Y(\log S))$. Writing δ for the number of singular fibres of f, which are not semistable, i.e. not reduced normal crossing divisors, one finds constants ν and e, depending only on the Hilbert polynomial h of some polarization of the family, with

$$\frac{\deg(f_*\omega^\nu_{X/Y})}{\operatorname{rank}(f_*\omega^\nu_{X/Y})} \leq (n \cdot (2g(Y) - 2 + \#S) + \delta) \cdot \nu \cdot e.$$

In Section 2 we will use [VZ05, 3.4] to get a similar bound for arbitrary semistable families.

Theorem 0.3. *Assume that $f : X \to Y$ is a semistable family of n-folds. If $Y = \mathbb{P}^1$ assume in addition that $\#S \geq 2$. Then for all $\nu \geq 1$ with $f_*\omega^\nu_{X/Y} \neq 0$*

$$\frac{\deg(f_*\omega^\nu_{X/Y})}{\operatorname{rank}(f_*\omega^\nu_{X/Y})} \leq \frac{n \cdot \nu}{2} \cdot (2g(Y) - 2 + \#S) = \frac{n \cdot \nu}{2} \cdot \deg(\Omega^1_Y(\log S)).$$

The assumption $\#S \geq 2$ is just added to guaranty that $\deg(\Omega^1_Y(\log S))$ is non-negative, and that the fundamental group of $Y \setminus S$ sufficiently large. Of course it will always hold true if one declares one or two smooth fibres to be singular.

There are families of Abelian varieties and of Calabi-Yau manifolds, with

$$\deg(f_*\omega^\nu_{X/Y}) = \frac{\deg(f_*\omega^\nu_{X/Y})}{\operatorname{rank}(f_*\omega^\nu_{X/Y})} = \frac{n \cdot \nu}{2} \cdot \deg(\Omega^1_Y(\log S)).$$

We do not know, whether there are families of manifolds of higher Kodaira dimension with such an equality.

Theorem 0.3 implies Theorem 0.2. In fact, if $\deg(\Omega^1_Y(\log S)) \leq 0$ the open set U is either an elliptic curve or it contains $\mathbb{C}^*$. In the first case the family is smooth, in the second one one finds a new family over an étale covering $\mathbb{C}^* \to \mathbb{C}^*$, which is semistable. For a semistable family $f : X \to Y$ Theorem

0.3 implies that $\deg(f_*\omega^\nu_{X/Y}) \leq 0$. On the other hand, the assumptions a) or b) in Theorem 0.2 imply that for $\nu \geq 2$

$$\deg(f_*\omega^\nu_{X/Y}) \geq 0,$$

and that $\deg(f_*\omega^\nu_{X/Y}) = 0$ if and only if f is isotrivial. The same argument is used to show Theorem 0.1:

If there is a morphism with 2 singular fibres, one uses the Hurwitz formula to show that the Stein factorization of $X \to \mathbb{P}^1$ is $\mathbb{P}^1$, and that the induced morphism has again at most 2 singular fibres. Here the positivity of $\deg(f_*\omega^\nu_{X/Y})$ follows from $\kappa(X) \geq 0$, and as above one obtains a contradiction to the inequality stated in Theorem 0.3.

In addition, the bound in Theorem 0.3 implies some weak analogue of the Shafarevich conjecture on the finiteness of smooth families of curves over a fixed curve U.

Corollary 0.4. *Fix (Y, S) and a polynomial h. Then up to deformation there are only finitely many non-isotrivial families $f : X \to Y$ smooth over $U = Y \setminus S$, such that:*

1. *ω_F is ample with Hilbert polynomial h.*
2. *$\omega_F^\rho = \mathcal{O}_F$ for some $\rho > 0$, and the smooth part $V \to U$ allows a polarization with Hilbert polynomial h.*

In fact, consider the moduli scheme M_h parameterizing either canonically polarized manifolds, or polarized manifolds with a torsion canonical divisor, and with Hilbert polynomial h. In both cases one can show (see [Vi05]) that for a given $\nu \geq 2$ with $h(\nu) \neq 0$ there is a projective compactification $\bar{M}_h$ and for some p an invertible sheaf $\lambda_\nu^{(p)}$ on $\bar{M}_h$ with:

1. $\lambda_\nu^{(p)}$ is numerically effective, and ample with respect to M_h.
2. If $f : X \to Y$ is a semistable family over a curve Y, whose general fibre belongs to the moduli functor, and if $\varphi : Y \to \bar{M}_h$ is the extension of the induced morphism to M_h, then

$$\varphi^*\lambda_\nu^{(p)} = \det(f_*\omega^\nu_{X/Y})^p.$$

Here an invertible sheaf λ is "ample with respect to M_h" if there exists some modification $\tau : \bar{M}'_h \to \bar{M}_h$, some $\mu \gg 1$ and an effective divisor E on $\bar{M}'_h$, supported in $\tau^{-1}(\bar{M}_h \setminus M_h)$, such that $\tau^*\lambda \otimes \mathcal{O}_{\bar{M}'_h}(-E)$ is ample.

So Theorem 0.3 says that for given Y and S the degree of $\varphi^*\lambda_\nu^{(p)}$ is bounded, which implies Corollary 0.4. Using a different argument (see [VZ02, 6.2]) one can extend 0.4 to families of minimal models of arbitrary (non-negative) Kodaira dimension.

As we will see in Section 2 the Theorems 0.1, 0.2 and 0.3 follow from the study of variations of Hodge structures of certain families obtained as cyclic coverings of $X \to Y$.

It remains the question, what is special about families with few singular fibres. Here the only results are for families controlled by their variation of Hodge structures $R^n f_* \mathbb{C}_V$ (or $R^1 f_* \mathbb{C}_V$ for families of Abelian varieties). Moreover, we will assume that the family has semistable reduction, or slightly weaker, that the local monodromies in all $s \in S$ are unipotent. Before stating the results, and before giving "few singular fibres" a precise meaning, we will need some notations.

Let $\mathbb{V} \subset R^k \mathbb{C}_V$ be a $\mathbb{C}$ sub variation of Hodge structures. $\mathbb{V} \otimes_C \mathcal{O}_U$ extends to a locally free sheaf $\mathcal{H}$ on Y in such a way that the Gauß-Manin connection acquires logarithmic singularities. We choose for $\mathcal{H}$ the Deligne extension, i.e. an extension such that the real part of the local residues are zero. The Hodge filtration extends to a holomorphic filtration on $\mathcal{H}$, and the extended Gauß-Manin connection defines on the associated graded bundle the structure of a logarithmic Higgs bundle (F, τ), i.e. a locally free sheaf F together with a collection of maps

$$\tau_{p,q} : F^{p,q} \longrightarrow F^{p-1,q+1} \otimes \Omega^1_Y(\log S), \qquad p+q=k.$$

The bundle maps $\tau_{p,q}$ can be iterated to obtain

$$\tau^{(\ell)} : F^{k,0} \longrightarrow F^{k-1,1} \otimes \Omega^1_Y(\log S) \longrightarrow \cdots \longrightarrow F^{k-\ell,\ell} \otimes S^\ell(\Omega^1_Y(\log S)).$$

Definition 0.5.

i. We call $\tau^{(k)} : F^{k,0} \to F^{0,k} \otimes S^k(\Omega^1_Y(\log S))$ *the Griffiths-Yukawa coupling of* $\mathbb{V}$ *(or of* f *in case* $\mathbb{V} = R^k f_* \mathbb{C}_V$*).*

ii. The Higgs field is strictly maximal, if $F^{k,0} \neq 0$ *and if the* $\tau_{p,q}$ *are all isomorphisms.*

As it will turn out, the property ii) is of numerical nature.

Lemma 0.6 ([VZ05]). *Assume that* $\mathbb{V}$ *is a variation of polarized complex Hodge structures of weight* n *with unipotent local monodromy in all* $s \in S$*, and with logarithmic Higgs bundle* $(\bigoplus F^{p,q}, \tau_{p,q})$*. If* $F^{k,0} \neq 0$ *one has the Arakelov inequality*

$$\deg(F^{k,0}) \leq \frac{k}{2} \cdot \operatorname{rank}(F^{k,0}) \cdot \deg(\Omega^1_Y(\log S)), \tag{1}$$

and (1) is an equality if and only if one has a decomposition $\mathbb{V} = \mathbb{V}_1 \oplus \mathbb{V}_2$ *where the Higgs field of* $\mathbb{V}_1$ *is strictly maximal and where* $\mathbb{V}_2$ *is a variation of polarized complex Hodge structures, zero in bidegree* $(k, 0)$.

For families of curves, the inequality (1) is due to Arakelov, and for families of Abelian varieties it has been shown by Faltings in [Fa83].

If $\#S$ is even, [VZ03, 3.4] gives a more precise description of $\mathbb{V}_1$. Choose a logarithmic theta characteristic, i.e. an invertible sheaf $\mathcal{L}$ with $\mathcal{L}^2 = \Omega^1_Y(\log S)$. The existence of $\mathbb{V}$ in 0.6 implies that $\deg(\Omega^1_Y(\log S)) > 0$. Then the Higgs bundle $\mathcal{L} \oplus \mathcal{L}^{-1}$ with Higgs field

$$\mathcal{L} \xrightarrow[\simeq]{\tau} \mathcal{L}^{-1} \otimes \Omega^1_Y(\log S)$$

is stable. As recalled in Section 1 it must be the Higgs bundle of a polarized variation of Hodge structures $\mathbb{L}$ of weight one. $\mathbb{L}$ is unique up to the tensor product with a unitary rank one local system, induced by a two-division point of $\mathrm{Pic}^0(Y)$.

Lemma 0.7. *Assume that* $\#S$ *is even, and that* $\mathbb{V}_1$ *is a variation of Hodge structures with a strictly maximal Higgs field and with unipotent local monodromies. Then there exists a unitary local system* $\mathbb{T}$ *on* Y*, regarded as a variation of Hodge structures in bidegree* $(0,0)$*, with* $\mathbb{V}_1 = S^k(\mathbb{L}) \otimes_C \mathbb{T}|_U$.

So "special families" or "families with few singular fibres" will be those where the variation of Hodge structures $R^k\mathbb{C}_V$ contains an irreducible sub variation $\mathbb{V}$ with a strictly maximal Higgs field, or equivalently a sub variation $\mathbb{V}$ for whose Higgs bundle the equality

$$\deg(F^{k,0}) = \frac{k}{2} \cdot \mathrm{rank}(F^{k,0}) \cdot \deg(\Omega^1_Y(\log S)) \tag{2}$$

holds. Here $k = n$, except for families of Abelian varieties, where we usually choose $k = 1$.

Let us first consider a semistable family $f : X \to Y$ of Abelian varieties, smooth over $U = Y \setminus S$, and $V = f^{-1}(U)$.

Theorem 0.8 ([VZ04]). *Assume that each irreducible and non-unitary sub variation* $\mathbb{V}$ *of Hodge structures in* $R^1 f_*\mathbb{C}_V$ *has a strictly maximal Higgs field. Then (replacing* U *by an étale covering and* V *by the pullback family)* U *is a Shimura curve of Hodge type, and* $f : V \to U$ *the corresponding universal family.*

The construction of Shimura curves will be recalled in Section 3. Let us just mention here, that a Shimura curve U is an étale covering of a certain moduli space of Abelian varieties with prescribed Mumford-Tate group and a suitable level structure. So whenever we talk about Shimura curves, this is a property up to étale coverings of U. This allows in particular to assume that $\#S$ is even.

As we will recall in Section 4 the converse of Theorem 0.8 was shown in [Moe3]:

Theorem 0.9. *If* $f : V \to U$ *is the universal family over a Shimura curve its Higgs field is strictly maximal.*

Because of Kollár's decomposition [Kol87] (see Lemma 1.9 below) one can write $f_*\Omega^1_{X/Y}(\log S)$ as a direct sum of an ample sheaf $\mathcal{A}$ and a subsheaf $\mathcal{B}$, flat for the Gauß-Manin connection. Correspondingly on the local system side one has a decomposition $R^1 f_*\mathbb{C}_V = \mathbb{W} \oplus \mathbb{U}$, where $\mathbb{U}$ is unitary and invariant under complex conjugation, and where the $(1,0)$ component of $\mathbb{W}$ is ample.

Hence the Higgs bundle corresponding to $\mathbb{W}$ is of the form $(\mathcal{A} \oplus \mathcal{A}^\vee, \theta)$ and using 0.6 one can restate the Theorem 0.8 as:

If $\deg(\mathcal{A}) = \frac{1}{2} \cdot \mathrm{rank}(\mathcal{A}) \cdot \deg(\Omega^1_Y(\log S))$, *then* U *is a Shimura curve of Hodge type, and* $f : V \to U$ *the corresponding universal family.*

The Lemma 0.7 implies that the Arakelov equality forces $\mathbb{W} = \mathbb{L} \otimes_{\mathbb{C}} \mathbb{T}$ for a unitary system $\mathbb{T}$. In particular, if $S \neq \emptyset$, replacing Y by an étale covering, one can assume that $\mathbb{T} = \mathbb{C}_U^{\oplus r}$ and $\mathbb{U} = \mathbb{C}_U^{\oplus 2 \cdot n - 2 \cdot r}$. As in [VZ04] one deduces the next Corollary.

Corollary 0.10. *If* $S \neq \emptyset$ *consists of an even number of points, and if*

$$\deg(\mathcal{A}) = \frac{1}{2} \cdot \mathrm{rank}(\mathcal{A}) \cdot \deg(\Omega^1_Y(\log S)),$$

then (replacing Y *by an étale covering)* $f : X \to Y$ *is isogenous to*

$$E \times_Y \cdots \times_Y E \times B,$$

where B *is an Abelian variety of dimension* $n - r$ *and where* $E \to Y$ *is a modular family of elliptic curves.*

The proof of Corollary 0.10 is easy if one assumes that the maximal unitary subsystem of $R^1 f_* \mathbb{C}_V$ is defined over $\mathbb{Q}$, and it will be sketched in Section 3. This condition holds true if $S \neq \emptyset$. For $S = \emptyset$ the proof of Theorem 0.8 in [VZ04] also gives back the known classification of Shimura curves.

As a supplement to 0.8 we will show in Section 3:

Corollary 0.11. *If the maximal unitary local subsystem* $\mathbb{U}$ *of* $R^1 f_* \mathbb{C}_V$ *is trivial, then the family* $f : V \to U$ *is rigid. In particular it is defined over* $\bar{\mathbb{Q}}$.

Let us consider next families of curves of genus $g \geq 2$, and let us return to the local systems $\mathbb{L}$, defined by logarithmic theta characteristics $\mathcal{L}$. Obviously $\mathbb{L}$ has a strictly maximal Higgs field.

Theorem 0.12 ([Moe2]). *Let* $f : X \to Y$ *be a semistable family of curves of genus* $g \geq 2$, *smooth over* $U = Y \setminus S$, *and* $V = f^{-1}(U)$.

1. $R^1 f_* \mathbb{C}_V$ *contains a rank two sub variation of Hodge structures* $\mathbb{L}$ *with a strictly maximal Higgs field if and only if* U *is a Teichmüller curve, and* $V \to U$ *the corresponding universal family.*
2. *Teichmüller curves are defined over number fields.*

The definition of a Teichmüller curve will be given in Section 4. Roughly speaking, one considers geodesics in the Teichmüller space, constructed by an $\mathrm{Sl}(2, \mathbb{R})$-action on the real and imaginary part of a given holomorphic differential form. If the quotient by a suitable lattice in $\mathrm{Sl}(2, \mathbb{R})$ is an algebraic curve, it is called a Teichmüller curve in M_g. As for Shimura curves, we always allow ourselves to replace the lattice by a smaller one, hence the Teichmüller curve by an étale cover. We say that $f : V \to U$ is the universal family if the morphism $U \to M_g$ is induced by f.

It is a striking fact, that in spite of the differential geometric definition of Teichmüller curves, they can be characterized analytically, or even by a numerical property of the Higgs bundle. This has a number of applications in the theory of Teichmüller curves (see [Moe2], [Moe3] and [BM05]), and it allows to construct new examples of such special curves in M_g.

At the same time, Theorem 0.12 allows to use differential geometric properties of Teichmüller curves to study variations of Hodge structures for families of curves. For example, at the present moment the only known proof of the next Corollary relies on Theorem 0.12, and on differential geometric methods.

Corollary 0.13. *In Theorem 0.12 the variation of Hodge structures $R^1 f_* \mathbb{C}_V$ can not contain two different sub variation of Hodge structures $\mathbb{L}_1$ and $\mathbb{L}_2$, both with a strictly maximal Higgs field.*

There remains the question whether there are higher rank irreducible sub variations of Hodge structures $\mathbb{V}$ with a strictly maximal Higgs field. By Lemma 0.7 those are of the form $\mathbb{L} \otimes_{\mathbb{C}} \mathbb{T}$, where $\mathbb{T}$ is an irreducible unitary system, at least after replacing U by an étale covering of degree two. As we will see in Section 1 $\operatorname{rank}(\mathbb{T}) \geq 2$ implies that $S = \emptyset$, and squeezing the methods used to prove 0.2 a bit more, one can show that this is not possible (see [VZ05]). So putting everything together one obtains:

Corollary 0.14. *Let $f : X \to Y$ be a semistable family of curves of genus $g \geq 2$, smooth over $U = Y \setminus S$. Then $R^1 f_* \mathbb{C}_V$ does not contain a sub variation of Hodge structures $\mathbb{V}$ with a strictly maximal Higgs field and with* $\operatorname{rank}(\mathbb{V}) > 2$.

If $S = \emptyset$ then $R^1 f_* \mathbb{C}_V$ does not contain any sub variation of Hodge structures $\mathbb{V}$ with a strictly maximal Higgs field.

As we will see in Sect. 4, the rank two local subsystem $\mathbb{L} \subset R^1 f_* \mathbb{C}_V$ can be defined over a number field K, i.e. it is of the form $\mathbb{L}_K \otimes_K \mathbb{C}$ for a local subsystem $\mathbb{L}_K \in R^1 f_* K_V$, but in general it will not be defined over $\mathbb{Q}$. Replacing K by its Galois hull, for $\sigma \in \operatorname{Gal}(K/\mathbb{Q})$ the conjugate local system $\mathbb{L}^\sigma$ can only have a strictly maximal Higgs field, if $\mathbb{L} = \mathbb{L}^\sigma$. The defect in the inequality (1) for $\mathbb{L}^\sigma$ has been studied in [BM05].

In general things are changing, if one replaces $f : X \to Y$ by its family of Jacobians. Passing from a family of curves to its Jacobian, one might replace the discriminant locus S by a subset S'. Singular fibres with a compact Jacobian, for example those with two components meeting in one point, are not contributing to the discriminant locus of the family of Jacobians. If $f : V \to U$ is the universal family over a Teichmüller curve, then the existence of the local subsystem $\mathbb{L}$ together with the inequality (1) applied to the family of Jacobians, shows that $S' = S$, hence that all singular fibres of f have a non-compact Jacobian. One can ask, whether there are any Teichmüller curves

$U \subset M_g$ in the moduli space of curves of genus g which are Shimura curves in the moduli space A_g of Abelian varieties (with a suitable level structure). By [Moe3] the answer is "no" for $g \geq 4$ and for $g = 2$, whereas for $g = 3$ there exists one example, essentially unique.

On the other hand, by the Corollaries 0.13 and 0.14 we know, that the only curves $U \subset M_g$, which are Shimura curves in A_g have to be induced by a family $f : X \to Y$ with $R^1 f_* \mathbb{C}_V = \mathbb{L} \oplus \mathbb{U}$ with $\operatorname{rank}(\mathbb{L}) = 2$ and with $\mathbb{U}$ unitary. This implies that U is a Teichmüller curve, and that U is not projective.

Theorem 0.15.

a. For $g \geq 2$ the moduli space M_g does not contain any compact Shimura curve.

b. M_g contains a non-compact Shimura curve U if and only if $g = 3$. The Shimura curve $U \in M_3$ is a Teichmüller curve, essentially unique.

In this article, we will explain the main ingredients used in the introduction, and we will sketch the proofs of some of the results mentioned above. In Section 1 we explain the Simpson correspondence for variations of Hodge structures over curves, and we will prove Lemma 0.6 and Lemma 0.7 for $k = 1$. For $k > 1$, Lemma 0.6 will be shown under the additional assumption that $\operatorname{rank}(F^{k,0}) = 1$.

In Section 2 we prove Theorem 0.3, and we give some hints, how one obtains Corollary 0.14 from Corollary 0.13.

The characterization of Shimura curves will be discussed in Section 3. We prove Theorem 0.8 for families where $R^1 f_* \mathbb{C}_V$ itself has a strictly maximal Higgs field, hence we exclude unitary direct factors. We sketch the proofs of Corollaries 0.10 and 0.11 and we also reproduce the proof of Theorem 0.9 from [Moe3].

Section 4 gives an introduction to the theory of Teichmüller curves. In particular we sketch the proof of Theorem 0.12 and of the Corollary 0.13.

Finally the non-existence of Teichmüller curves in M_g, for $g = 2$ and $g \geq 4$ and the proof of Theorem 0.15, b), will be discussed in Section 5.

1 Higgs Bundles over Curves and Arakelov Inequalities

We will frequently use C. Simpson's correspondence between polystable logarithmic Higgs bundles of degree zero and representations of the fundamental group $\pi_1(U, *)$. Recall that a logarithmic Higgs bundle is a locally free sheaf E on Y together with an $\mathcal{O}_Y$ linear morphism $\theta : E \to E \otimes \Omega^1_Y(\log S)$ with $\theta \wedge \theta = 0$. The usual definitions of stability (and semistability) for locally free sheaves extend to Higgs bundles, by requiring that

$$\mu(F) = \frac{\deg(F)}{\operatorname{rank}(F)} < \mu(E) = \frac{\deg(E)}{\operatorname{rank}(E)}$$

(or $\mu(F) \leq \mu(E)$) for all subsheaves F with $\theta(F) \subset F \otimes \Omega^1_Y(\log S)$.

Theorem 1.1 (C. Simpson [Si90]). *There exists a natural equivalence between the category of direct sums of stable filtered regular Higgs bundles of degree zero, and of direct sums of stable filtered local systems of degree zero.*

We will not recall the definition of a "filtered regular" Higgs bundle [Si90, page 717], and just remark that for a Higgs bundle corresponding to a local system $\mathbb{V}$ with unipotent monodromy around the points in S the filtration is trivial, and automatically $\deg(\mathbb{V}) = 0$.

In general it is impossible to describe the Higgs bundle (E, θ) explicitly in terms of the corresponding local system $\mathbb{V}$, with two exceptions:

Example 1.2. If $\mathbb{T}$ is a unitary local system on U with unipotent monodromy operators in $s \in S$, then the corresponding Higgs bundle is the Deligne extension N of $N_0 = \mathbb{T} \otimes \mathcal{O}_U$ and the Higgs field θ is the zero map.

The second example already occurred in the Introduction.

Example 1.3. Let $\mathbb{V}$ be a polarized $\mathbb{C}$ variation of Hodge structures of weight k and with unipotent local monodromy operators. The $\mathcal{F}$-filtration on $F_0 = \mathbb{V} \otimes_{\mathbb{C}} \mathcal{O}_U$ extends to a locally splitting filtration on the Deligne extension F

$$\mathcal{F}^{k+1} \subset \mathcal{F}^k \subset \cdots \subset \mathcal{F}^0.$$

We will usually assume that $\mathcal{F}^{k+1} = 0$ and $\mathcal{F}^0 = F$. The Griffiths transversality condition for the Gauß-Manin connection ∇ says that

$$\nabla(\mathcal{F}^p) \subset \mathcal{F}^{p-1} \otimes \Omega^1_Y(\log S),$$

and hence ∇ induces a $\mathcal{O}_Y$ linear map

$$\theta_{p,k-p} : F^{p,k-p} = \mathcal{F}^p/\mathcal{F}^{p+1} \longrightarrow F^{p-1,k-p+1} = \mathcal{F}^{p-1}/\mathcal{F}^p \otimes \Omega^1_Y(\log S).$$

So

$$\big(F = \bigoplus_p F^{p,k-p}, \theta = \bigoplus \theta_{p,k-p}\big)$$

is a Higgs bundle, and it is the image of $\mathbb{V}$ under the Simpson correspondence in Theorem 1.1.

Properties 1.4. Let $\mathbb{V}$ be a direct sum of irreducible $\mathbb{C}$ local system and let (F, θ) be the corresponding Higgs bundle.

1. $F = \bigoplus_{p+q=k} F^{p,q}$ with $\theta(F^{p,q}) \subset F^{p-1,q+1} \otimes \Omega^1_Y(\log S)$ if and only if $\mathbb{V}$ is a local system underlying a complex polarized variation of Hodge structures.
2. Under the equivalent conditions in 1) let $\mathbb{T}$ be a local subsystem of $\mathbb{V}$ with Higgs bundle

$$\big(N = \bigoplus_p N^{p,k-p}, 0\big) \ \subset \ \big(F = \bigoplus_p F^{p,k-p}, \theta = \bigoplus \theta_{p,k-p}\big).$$

Then $\mathbb{T}$ is unitary.

Proof. The condition on (F,θ) in 1) is just saying, that it is a system of Hodge bundles, as defined in [Si88]. So the first part follows from [Si88] and [Si90].

Let $\Theta(N,h)$ denote the curvature of the Hodge metric h on F restricted to N, then by [Gr84], chapter II we have

$$\Theta(N,h|_N) = -\theta_N \wedge \bar{\theta}_N - \bar{\theta}_N \wedge \theta_N = 0.$$

This means that $h|_N$ is a flat metric. Hence, $\mathbb{T}$ is a unitary local system. □

The Simpson correspondence does not say anything about the field of definition for $\mathbb{V}$. Here we say that $\mathbb{V}$ is defined over a subfield K of $\mathbb{C}$ if there is a K-local system $\mathbb{V}_K$ with $\mathbb{V} = \mathbb{V}_K \otimes_K \mathbb{C}$. In different terms, for $\mu = \mathrm{rank}(\mathbb{V})$ the representation

$$\gamma_{\mathbb{V}} : \pi_0(U,*) \longrightarrow \mathrm{Gl}(\mu,\mathbb{C})$$

is conjugate to one factoring like

$$\gamma_{\mathbb{V}} : \pi_0(U,*) \longrightarrow \mathrm{Gl}(\mu,K) \longrightarrow \mathrm{Gl}(\mu,\mathbb{C}).$$

If $\mathbb{V}$ is defined over K, and if $\sigma : K \to K'$ is an isomorphism, we will write $\mathbb{V}_K^\sigma$ for the local system defined by

$$\gamma_{\mathbb{V}} : \pi_0(U,*) \longrightarrow \mathrm{Gl}(\mu,K) \xrightarrow{\sigma} \mathrm{Gl}(\mu,K'),$$

and $\mathbb{V}^\sigma = \mathbb{V}_K^\sigma \otimes_{K'} \mathbb{C}$.

By [De71] (for $K = \mathbb{Q}$) and by [De87] the category of polarized K-variations of Hodge structures is semisimple. By [De87, Proposition 1.13] one has:

Lemma 1.5. *A local system $\mathbb{V}$, underlying a polarized variation of Hodge structures, decomposes as*

$$\mathbb{V} = \bigoplus_{i=1}^{r} (\mathbb{V}_i \otimes W_i),$$

where $\mathbb{V}_i$ are pairwise non-isomorphic irreducible $\mathbb{C}$-local systems and W_i are non-zero $\mathbb{C}$-vector spaces.

Moreover the $\mathbb{V}_i$ and the W_i carry polarized variations of Hodge structures, whose tensor product and sum gives back the Hodge structure on $\mathbb{V}$. The Hodge structure on the $\mathbb{V}_i$ (and W_i) is unique up to a shift of the bigrading.

Suppose that $\mathbb{W}$ is a local system defined over a number field L. The local system $\mathbb{W}_L$ is given by a representation $\rho : \pi_1(U,*) \to \mathrm{Gl}(W_L)$ for the fibre W_L of $\mathbb{W}_L$ over the base point $*$.

Fixing a positive integer $r < \mu$ let $\mathcal{G}(r,\mathbb{W})$ denote the set of all rank-r local subsystems of $\mathbb{W}$ and let $\mathrm{Grass}(r,W_L)$ be the Grassmann variety of r-dimensional subspaces. Then $\mathcal{G}(r,\mathbb{W})$ is the subvariety of

$$\mathrm{Grass}(r,W_L) \times_{\mathrm{Spec}(L)} \mathrm{Spec}(\mathbb{C})$$

consisting of the $\pi_1(U,*)$-invariant points. In particular, it is a projective variety defined over L. A K-valued point of $\mathcal{G}(r,\mathbb{W})$ corresponds to a local subsystem of $\mathbb{W}_K = \mathbb{W}_L \otimes_L K$. One obtains the following well known property.

Lemma 1.6. *If* $[\mathbb{V}] \in \mathcal{G}(r,\mathbb{W})$ *is an isolated point, then* $\mathbb{V}$ *is defined over* $\bar{\mathbb{Q}}$.

Lemma 1.7. *Let* $\mathbb{W}$ *be a polarized variation of Hodge structures defined over* L*, and let* $\mathbb{V} \subset \mathbb{W}$ *be an irreducible local subsystem of rank* r *defined over* $\mathbb{C}$,. *Then* $\mathbb{V}$ *can be deformed to a local subsystem* $\mathbb{V}_t \subset \mathbb{W}$*, which is isomorphic to* $\mathbb{V}$ *and which is defined over a finite extension of* L.

Proof. By Lemma 1.5 $\mathbb{W}$ is completely reducible over $\mathbb{C}$. Hence we have a decomposition $\mathbb{W} = \mathbb{V} \oplus \mathbb{V}'$.

The space $\mathcal{G}(r,\mathbb{W})$ of rank r local subsystems of $\mathbb{W}$ is defined over L and the subset

$$\{\mathbb{V}_t \in \mathcal{G}(r,\mathbb{W});\ \text{the composite } \mathbb{V}_t \subset \mathbb{V} \oplus \mathbb{V}' \xrightarrow{pr_1} \mathbb{V} \text{ is non zero }\}$$

forms a Zariski open subset. So there exists some $\mathbb{V}_t$ in this subset, which is defined over some finite extension of L. Since $p : \mathbb{V}_t \to \mathbb{V}$ is non zero, since $\mathrm{rank}(\mathbb{V}_t) = \mathrm{rank}(\mathbb{V})$, and since $\mathbb{V}$ is irreducible, p is an isomorphism. □

The Lemmata 1.6 and 1.7 are just the starting points to show, that certain local subsystems of $R^k f_*\mathbb{C}_V$ are defined over number fields (see [VZ04]). Let us give a typical example:

Lemma 1.8. *Let* $\mathbb{W}$ *be defined over a (real) number field, and let* $\mathbb{W} = \mathbb{V} \oplus \mathbb{U}$ *be a decomposition such that the Higgs field of* $\mathbb{V}$ *is maximal, and such that* $\mathbb{U}$ *is unitary.*

1. *Then* $\mathbb{V}$ *and* $\mathbb{U}$ *are defined over a (real) number field, as well as the decomposition.*
2. *If* $S \neq \emptyset$*, then* $\mathbb{U}$ *is defined over* $\mathbb{Q}$ *and it trivializes over an étale covering of* Y.

Proof. Consider a family $\mathbb{V}_t$ of local subsystems of $\mathbb{W}$ for t in a small disk Δ, and with $\mathbb{V}_0 = \mathbb{V}$. Since the Higgs field of $\mathbb{V}_0$ is maximal, one may assume that the one of $\mathbb{V}_t$ is maximal for all $t \in \Delta$. Then the projection $\mathbb{V}_t \to \mathbb{U}$ must be zero. Otherwise, the complete reducibility of local systems coming from variations of Hodge structures in 1.5 implies that $\mathbb{V}_t$ and $\mathbb{U}$ have a common factor, obviously a contradiction.

So $\mathbb{V}$ is rigid as a local subsystem, hence defined over $\bar{\mathbb{Q}}$. The same argument works for $\mathbb{U}$ instead of $\mathbb{V}$.

If $\mathbb{W}$ is defined over $\mathbb{R}$, then $\bar{\mathbb{V}} \to \mathbb{U}$ again has to be the zero map. So $\mathbb{V}$ and $\mathbb{U}$ have to be defined over $\mathbb{R}$.

Assume now that $S \neq \emptyset$. By (1) we know that the decomposition is defined over a number field. For the local monodromy operators "unitary and unipotent" implies that the nilpotent part of the monodromy is zero. This is invariant under conjugation by $\sigma \in \mathrm{Gal}(\bar{\mathbb{Q}}/\mathbb{Q})$, and $\mathbb{U}^\sigma = \mathbb{U}$.

Finally, since $\mathbb{U}$ is a local subsystem of a variation of Hodge structures, it carries a $\mathbb{Z}$-structure. Then the image of the corresponding monodromy representation is finite. □

Lemma 1.5 together with Theorem 1.1 implies that the Higgs bundle (F, θ) of a variation of Hodge structures $\mathbb{V}$ is polystable (as a Higgs bundle) and of degree zero. As a first application one obtains Kollár's decomposition of the sheaf $F^{k,0}$, mentioned in the introduction.

Lemma 1.9. *Let* $(F = F^{k,0} \oplus \cdots \oplus F^{0,k}, \theta)$ *be the logarithmic Higgs bundle of a variation of Hodge structures* $\mathbb{V}$ *with unipotent local monodromies. Then* $F^{k,0} = \mathcal{A} \oplus \mathcal{B}$ *with* $\mathcal{A}$ *ample and with* $\mathcal{B}$ *flat.*

Proof. Replacing $\mathbb{V}$ by one of its irreducible direct factors, one has to show that $F^{k,0}$ is ample, provided that $\theta \neq 0$.

A quotient sheaf $\mathcal{N}$ of $F^{k,0}$ gives rise to a quotient Higgs bundle $(\mathcal{N}, 0)$ of (F, θ), hence 1.1 implies that $\deg(\mathcal{N}) \geq 0$. If $\deg(\mathcal{N}) = 0$, then it corresponds to a local subsystem, which is excluded by the irreducibility of $\mathbb{V}$. Hence all quotients of $F^{k,0}$ have strictly positive degree, which implies that $F^{k,0}$ is ample. □

Let us consider for a moment the case $k = 1$ and $\mathbb{V} = R^1 f_* \mathbb{C}_V$. Then $(\mathcal{B} \oplus \mathcal{B}^\vee, 0)$ is a sub Higgs bundle, hence by Lemma 1.4, 2), it corresponds to a unitary subbundle of $\mathbb{V}$. The latter is defined over $\mathbb{Q}$ and by Lemma 1.8, (1), this decomposition is defined over $\bar{\mathbb{Q}} \cap \mathbb{R}$.

The Arakelov inequality stated in Lemma 0.6 follows from the polystability of the Higgs bundles (see [VZ03] and [VZ05]). We will indicate the proof just in two simple cases, the one of weight one variations of Hodge structures, and the one where the $(k, 0)$ part is one dimensional.

Proof of Lemma 0.6 for weight one. Let $\mathcal{A} \subset F^{1,0}$ be a subsheaf, and let $\mathcal{C} \otimes \Omega^1_Y(\log S)$ be its image under $\theta_{1,0}$. Then $\mathcal{A} \oplus \mathcal{C}$ is a Higgs subbundle of $F^{1,0} \oplus F^{0,1}$, and 1.1 implies that $\deg(\mathcal{A}) + \deg(\mathcal{C}) \leq 0$. Since $(\ker(\theta|_{\mathcal{A}}), 0)$ is a sub Higgs bundle, one has

$$\begin{aligned}\deg(\mathcal{A}) &\leq \deg(\mathcal{C}) + \mathrm{rank}(\mathcal{C}) \cdot \deg(\Omega^1_Y(\log S)) \\ &\leq \deg(\mathcal{C}) + \mathrm{rank}(\mathcal{A}) \cdot \deg(\Omega^1_Y(\log S)) \\ &\leq -\deg(\mathcal{A}) + \mathrm{rank}(\mathcal{A}) \cdot \deg(\Omega^1_Y(\log S)), \end{aligned} \tag{3}$$

and

$$\frac{\deg(\mathcal{A})}{\mathrm{rank}(\mathcal{A})} \leq \frac{1}{2} \deg(\Omega^1_Y(\log S)).$$

For $\mathcal{A} = F^{1,0}$ one obtains the inequality (1) in 0.6.

If (1) is an equality, all the inequalities in (3) are equalities. This implies that $\mathrm{rank}(\mathcal{A}) = \mathrm{rank}(\mathcal{C})$, hence that $\theta|_{\mathcal{A}}$ is injective. Furthermore $\deg(\mathcal{A}) + \deg(\mathcal{C}) = 0$, hence $\mathcal{A} \oplus \mathcal{C}$ corresponds to a sub-local system of $\mathbb{V}$ with a maximal Higgs field. □

In fact we have shown a bit more. Assume that (1) in Lemma 0.6 is an equality. If $\mathbb{V}$ is irreducible

$$\frac{\deg(\mathcal{A})}{\mathrm{rank}(\mathcal{A})} < \frac{1}{2}\deg(\Omega^1_Y(\log S)) = \frac{\deg(F^{1,0})}{g_0},$$

except for $\mathcal{A} = F^{1,0}$. Hence $F^{1,0}$ is stable. By duality one obtains the same for $F^{0,1}$.

If $\mathbb{V}$ is not irreducible, applying this argument to all the direct factors of $\mathbb{V}$ one finds:

Lemma 1.10. *If $(F^{1,0} \oplus F^{0,1}, \theta)$ is the logarithmic Higgs bundle of a variation of Hodge structures $\mathbb{V}$ with unipotent local monodromies and with a strictly maximal Higgs field, then the sheaves $F^{1,0}$ and $F^{0,1}$ are polystable and the Higgs field $\theta : F^{1,0} \to F^{0,1} \otimes \Omega^1_Y(\log S)$ is a morphism between polystable sheaves of the same slope.*

Although in this survey we only consider families over curves, let us make one remark about families over a higher dimensional basis. One can hope that the polystability of the Hodge bundles $F^{1,0}$ and $F^{0,1}$ is again enforced by a numerical condition on the degrees with respect to $\omega_Y(S)$, and that it forces $U = Y \setminus S$ to be a Shimura variety. Some first results in this direction have been obtained in [VZ05b].

Proof of Lemma 0.7 for $k = 1$. By assumption $\#S$ is even, so we can choose a logarithmic theta characteristic $\mathcal{L}$ and an isomorphism

$$\tau : \mathcal{L} \to \mathcal{L}^{-1} \otimes \Omega^1_Y(\log S),$$

giving us the $\mathbb{C}$-variation of Hodge structures $\mathbb{L}$. By Lemma 1.10, the sheaf $\mathcal{T} = F^{1,0} \otimes \mathcal{L}^{-1}$ is polystable of degree zero, hence isomorphic to $\mathbb{T} \otimes \mathcal{O}_Y$ for a unitary local system $\mathbb{T}$. The isomorphism

$$\mathcal{T} \otimes \mathcal{L} = F^{1,0} \xrightarrow[\simeq]{\theta} F^{0,1} \otimes \Omega^1_Y(\log S) \xrightarrow[\simeq]{} F^{0,1} \otimes \mathcal{L}^2$$

induces an isomorphism $\phi : \mathcal{T} \otimes \mathcal{L}^{-1} \xrightarrow{\simeq} F^{0,1}$, such that $\theta = \phi \circ (\mathrm{id}_{\mathcal{T}} \otimes \tau)$. Hence the Higgs bundles $(F^{1,0} \oplus F^{0,1}, \theta)$ and $(\mathcal{T} \otimes (\mathcal{L} \oplus \mathcal{L}^{-1}), \mathrm{id}_{\mathcal{T}} \otimes \tau)$ are isomorphic, and $\mathbb{V} \simeq \mathbb{T} \otimes_{\mathbb{C}} \mathbb{L}$. □

Proof of Lemma 0.6 under the additional assumption $\mathrm{rank}(F^{k,0}) = 1$. For later use, let us consider a slightly more general situation:

$\mathbb{V}$ is a variation of polarized complex Hodge structures and with unipotent local monodromy in $s \in S$, and with logarithmic Higgs bundle $(\bigoplus F^{k,0}, \theta)$. Let $\mathcal{H} \subset F^{k,0}$ be an invertible subsheaf, and let $E \subset F$ be the sub Higgs bundle generated by $\mathcal{H}$. Writing $T_Y(-\log S)$ for the dual of $\Omega^1_Y(\log S)$, for some q_0

$$E^{k-q,q} = F^{k-q,q} \cap E = \begin{cases} \mathcal{H} \otimes T_Y(-\log S)^q & \text{for } \ q \leq q_0 \\ 0 & \text{for } \ q > q_0. \end{cases} .$$

Theorem 1.1 implies that

$$\deg(E) = (q_0 + 1) \cdot \deg(\mathcal{H}) - \frac{q_0 \cdot (q_0 + 1)}{2} \deg(\Omega^1_Y(\log S)) \leq 0,$$

hence

$$\deg(\mathcal{H}) \leq \frac{q_0}{2} \deg(\Omega^1_Y(\log S)) \leq \frac{k}{2} \deg(\Omega^1_Y(\log S)). \tag{4}$$

In Lemma 0.6 we choose $\mathcal{H} = F^{k,0}$, and we obtain the Arakelov inequality. If this is an equality, then $q_0 = k$ and E corresponds to a local subsystem, by construction with a strictly maximal Higgs field. □

2 Coverings and Bounds for Subsheaves of the Direct Images

Let us recall from [VZ05] the proof of the following proposition, as a first application of the theory of Higgs bundles.

Proposition 2.1. *Let $f : X \to Y$ be a semistable family of n-folds over a curve Y, and smooth over $U = Y \setminus S$. If $Y = \mathbb{P}^1$ assume that $\#S \geq 2$, and consider for $\nu \geq 1$ an invertible subsheaf $\mathcal{H}$ of $f_*\omega^{\nu}_{X/Y}$. Then*

$$\deg \mathcal{H} \leq \frac{n \cdot \nu}{2} \cdot \deg(\Omega^1_Y(\log S)).$$

Before sketching the proof of the proposition, let us show that it implies Theorem 0.3.

Proof of Theorem 0.3. Since either $g(Y) \geq 1$, or $Y = \mathbb{P}^1$ and $\#S \geq 2$, one can always find a covering $Y' \to Y$, which is unramified over U and which has a prescribed ramification order in $s \in S$. Since f is semistable, the inequality in Theorem 0.3 is compatible with replacing Y by Y' and f by a desingularization of the pullback family.

For $r = \operatorname{rank}(f_*\omega^{\nu}_{X/Y})$ consider the family $f^{(r)} : X^{(r)} \to Y$, obtained as a desingularization of the total space of the r fold product

$$X^r = X \times_Y \cdots \times_Y X \longrightarrow Y.$$

Remark that X^r is normal, Gorenstein with at most rational singularities. Hence flat base change implies that

4 Teichmüller Curves and their Variation of Hodge Structures

We start with the assumptions of Theorem 0.12: Let $f : X \to Y$ be a semistable family of curves of genus $g \geq 2$, smooth over $U = Y \setminus S$ and let $V = f^{-1}(U)$. Suppose that $R^1 f_* \mathbb{C}_V$ contains a sub variation of Hodge structures $\mathbb{L}$ of rank two with a strictly maximal Higgs field. Let us for the moment admit the following:

Lemma 4.1. $\mathbb{L}$ *is defined over* $\mathbb{R}$

By Theorem 0.2 the universal covering of U is the upper half plane $\mathcal{H}$. Let $\widetilde{\varphi} : \mathcal{H} \to \mathcal{H}$ the period map for $\mathbb{L}$. The strict maximality of the Higgs field is now equivalent to $\widetilde{\varphi}$ being an isomorphism (compare [VZ04] Lemma 2.1). In different terms $\widetilde{\varphi}$ is an isometry for the Kobayashi metric on $\mathcal{H}$. The choice of a Teichmüller marking (see below) on one of the smooth fibres of f defines a lift of the moduli map $m : U \to M_g$ to Teichmüller space. We denote this lift by $\widetilde{m} : \mathcal{H} \to T_g$ and we let $j : T_g \to \mathcal{H}_g$ the natural map to the Siegel half space, which associates to the curve its Jacobian and to the Teichmüller marking the choice of a symplectic basis. Finally we let $p_{11} : \mathcal{H}_g \to \mathcal{H}$ the projection of the matrix in $\mathcal{H}_g$ to its $(1,1)$-entry. If we have chosen the symplectic basis B suitably, i.e. such that the first pair in B spans the fibres of $\mathbb{L}$, then

$$\widetilde{\varphi} = p_{11} \circ j \circ \widetilde{m}.$$

Since the composite map $\widetilde{\varphi}$ is a Kobayashi isometry, also $\widetilde{m}$ is an isometry, if we provide the image with the restriction of the Kobayashi metric on T_g. By a theorem of Royden the Kobayashi metric on T_g coincides with the Teichmüller metric. To sum up:
The image of U in M_g is an algebraic curve, whose lift in T_g is a complex geodesic for the Teichmüller metric. These objects are called *Teichmüller curves*. We have thus proved one implication of Theorem 0.12.1.

Before showing the converse implication we need some background on geodesics for the Teichmüller metric. Details may be found in [IT92].
One of the equivalent definitions of Teichmüller space is the following. Let T_g be the space of pairs (R, h) of a Riemann surface plus a quasi-conformal mapping $h : R_0 \to R$ up to isotopy (the *Teichmüller marking*) from a 'reference surface' R_0 to R. By Teichmüller's theorem the isotopy class of h contains a unique representative with minimal maximal dilatation. Its Beltrami coefficient (a $(-1,1)$-form) $\mu = h_{\overline{z}}/h_z$ is of the form $\mu = t|q|/q$ for some quadratic differential $q \in \Gamma(R_0, (\Omega^1_{R_0})^{\otimes 2})$ and $|t| < 1$. Conversely, one can solve the Beltrami equation for any μ of with $|\mu|_\infty < 1$. In particular for each $\mu = t|q|/q$ there is a quasi-conformal map $h : R_0 \to R$ for some Riemann surface R whose Beltrami coefficient is μ.

A quadratic differential q on a Riemann surface R_0 determines an atlas of R minus the zero set of q_0 such that the transition functions are translations maybe composed by multiplication with ±1: The charts $\psi_i : U_i \to \mathbb{C}$ are given by integrating by a square root of q that exists locally. The condition for h to have minimal maximal dilatation may be rephrased by saying that h is affine in the charts ψ_i for some q on R_0 and some ('terminal') quadratic differential on R. The Teichmüller geodesic from id to h is given by the conformal maps with Beltrami coefficient $ct|q|/q$ for $c \in [0,1]$. Thus for each q, the set

$$\{\mu_q(t) := t|q|/q,\ |t| < 1\}$$

defines totally geodesic subset of T_g.

We briefly recall the construction of the complex structure on T_g that makes $T_g \to M_g$ holomorphic. Given (R,h) or rather its Beltrami coefficient μ on R_0, pull it back to universal covering $\mathcal{H}$ of R_0 and extend it by zero to obtain a Beltrami coefficient $\tilde{\mu}$ on $\mathbb{C}$. Solving the Beltrami equation for μ gives a quasi-conformal mapping $\tilde{h} : \mathbb{C} \to \mathbb{C}$, conformal on the lower half plane $\mathcal{H}^*$. The Schwarzian derivative of $\tilde{h}|_{\mathcal{H}^*}$ is a quadratic differential on $\mathcal{H}^*$. Moreover, since μ was pulled back from $R = \mathcal{H}/\Gamma_R$, the Schwarzian derivative descends from $\mathcal{H}^*$ to a quadratic differential

$$q^*_\mu \in H^0(\mathcal{H}^*/\Gamma_R, (\Omega^1_{\mathcal{H}^*/\Gamma_R})^{\otimes 2}).$$

The map $\mu \mapsto q^*_\mu$ factors through Teichmüller space and the complex structure on $H^0(\mathcal{H}^*/\Gamma_R, (\Omega^1_{\mathcal{H}^*/\Gamma_R})^{\otimes 2})$ is the one we want.

The map $\mu \mapsto q^*_\mu$ has a section locally around 0 (due to Bers) given by $q^*(z) \mapsto -2\mathrm{Im}(z) q^*(\bar{z})$. This implies that a neighborhood of 0 of

$$\{\mu_q(t),\ |t| < 1\}$$

is a holomorphic submanifold of T_g. Since the complex structure on T_g is independent of the base point, all of $\{\mu_q(t),\ |t| < 1\}$ is a holomorphic submanifold.

To sum up: For a fixed Riemann surface R_0 and $q \in \Gamma(R_0, (\Omega^1_{R_0})^{\otimes 2})$ fixed, the set $t|q|/q$, $|t| < 1$ is a totally geodesic and holomorphic submanifold of T_g, a *Teichmüller disc*.

In order to characterize which (few!) Teichmüller discs descend to Teichmüller curves in M_g we provide another description of a Teichmüller disc. There is a natural $\mathrm{Sl}(2,\mathbb{R})$-action on the bundle of triples (R,φ,q) over T_g. Post-compose local charts ψ_i of R with $A \in \mathrm{Sl}(2,\mathbb{R})$ acting on $\mathbb{C} \cong \mathbb{R}^2$. Since overlapping charts differ only by translations and multiplication by ±1, the compositions

$$\widetilde{\psi_i} : U_i \longrightarrow \mathbb{C} \cong \mathbb{R}^2 \xrightarrow{A} \mathbb{R}^2 \cong \mathbb{C}$$

determine a new complex structure on R. We let this new Riemann surface be $A \cdot R$. There is a unique quadratic differential $A \cdot q$ on $A \cdot R$ whose integration charts are $\widetilde{\psi_i}$.

The action of $\mathrm{SO}(2,\mathbb{R})$ does not change the complex structure of R. Hence the orbit $\mathrm{Sl}(2,\mathbb{R}) \cdot (R,\varphi,q)$ projects to a disc in T_g. If we lift

$$\begin{aligned} \mathcal{H} &\to \mathrm{Sl}(2,\mathbb{R}) \\ \tau \ &\mapsto \begin{pmatrix} 1 \ \mathrm{Re}\,\tau \\ 0 \ \mathrm{Im}\,\tau \end{pmatrix} \end{aligned}$$

one verifies that the Beltrami coefficient of the composition $\widetilde{\psi}_i$ is $\frac{i-\tau}{i+\tau}\frac{|q|}{q}$. Hence the image of the $\mathrm{Sl}(2,\mathbb{R})$-orbit is a Teichmüller disc.

Proposition 4.2. *A Teichmüller disc descends to a Teichmüller curve, if and only if the setwise stabilizer of the disc in the mapping class group is a lattice in* $\mathrm{Aut}(\mathcal{H}) = \mathrm{Sl}(2,\mathbb{R})$. *This stabilizer coincides up to conjugation with a quotient (by a finite group) of the group of orientation-preserving diffeomorphisms that are affine in the charts provided by* q.

Proof. Proposition 3.2 and Proposition 3.3 in [McM03]. □

When referring to a Teichmüller curve in the sequel we always assume that it is *generated by* $q = \omega^2$ *the square of a holomorphic one-form.* If a Teichmüller curve is generated by a quadratic differential on R, take the double covering of R where it admits a square root. The above criterion gives an easy way to check that this pair generates again a Teichmüller curve.

Proof of Corollary 0.13. This is [McM03] Theorem 4.2 in a different language. Suppose the contrary was true. Then $U \to M_g$ defines a Teichmüller curve. Over the universal cover $\mathcal{H}$ of U we may choose sections $\omega_j = \omega_j(\tau)$ for $j = 1, 2$ generating the $(1,0)$-part of $\mathbb{L}_j$. We may moreover choose a symplectic basis $\{a_k, b_k\}$ for $k = 1, \ldots g$ of $R^1(f_{\mathcal{H}})_*\mathbb{Z}_V$ such that $\int_{b_k} \omega_j(\tau) = \delta_{j,k}$ for $\tau \in \mathcal{H}$. We consider the maps

$$F_j : \mathcal{H} \to \mathcal{H},\ \tau \mapsto \int_{a_j} \omega_j(\tau) \quad \text{for} \quad j = 1, 2.$$

Since the local systems $\mathbb{L}_j$ are strictly maximal Higgs both F_1 and F_2 are isometries.

Let R be the fibre of f over $i \in \mathcal{H}$. Since $\mathcal{H} \to T_g$ is the Teichmüller disc generated by ω_1 (say), Ahlfors' variational formula implies that

$$\left.\frac{dF_j}{dt}\right|_{t=i} = \int_R \omega_j(i) \frac{\overline{\omega_1(i)}}{\omega_1(i)}.$$

Hence the norm of dF_j at $\tau = i$ in the hyperbolic metric equals

$$||dF_j|| = \left| \int_R \omega_j(i) \frac{\overline{\omega_1(i)}}{\omega_1(i)} \right| \ / \, \mathrm{Im} F_j(i) = \left| \int_R \omega_j(i) \frac{\overline{\omega_1(i)}}{\omega_1(i)} \right| \ \ / \int_R |\omega_(i)|^2.$$

Since F_j is an isometry, this implies by the Schwarz Lemma that $||dF_j|| = 1$. Since ω_2 is not proportional to ω_1 this violates the Cauchy–Schwarz inequality. □

Sketch of the proof of Lemma 4.1. Since $\overline{\mathbb{L}}$ is also strictly maximal Higgs we have $\mathbb{L} \cong \overline{\mathbb{L}}$ by Corollary 0.13. It remains to check that $\mathbb{L}$ can indeed be defined over $\mathbb{R}$, see [Moe2], proof of Theorem 5.3, or repeat the argument used in the proof of Lemma 1.8. □

Proof of Theorem 0.12. We fix a fibre R of f and $\omega \in \Gamma(R, \Omega^1_R)$ that generates the Teichmüller curve. By its construction as $\mathrm{Sl}(2,\mathbb{R})$-orbit the fundamental group of U maps to a lattice Γ in $\mathrm{Sl}(2,\mathbb{R})$ and the subspace

$$\langle \mathrm{Re}\,\omega, \mathrm{Im}\,\omega \rangle \subset H^1(R,\mathbb{R})$$

is invariant under the action of the fundamental group. Let $\mathbb{L}$ be the corresponding irreducible rank two $\mathbb{C}$-local system. As in Lemma 1.8 one finds that $\mathbb{L}$ is defined over a number field, whose Galois closure we denote by $\tilde{K}$. Moreover we let K the number field generated by the traces of Γ. If we apply Deligne's semisimplicity (Lemma 1.5) to the polarized $\mathbb{C}$-variation of Hodge structures $R^1 f_* \mathbb{C}_V$ the local system $\mathbb{L}$ and all its Galois conjugates will appear. Moreover we may read the above argument of [VZ04] Lemma 2.1 backwards to conclude that $\mathbb{L}$ is strictly maximal Higgs. This proves 1.

By Corollary 0.13 the local system $R^1 f_* \mathbb{C}_V$ contains no other local subsystem isomorphic to $\mathbb{L}$. We claim that

$$R^1 f_* \mathbb{C}_V = \mathbb{W} \oplus \mathbb{M}, \quad \mathbb{W}_{\tilde{K}} = \bigoplus_{\sigma \in \mathrm{Gal}(\tilde{K}/\mathbb{Q})/\mathrm{Gal}(\tilde{K}/K)} \mathbb{L}^\sigma,$$

where the summands $\mathbb{W}$ and $\mathbb{M}$ are defined over $\mathbb{Q}$ and $\mathbb{L}^\sigma$ are pairwise non-isomorphic rank two local systems. The fact that L and L^σ are isomorphic if and only if σ fixes K is not needed here, but see the remark at the end of this section.

We now prove 2. The $\mathbb{Q}$-sub variation $\mathbb{W}$ determines, after choosing a $\mathbb{Z}$-lattice and fixing a polarization of type δ, a family of Abelian varieties $A \to U$ of dimension r. By [Fa83] the tangent space to the space of deformations of the moduli map $U \to A_{r,\delta}$ is a subspace of the global sections of the local system $\mathrm{End}(\mathbb{W}_{\mathbb{C}})$ of bidegree $(-1,1)$. Using above decomposition of $\mathbb{W}_{\mathbb{C}}$ into irreducible summands, one checks ([Moe2] Lemma 3.3) that this tangent space is trivial. Hence $U \to A_{r,\delta}$ is rigid and U is defined over a number field. □

The above way of characterizing Teichmüller curves inverts the history of these objects: The first examples, starting with Veech ([Ve89]), of Teichmüller curves were shown to have this property by checking that the stabilizer of $\mathcal{H} \hookrightarrow T_g$ is a lattice. Next, in [McM03], Teichmüller curves were constructed as the image in the moduli space M_2 of the intersection of two higher-dimensional $\mathrm{Sl}(2,\mathbb{R})$-invariant loci in the bundle of one-forms over M_2. Only recently ([BM05]) Theorem 0.12 was used to construct an infinite series of Teichmüller curves, including the examples of Veech.

We address once again the decomposition of the variation of Hodge structures of a Teichmüller curves. Obviously, if $\mathbb{L} \cong \mathbb{L}^\sigma$ then σ fixes the trace field.

The converse is needed in 5.1. We reproduce the full proof, since it is, besides Corollary 0.13, the only argument in this context that relies essentially on Teichmüller theory.

By Proposition 4.2, elements in the fundamental group of U may be represented by diffeomorphisms that are affine in the ω-charts. We want to show that if σ does not fix the trace field, then $\mathbb{L} \not\cong \mathbb{L}^\sigma$. Choose a hyperbolic element γ in the fundamental group whose trace $t = \mathrm{tr}\gamma$ is not fixed by σ. Lift γ to a diffeomorphism ϕ of some smooth fibre R of f. Let ϕ^* be the induced diffeomorphism of $H^1(R, \mathbb{R})$. The endomorphism $\phi^* + (\phi^*)^{-1}$ acts on $\mathbb{L}|_R$ by multiplication by $t = \mathrm{tr}\gamma$. We need to show that $\mathrm{Ker}(\phi^* + (\phi^*)^{-1} - t \cdot \mathrm{id})$ has dimension two. It suffices to show that the eigenvalues λ^+ (resp. λ^-) of ϕ^* of maximal (resp. minimal) absolute values are unique and that these are the eigenvalues of ϕ^* acting on $\mathbb{L}|_R$. This is shown in [McM03] Theorem 5.3:

The diffomorphism ϕ is not of finite order nor does it fix a closed loop in R. Hence ϕ is pseudo-Ansov ([FLP79]). For such a diffeomorphism there are two transverse measured foliations μ^+, μ^- on R, one is expanded by λ^+ and one is contracted by $\lambda^- = (\lambda^+)^{-1}$. These two foliations represent real cohomology classes in $\langle \mathrm{Re}\,\omega, \mathrm{Im}\,\omega \rangle = \mathbb{L}|_R$. It remains to show that λ^+ is simple and of largest absolute value. The corresponding statement for λ^- follows by considering ϕ^{-1}.

The cohomology $H^1(R, \mathbb{R})$ is spanned by $\mathbb{R}$-linear combinations of the Poincaré duals $C^\vee$ to simple closed curves. We know how φ acts on $C^\vee$: Since C is stretched in the direction of μ^+ and contracted in the direction of μ^-, we have for $n \to \infty$ that $(\lambda^+)^{-n}(\phi^*)^n C^\vee \to \alpha\mu^+$ for some $\alpha \in \mathbb{R}$. This proves the nonexistence of an eigenspace for ϕ^* in $H^1(R, \mathbb{R})$ with larger eigenvalue than λ^+ and the simplicity of λ^+.

5 The only Teichmüller-Shimura Curve

This section is a comparison between Teichmüller- and Shimura curves. Recall that in the proof of Theorem 0.12 we defined the family Abelian varieties $A \to U$ corresponding to the local system $\mathbb{W}$. It is determined up to isogeny by the Teichmüller curve and coincides with the Jacobian of the universal family over the Teichmüller curve in case $r = g$.

Theorem 5.1. *The family $A \to U$ has real multiplication by K. The locus of real multiplication is the smallest Shimura subvariety of A_r that contains the image of the moduli map $U \to A_r$.*

Proof. For each $a \in K$ the cycle

$$C_a := \bigoplus_{\mathrm{Gal}(\tilde{K}/\mathbb{Q})/\mathrm{Gal}(\tilde{K}/K)} \sigma(a) \cdot \mathrm{id}_{\mathbb{L}^\sigma} \in \mathrm{End}(\mathbb{W}_{\tilde{K}}) = H^0(U, \mathrm{End}(\mathbb{W}_{\tilde{K}}))$$

is defined over $\mathbb{Q}$ and of bidegree $(0, 0)$. It is hence an endomorphism of A/U ([De71] Remark 4.4.6). Since K is a trace field of a lattice in $\mathrm{Sl}(2, \mathbb{R})$ it is real.

By the classification of endomorphisms of Abelian varieties it is totally real. This proves the first claim.

For the second statement we have to show that the local systems $\mathbb{W}^{\otimes m} \otimes (\mathbb{W}^{\vee})^{\otimes m'}$ do not contain Hodge cycles other than products and tensor powers of the cycles C_a. This is shown in [Moe2] Lemma 3.3. The spirit of this Lemma is similar to the decomposition into Schur functors of exterior powers of the variation of Hodge structures over a Shimura curve in Section 3. The difference consists of an essential use of the uniqueness of the strictly maximal Higgs local system at some point. □

We now address the question of classifying non-compact Shimura curves that lie entirely inside M_g for $g \geq 2$. By Theorem 0.8 the variation of Hodge structures consists of unitary and strictly maximal Higgs local subsystems. By Corollary 0.14 the strictly maximal Higgs part splits off a rank two local subsystem. By Theorem 0.12 such a curve is automatically also a Teichmüller curve. We may now look at the decomposition of the variation of Hodge structures in the proof of Theorem 0.12. Since the Galois conjugate of a non-cocompact lattice in $\mathrm{Sl}(2,\mathbb{R})$ still contains non-trivial parabolic elements none of the local systems $\mathbb{L}^{\sigma}$ is unitary. By Theorem 0.8 again there is no $\mathbb{L}^{\sigma}$ for $\sigma \neq \mathrm{id}$. To sum up:

Lemma 5.2. *Suppose $U \to M_g$ is a non-compact Shimura curve. Then there is an unramified cover $U' \to U$ such that the pullback of the universal family over M_g to U' has a family of Jacobians $\mathrm{Jac(f)} : J \to U'$ with fixed part of dimension $g-1$, i.e. there is an Abelian variety A of dimension $g-1$ such that $A \times U'$ injects into J.*

Proof. The only thing left to remark is that the unitary parts in the variation of Hodge structures can be trivialized after an unramified cover $U' \to U$ (see Lemma 1.8). □

The possible dimensions d of a fixed part in a family of Jacobians of dimension g over a one-dimensional base have been studied by Xiao. He proves in [Xi87] that

$$d \leq \frac{5g+1}{6}.$$

This implies that a fixed part of dimension $g-1$ can only occur for $g \leq 7$. Families of curves of genus $g=2$, $g=3$ and $g-4$ with $g-1$-dimensional fixed part are known to exist, but for $g = 5, 6, 7$ existence is still an open question.

Theorem 0.15 may be considered as a non-existence statement for such families under the additional assumption 'Shimura curve'.

Sketch of the proof of Theorem 0.15, b. There are four main ingredients: First, the large fixed part limits the number of possible singular fibres the family $f : X \to Y$.

Second, the projection to $J \to J/A$ defines a covering $\pi : V \to E$ of a family of elliptic curves. By [Moe1] we may assume that $U = X(d)$ is a modular curve and $d = \deg(\pi)$.

Third, all invariants, in particular some intersection numbers, of the complex surface E (or rather its completion) are known. We factor $\pi = i \circ \pi_{\mathrm{opt}}$, where i is an isogeny and π_{opt} does not factor through a non-trivial isogeny. The knowledge of intersection number on V will then be used to bound the degree d_{opt} of π_{opt}.
Finally, the translation structure on a fibre R of f given by the one-form $\omega \in H^0(R, \Omega^1_R)$ that generates the Teichmüller curve is shown to have very special properties. In a case-by-case discussion depending on d_{opt} and the number of zeros of ω we show that these properties are absurd, except for the case of the Legendre family and the family

$$f_W : y^4 = x(x-1)(x-t)$$

over $X(2) \cong \mathbb{P}^1 \setminus \{0, 1, \infty\}$ with local coordinate t in genus three.

We now give more details on the first step. Let $P_1, \ldots, P_s \in R$ be the zeros of ω and let k_i ($i = 1, \ldots, s$) be the multiplicity of the zero. Since $U \to M_g$ is a Teichmüller curve, we may suppose by [GJ00] Theorem 5.5 that $\pi|_R$ is ramified over one point $O \in E_0 := |\pi(R)$ only. Equivalently, the translation structure determined by ω is such that $\pi|_{R \setminus \{P_1, \ldots, P_s\}}$ is a square-tiled covering (see e.g. loc. cit.). One can deduce from this that singular fibres of f do not contain separating nodes ([Moe3] Proposition 2.3) and, more precisely, that the dual graph of a singular fibre is a ring, say of length $\ell(y)$ for $y \in S = Y \setminus U$. (loc. cit. Lemma 2.1).

Concerning the second step, we recall that we constantly consider Teichmüller and Shimura curves up to unramified cover outside S, since this does not change the property 'strictly maximal Higgs'. We may hence replace U by $X(d)$ for $d \geq 3$ sufficiently large and post-compose π by an isogeny to maintain the property $d = \deg(\pi)$.

Concerning the third step, we remark that the genus of $X(d)$, the number of cusps and the self-intersection of the zero-section of E are well-known as functions of d. From the construction of a Teichmüller curve as $\mathrm{Sl}(2, \mathbb{R})$-orbit one deduces that the zeros P_i extend to sections $p_i : U \to V$ of f for $i = 1, \ldots, s$. We denote the closure of the image of p_i in X by $\overline{P_i}$. Since we assume X to be a minimal semistable model, we have

$$\omega_{X/Y} = \mathcal{O}_X \left(\sum \overline{P_i} + d\Delta_d \cdot R + D \right),$$

where R is a fibre of f, D is a divisor supported in the singular fibres of f and

$$\Delta_d = \frac{d^2}{24} \prod_{p|d} \left(1 - \frac{1}{d^2} \right).$$

Using the geometry of the singular fibres one checks ([Moe3] Lemma 3.13) that in fact $D = 0$. From the intersection numbers on E one deduces that on X we have

$$\overline{P_i} = -d\Delta_d/(k_i+1).$$

Since $\mathbb{L}$ satisfies the Arakelov equality and since the remaining local subsystems of $R^1 f_* \mathbb{C}$ are trivial, we have

$$\deg f_* \omega_{X/Y} = d\Delta_d.$$

We claim that for each of the singular fibres R_y for $y \in S$ of f we have

$$\Delta\chi_{\mathrm{top}}(R_y) := \chi_{\mathrm{top}}(R_y) - \chi_{\mathrm{top}}(R) = d/d_{\mathrm{opt}}.$$

Putting all these data in the Noether formula

$$12 \deg f_* \omega_{X/Y} - \sum_{y \in S} \Delta\chi_{\mathrm{top}}(R_y) = \omega^2_{X/Y}$$

we obtain

$$d_{\mathrm{opt}} = \frac{12}{\left(\sum_{i=1}^{s} \frac{k_1^2}{k_1+1}\right) + 16 - 4g}.$$

Since by definition $\sum_{i=1}^{s} k_i = 2g-2$ there is only a finite number of integer solution to this equation. We thus obtain the desired bound on d_{opt}.

To prove the claim, notice first that $\Delta\chi_{\mathrm{top}}(R_y)$ coincides with the number of nodes of the dual graph of R_y or equivalently with the local component group of the Néron model of the family of Jacobians around at y. The size of the component group at y is known to be d for the universal family of elliptic curves over $X(d)$. The details how to related the two groups are in [Moe3] Proposition 3.15.

The reader is referred to [Moe3] for details on the last step. □

We remark that the exceptional family f_W is generated by the degree 8 covering $\pi|_R$ of the once-punctured torus with Galois group the quaternion group. The differential ω is the pullback of a holomorphic differential on E_0. This covering $\pi|_R$ can also be obtained by a double covering of an elliptic curve ramified precisely over all four 2-torsion points post-composed by the multiplication by two.

the problem of completing the computation of the character of this K-cycle for discrete subgroups of higher rank Lie groups. The second example is the supersymmetric Wess-Zumino model of quantum field theory. We prove there the new unexpected result that, even for the free theory, the K-theory of the algebra $\mathcal{A}(\mathcal{O})$ of observables localized in an open subset $\mathcal{O}$ of space-time is very nontrivial, of infinite rank as an abelian group, and pairs nontrivially with the K-homology class given by the supercharge operator Q of the theory.

We have already explained that Chapter V is a detailed account of the theory of von Neumann algebras. In its last section we explain our joint work with J.-B. Bost, motivated by earlier work of B. Julia, on a natural system of quantum statistical mechanics related to the arithmetic of $\mathbb{Z}$ and the Riemann zeta function. We show that our system, formulated as a C^*-dynamical system, undergoes a phase transition with spontaneous symmetry breaking with symmetry group the Galois group of the field of roots of unity.

5. The metric aspect of noncommutative geometry

In the last chapter of this book we shall develop operator theoretic ideas about the metric aspect of geometry and then apply these ideas to a fundamental example: space-time.

Given a (not necessarily commutative) $*$-algebra $\mathcal{A}$ corresponding to the functions on a “space X”, our basic data in order to develop geometry on X is simply a K-cycle $(\mathcal{H}, D)$ over $\mathcal{A}$ in the above sense (cf. D). A first example is provided by ordinary Riemannian geometry. Given a Riemannian manifold (K-oriented for convenience) we let its algebra $\mathcal{A}$ of functions act by multiplication in the Hilbert space $\mathcal{H}$ of L^2 spinors on X, and we let D be the Dirac operator in $\mathcal{H}$. One thus obtains a K-cycle over $\mathcal{A}$ which represents the fundamental class of X in K-homology. We shall give (Section 1 of Chapter VI) four simple formulas showing how to recover, from the K-cycle $(\mathcal{H}, D)$ the following classical geometric notions on X:

1) The geodesic distance d on X

2) The integration against the volume form $\det(g_{\mu\nu})^{1/2}\ dx^1 \wedge \ldots \wedge dx^n$

3) The affine space of gauge potentials

4) The Yang-Mills action functional.

The essential fact is that all these notions will continue to make sense in our general framework, and in particular will apply nontrivially even to the case of finite spaces X.

The operator theoretic formula 1) for the geodesic distance is in essence the dual of the usual formula in terms of the length of paths γ in X. Recall that given two points p and q in a Riemannian manifold X, their geodesic distance $d(p, q)$ is given as the infimum of the lengths of paths γ from p to q. The latter length is computed by means of an integral along γ of the square root of $g_{\mu\nu}\, dx^\mu\, dx^\nu$. Our formula for the same quantity $d(p,q)$ is different in nature in that it is a supremum (instead of an infimum) and it invokes as a variable a *function* f on X instead of a path γ in X. It is the following:

$$d(p,q) = \mathrm{Sup}\,\{|f(p) - f(q)| \;;\; f \in \mathcal{A}\;,\; \|[D,f]\| \leq 1\}\,.$$

The norm involved in the right-hand side is the norm of operators in Hilbert space. Note also that the points p and q of X are used to convert the element f of $\mathcal{A}$ into a scalar, namely they are used, in conformity with Gelfand's theorem, as characters of the algebra $\mathcal{A}$.

There are two important features of this formula. The first is that since it does not invoke paths but functions it continues to be meaningful and gives a finite nonzero result when the space X is no longer arcwise connected. Indeed, one can take a space X with two points $a \neq b$: the algebra $\mathcal{A}$ of functions on X is then simply $\mathcal{A} = \mathbb{C}\oplus\mathbb{C}$, the direct sum of two copies of $\mathbb{C}$, and a natural K-cycle is given by the diagonal action of $\mathcal{A}$ in $\ell^2(X)$ with operator

$$D = \begin{bmatrix} 0 & \mu \\ \mu & 0 \end{bmatrix}$$

One then checks that with our formula the distance between a and b is given by $\ell = \mu^{-1}$.

An equally important feature of our formula is that, since it uses functions instead of paths, it is directly compatible with the formalism of quantum mechanics in which particles are described by wave functions rather than by any classical path.

The next step is to recover the tools of Riemannian geometry which go beyond the mere "metric space" attributes of such spaces such as 3) and 4). First, the volume form and the corresponding integral are recovered by the Dixmier trace, already mentioned in the discussion of Chapter IV. In fact the case already covered in Chapter IV of the Hausdorff measure on Julia sets in terms of the Dixmier trace was far more difficult. In Section 1 we shall develop the formalism of gauge theory (commutative or not, of course) and the Yang-Mills action functional from our operator theoretic data. The main mathematical result of Section 2 is the analogue of the basic inequality between the second Chern number of a Hermitian vector bundle and the minimum of the Yang-Mills functional on compatible connections on this bundle. This is proved in Section 2 using the main theorem of Chapter IV Section 2. In Section 3 we determine the Yang-Mills connections on the noncommutative torus, a joint result of M. Rieffel and myself, after defining the metric structure of that simple noncommutative space in great detail. As it turns out, even though the space we start with is non commutative, the moduli space of Yang-Mills connections is nicely behaved and finite-dimensional.

The end of the chapter (and the book) is occupied by the analysis, with the above new geometric tool, of the structure of space-time. The idea can be simply stated as follows:

It was originally through the Maxwell equations that, by the well-known steps due to Lorentz, Michelson, Morley, Poincaré and Einstein, the model of Minkowski's space-time was elaborated. In more modern terms the Maxwell-Dirac Lagrangian accounts perfectly for all phenomena involving only the electromagnetic interaction. However, a century has passed since then and essential discoveries, both experimental and theoretical, have shown that in order to account for weak and strong forces a number of modifications in the above Lagrangian were necessary. (See the small chronological table below for the early development of weak forces.)

Chronological table

- 1896 H. Becquerel discovers radioactivity
- 1898 M. Curie shows that radioactivity is an intrinsically atomic property
- 1901 E. Rutherford shows the inhomogeneity of uranic rays and isolates the β rays (i.e. the weak interaction part)
- 1902 W. Kaufman shows that the β rays are formed of electrons
- 1907-14 J. Chadwick shows that the spectrum of β rays is continuous
- 1930 W. Pauli introduces the neutrino to account for the above continuous spectrum
- 1932 W. Heisenberg introduces the concept of isospin (in the other context of strong forces)
- 1934 E. Fermi gives a phenomenological theory of weak interactions
- 1935 H. Yukawa introduces the idea of heavy bosons mediating short range forces.

Among the next steps which led finally to the Glashow-Weinberg-Salam Lagrangian of the standard model let us mention the discovery of the vector-axial form of the weak currents, and the intermediate boson hypothesis which replaces the 4-fermion interaction of the Fermi theory by a renormalizable interaction. This requires a considerable mass for the intermediate-boson in order to get a possible unification of the weak and electromagnetic forces using the ideas of nonabelian gauge theory of Yang and Mills. There was a major difficulty at this point since a nonabelian pure Yang-Mills field is necessarily massless. This difficulty was resolved by the theoretical discovery of the Higgs mechanism, allowing for the generation, by spontaneous symmetry breaking, of nontrivial masses for fermions and intermediate bosons. The Higgs field thus introduced appears in three of the five natural terms of the Lagrangian and completely spoils their geometric significance.

Now our idea is quite simple. We have at our disposal a more flexible notion of geometric space in which the continuum (i.e. manifolds say) and the discrete (cf. the two-point space example above) are treated on the same footing, and in which the Maxwell-Dirac Lagrangian does make sense: its bosonic part is the already treated

Yang-Mills action and the fermionic part is easy to get since we are given the Dirac operator to start with. Thus we can keep track of the above modifications of the Lagrangian as modifications of the geometry of space-time. In other words, we look for a geometry in our sense, i.e. a triple $(\mathcal{A}, \mathcal{H}, D)$ as above, such that the associated Maxwell-Dirac action functional produces the standard model of electroweak and strong interactions with all its refinements dictated by experimental results.

The result that we obtain is canonically derived from the standard model considered as a *phenomenological* model. What we find is a geometric space which is neither a continuum nor a discrete space but a mixture of both. This space is the product of the ordinary continuum by a discrete space with only two points, which, for reasons which will become clear later, we shall call L and R. The geometry, in our sense, of the finite space $\{L, R\}$ is given by a finite-dimensional Hilbert space representation $\mathcal{H}$ and a selfadjoint operator D in $\mathcal{H}$. These have direct physical meaning since the operator D is given by the Yukawa coupling matrix which encodes the masses of the elementary fermions as well as their mixing, i.e. the Kobayashi-Maskawa mixing parameters. Computing the distance between the two points L and R thus gives a number of the order of 10^{-16}cm, i.e. the inverse mass of the heaviest fermion.

The naive picture that emerges is that of a double space-time, i.e. the product of ordinary space-time by a very tiny discrete two-point space. By construction, purely left-handed particles such as neutrinos live on the left-handed copy X_L while electrons involve both X_L and X_R in $X = X_L \cup X_R$. Note that each point p of X_L is extremely close to a corresponding point p' of X_R, and when computing the differential of a function f on $X = X_L \cup X_R$ we shall find that it invokes not only the ordinary differential of f on X_L or on X_R but also the finite difference $f(p) - f(p')$ of the values of f on corresponding points of X_L and X_R. It is this finite difference, occurring as a new "transverse" component of the gauge potential, which yields the famous Higgs fields which appear in the three non-geometric terms of the standard model Lagrangian (cf. Chapter VI) $\mathcal{L} = \mathcal{L}_G + \mathcal{L}_f + \mathcal{L}_\varphi + \mathcal{L}_Y + \mathcal{L}_V$.

Note that there is no symmetry whatsoever between the points L and R, and in fact the natural vector bundle used over that space has fiber $\mathbb{C}^2$ over L and $\mathbb{C}$ over R. All this works very well for the electroweak sector of the standard model, but in order to account for the (already essentially geometric) strong structure much more work was necessary. It has been done in collaboration with J. Lott and is described in the last two Sections 4 and 5. It hinges on the fundamental problem of defining correctly what is a "manifold" in the setup of noncommutative geometry. Our proposed answer, which is essentially dictated by the $SU(2)\times SU(3)$ structure of up-down quark iso-doublets, is given by Poincaré duality discussed in Section 4. It fits remarkably well with the work of Sullivan on the fundamental role of Poincaré duality in K-homology for ordinary manifolds (cf. Section 4).

In Section 5 we discuss the full standard model, and also account for the hypercharge assignment of particles from a general unimodularity condition. One should understand this work as pure phenomenology, at the classical level, interpreting the detailed structure of the best phenomenological model, as the *fine structure* of space-time rather than as a long list of new particles. Applications of this point of view in quantum field theory, say as a model building device, are still ahead of us.

CHAPTER 6

The metric aspect of noncommutative geometry

The geometric spaces of Gauss and Riemann are defined as manifolds in which the metric is given by the formula

$$\delta(p,q) = \text{ infimum of length of paths } \gamma \text{ from } p \text{ to } q \tag{6.1}$$

where the length of a path γ is computed as the integral of the square root of a quadratic form in the differential of the path

$$\text{Length of } \gamma = \int_p^q (g_{\mu\nu}\, dx^\mu \ \ dx^\nu)^{1/2} \tag{6.2}$$

These geometric spaces form a relevant class of metric spaces, inasmuch as:

α) They are general enough to include numerous examples ranging from non-Euclidean geometries through surfaces embedded in $\mathbb{R}^3$ to space like hypersurfaces in general relativity.

β) They are special enough to deserve the name "geometry", since, being determined by local data, all the tools of differential and integral calculus are available to analyse them.

We have developed in Chapter IV a differential and integral calculus of "infinitesimals", given a Fredholm module $(\mathcal{H}, F)$ over the algebra $\mathcal{A}$ of coordinates on a possibly noncommutative space X. The Fredholm module $(\mathcal{H}, F)$ over $\mathcal{A}$ specifies the calculus on X but not the metric structure. For instance, the construction of $(\mathcal{H}, F)$ in the manifold

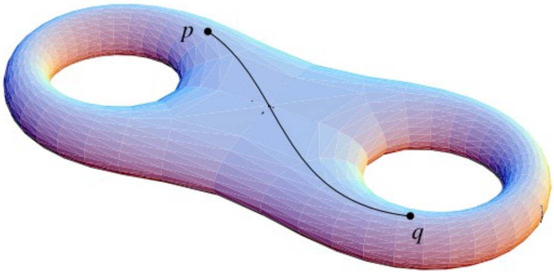

FIGURE 1. Geodesic

case (Section IV.4) only used the conformal structure. In fact, in the example of Section IV.3, where $X = \mathbb{S}^1$ and $(\mathcal{H}, F)$ is the Hilbert transform, the quantum differential expression

$$\mathrm{d}Z \; \mathrm{d}\overline{Z} = [F, Z][F, \overline{Z}] \quad , \quad Z : \mathbb{S}^1 \to \mathbb{C} \tag{6.3}$$

where Z is the boundary value of a univalent map, yields an infinitesimal unit of length intimately tied up with the metric on $Z(\mathbb{S}^1)$ induced by the usual Riemannian metric $\mathrm{d}z\mathrm{d}\overline{z}$ of $\mathbb{C}$. If we vary Z, even the *dimension* of $\mathbb{S}^1$ for the "metric" (3) will change (cf. Section IV.3).

Let $\mathcal{A}$ be an involutive algebra and $(\mathcal{H}, F)$ a Fredholm module over $\mathcal{A}$. To define a "unit of length" in the corresponding space X, we shall consider an operator of the form

$$G = \sum_{1}^{q} (\mathrm{d}x^\mu)^* \; g_{\mu\nu} (\mathrm{d}x^\nu) \tag{6.4}$$

where $\mathrm{d}x = [F, x]$ for any $x \in \mathcal{A}$, the x^μ are elements of $\mathcal{A}$ and where $g = (g_{\mu\nu})_{\mu,\nu=1,\ldots,q}$ is a positive element of the matrix algebra $M_q(\mathcal{A})$.

We want to think of G as the $\mathrm{d}s^2$ of Riemannian geometry. It is by construction a positive "infinitesimal", i.e. a positive compact operator on $\mathcal{H}$. The unit of length is its positive square root

$$\mathrm{d}s = G^{1/2}. \tag{6.5}$$

To measure distances in the possibly noncommutative space X we first replace the points $p, q \in X$ by the corresponding pure states φ, ψ on the C^*-algebra closure of $\mathcal{A}$

$$\varphi(f) = f(p) \; , \; \psi(f) = f(q) \quad \forall f \in \mathcal{A}. \tag{6.6}$$

We then dualise the basic formula (1) as follows

$$\mathrm{dist}(p, q) = \mathrm{Sup}\,\{|f(p) - f(q)| \; ; \; f \in \mathcal{A} \; , \; \|\mathrm{d}f/\mathrm{d}s\| \leq 1\} \tag{6.7}$$

which only involves p, q through the associated pure states (6). Since we are in the noncommutative set up we need to deal with the ambiguity in the order of the terms in an expression such as $\mathrm{d}f/\mathrm{d}s$ which can be either $\mathrm{d}f(\mathrm{d}s)^{-1}$ or $(\mathrm{d}s)^{-1}\,\mathrm{d}f$ or $(\mathrm{d}s)^{-\alpha}\,\mathrm{d}f(\mathrm{d}s)^{-(1-\alpha)}$ for instance. Instead of handling this problem directly we shall assume that G commutes with F, i.e. that $\mathrm{d}G = 0$, a condition similar to the Kähler condition, and introduce the following selfadjoint operator

$$D = FG^{-1/2} = F\;\mathrm{d}s^{-1}, \tag{6.8}$$

whose existence assumes that G is nonsingular, i.e. $\ker G = 0$. We shall then formulate (7) as follows

$$\mathrm{d}(p, q) = \mathrm{Sup}\,\{|f(p) - f(q)| \; ; \; f \in \mathcal{A} \; , \; \|[D, f]\| \leq 1\}\,. \tag{6.9}$$

Now the operator F is by construction the sign of D, while G is obtained from D by the formula

$$G = D^{-2}. \tag{6.10}$$

Thus it is more economical to take as our basic data the triple $(\mathcal{A}, \mathcal{H}, D)$ consisting of a Hilbert space $\mathcal{H}$, an involutive algebra $\mathcal{A}$ of operators on $\mathcal{H}$ and an unbounded selfadjoint operator D on $\mathcal{H}$. The conditions satisfied by such triples are

$$\begin{gathered}[D, a] \text{is bounded for any} a \in \mathcal{A} \\ (D-\lambda)^{-1} \text{is compact for any} \lambda \notin \mathbb{R}\end{gathered} \tag{6.11}$$

and were already formalised in Chapter IV Definition 2.11. In the present chapter we shall begin a systematic investigation of those geometric spaces. Besides Riemannian manifolds (see below) and spaces of non integral Hausdorff dimension (Section IV.3) the following are examples of geometric spaces described by our data:

a) Discrete spaces
b) Duals of discrete subgroups of Lie groups
c) Configuration space in supersymmetric quantum field theory.

We shall deal with Example a in Section 3 below. We have described already in great detail the triples $(\mathcal{A}, \mathcal{H}, D)$ corresponding to b) and c) in Section IV.9.

Our first task in this chapter will be to show that the Riemannian spaces are special cases of the above notion of geometric spaces. This will be done using an elliptic differential operator of order one, the Dirac operator (or the signature operator in the non-spin case). We shall first see that formula (9) applied to the triple (algebra of functions, Hilbert space of spinors, Dirac operator) readily gives back the geodesic distance (1) on the Riemannian manifold. Our next task will be to develop the analogue of the Lagrangian formulation of electrodynamics involving matter fields and gauge bosons for our more general geometric spaces. This will be done using the tools of the quantized calculus developed in Chapter IV Section 2. As mentioned above the commutator $[D, f]$, $f \in \mathcal{A}$ will play the role of the differential quotient $\mathrm{d}f/\mathrm{d}s$. As a central result we shall prove the inequality between the second Chern number of a "vector bundle" and the minimum of the Yang-Mills action on vector potentials. We shall see that our new notion of geometric space treats on an equal footing the continuum and the discrete, while the action for electrodynamics on the simplest mixture of continuum and discrete–the product of 4-dimensional continuum by a discrete 2-point space–gives the Glashow-Weinberg-Salam model for leptons. The notion of manifold in noncommutative geometry will be reached only after an understanding of Poincaré duality, i.e., that the K-homology cycle $(\mathfrak{H}, D)$ yields the fundamental class of the space under consideration. The notion of manifold obtained is directly inspired by the work of D. Sullivan [**543**] who discovered the basic role played by the K-homology fundamental class of a manifold.

The main example of a space to which all these considerations will be applied is Euclidean space-time in physics, i.e., space-time but with imaginary time. What we shall give is a geometric interpretation of the now experimentally confirmed effective low-energy model of particle physics, namely the Glashow–Weinberg–Salam standard model. This model is a gauge theory model with gauge group $U(1) \times SU(2) \times SU(3)$ and a pair of complex Higgs fields providing masses by the symmetry-breaking mechanism. We interpret this model geometrically as a pure gauge theory, i.e. electrodynamics, but on a more elaborate space-time $E' = E \times F$, the product of ordinary Euclidean space-time by a finite space F. The geometry of this finite space is specified by a pair $(\mathfrak{H}, D)$ as above, where $\mathfrak{H}$ is finite-dimensional and the selfadjoint operator D encodes the nine fermion masses and the four Kobayashi–Maskawa mixing parameters of the standard model.

The values of the hypercharges do not have to be fitted artificially to their experimental values but come out right from a simple unimodularity condition on the space E'.

Our analysis is limited to the classical context and does not at the moment address the questions related to renormalization, such as the existence of relations between coupling constants or the naturalness problem. Nevertheless, our more geometric and conceptual interpretation of the standard model gives a clear indication that particle physics is not so much a long list of elementary particles as the unveiling of the fine geometric structure of space-time.

The content of this Chapter Is organized as follows:

1. Riemannian geometry and the Dirac operator.
2. Positivity in Hochschild cohomology and inequalities for the Yang Mills action.
3. Product of continuum by discrete and the symmetry breaking mechanism.
4. The commutant and Poincaré duality.
5. The standard $U(1) \times SU(2) \times SU(3)$ model.

1. Riemannian Manifolds and the Dirac Operator

Let M be a compact Riemannian spin manifold, and let $D = \partial_M$ be the corresponding Dirac operator (cf. [**227**]). Thus, D is an unbounded selfadjoint operator acting in the Hilbert space $\mathfrak{H}$ of L^2-spinors on the manifold M.

We shall give four formulas below that show how to reconstruct the *metric space* (M, d), where d is the geodesic distance, the *volume measure* $\mathrm{d}v$ on M, the space of *gauge potentials*, and, finally, the *Yang–Mills* action functional, from the purely operator-theoretic data

$$(\mathcal{A}, \mathfrak{H}, D),$$

where D is the Dirac operator on the Hilbert space $\mathfrak{H}$ and where $\mathcal{A}$ is the abelian von Neumann algebra of multiplication by bounded measurable functions on M.

Thus, $\mathcal{A}$ is an abelian von Neumann algebra on $\mathfrak{H}$, and knowing the pair $(\mathfrak{H}, \mathcal{A})$ yields essentially no information (cf. Chapter V) except for the multiplicity, which is here the constant $2^{[d/2]}$, where $d = \dim M$. Similarly, the mere knowledge of the operator D on $\mathfrak{H}$ is equivalent to giving its list of eigenvalues $(\lambda_n)_{n\in\mathbb{N}}$, $\lambda_n \in \mathbb{R}$, and is an impractical point of departure for reconstructing M. The growth of these eigenvalues, i.e., the behavior of $|\lambda_n|$ as $n \to \infty$, is again governed by the dimension d of M, namely, $|\lambda_n| \sim Cn^{1/d}$ as $n \to \infty$.

What is relevant is the triple $(\mathcal{A}, \mathfrak{H}, D)$. Elements of $\mathcal{A}$ other than the constants do not commute with D, and the *boundedness* of the commutator $[D, a]$ already implies the following regularity condition on a measurable function a:

Lemma 1. *If a is a bounded measurable function on M then the densely defined operator $[D, a]$ is bounded if and only if a is almost everywhere equal to a Lipschitz function f, $|f(p) - f(q)| \leq Cd(p, q)$ $(\forall p, q \in M)$.*

Here, d is the geodesic distance in M. The operator $[D, a]$ should be viewed in effect as a quadratic form

$$\xi, \eta \mapsto \langle a\xi, D\eta\rangle - \langle D\xi, a^*\eta\rangle,$$

which is well-defined for ξ and η in the domain of D; its boundedness means an inequality

$$|\langle a\xi, D\eta\rangle - \langle D\xi, a^*\eta\rangle| \leq c\|\xi\|\|\eta\| \ \forall \xi, \eta \in \operatorname{dom} D.$$

The proof of the lemma follows immediately from results in [**202**].

Now, every Lipschitz function on M is continuous and the algebra of Lipschitz functions is norm-dense in the algebra of continuous functions on M; it follows that the C^*-algebra $C(M)$ of continuous functions on M is identical to the *norm closure* A in $\mathcal{L}(\mathfrak{H})$ of

By Gel'fand's theorem (Chapter II), we recover the compact topological space M as the spectrum of A. Thus, a point p of M is a $*$-homomorphism $\rho : A \to \mathbb{C}$,

$$\rho(ab) = \rho(a)\rho(b) \ \forall a, b \in A.$$

Any such homomorphism ρ is given by evaluation of a at p for some point $p \in M$,

$$\rho(a) = a(p) \in \mathbb{C}.$$

All of this is still qualitative; we now come to the first interesting formula, giving us a natural distance function, which turns out in this case to be the geodesic distance

Formula 1. *For any pair of points $p, q \in M$, their geodesic distance is given by the formula*

$$d(p, q) = \sup\{|a(p) - a(q)|;\ a \in \mathcal{A},\ \|[D, a]\| \leq 1\}.$$

The proof is straightforward, but it is relevant to go through it to see what is involved. The operator $[D, a]$, which by Lemma 1 is bounded iff a is Lipschitz, is then given by the Clifford multiplication $i^{-1}\gamma(\mathrm{d}a)$ by the gradient $\mathrm{d}a$ of a. This gradient is ([**202**]) a bounded measurable section of the cotangent bundle T^*M of M, and we have

$$\|[D, a]\| = \operatorname{ess\,sup} \|\mathrm{d}a\| = \text{the Lipschitz norm of } a.$$

It follows at once that the right-hand side of Formula 1 is less than or equal to the geodesic distance $d(p, q)$. However, fixing the point p and considering the function $a(q) = d(q, p)$, one checks that a is Lipschitz with constant 1, so that $\|[D, a]\| \leq 1$, which yields the desired equality. Note that Formula 1 is in essence dual to the original formula

$$(*) \qquad d(p, q) = \text{infimum of the length of paths } \gamma \text{ from } p \text{ to } q,$$

in the sense that, instead of involving arcs, namely copies of $\mathbb{R}$ inside the manifold M, it involves *functions* a, that is, maps from M to $\mathbb{R}$ (or to $\mathbb{C}$).

This is an essential point for us since, in the case of discrete spaces or of noncommutative spaces X, there are no interesting arcs in X but there are plenty of *functions*, namely, the elements $a \in \mathcal{A}$ of the defining algebra. We note at once that the right-hand side of Formula 1 is meaningful in that general context and it defines a metric on the space of *states* of the C^*-algebra A, the norm closure of $\mathbf{A} = \{a \in \mathcal{A};\ [D, a] \text{ is bounded}\}$

$$d(\varphi, \psi) = \sup\{|\varphi(a) - \psi(a)|;\ \|[D, a]\| \leq 1\}.$$

Finally, we also note that, although both Formula 1 and the formula $(*)$ give the same result for Riemannian manifolds, they are of quite different nature if we try to use them in actual measurements of distances. The formula $(*)$ uses the idealized notion of a path, and quantum mechanics teaches us that there is nothing like "the path followed by a particle". Thus, for measurements of very small distances, it is more natural to use wave functions and Formula 1.

We have now recovered from our original data $(\mathcal{A}, \mathfrak{H}, D)$ the metric space (M, d), where d is the geodesic distance. Let us now deal with the tools of differential and integral calculus, the first obvious example being the measure given by the volume form

$$f \mapsto \int_M f \mathrm{d}v,$$

where, in local coordinates $x^\mu, g_{\mu\nu}$, we have

$$\mathrm{d}v = \big(\det(g_{\mu\nu})\big)^{1/2} |\mathrm{d}x^1 \wedge \cdots \wedge \mathrm{d}x^n|.$$

This takes us to our second formula, which is nothing more than a restatement of H. Weyl's theorem about the asymptotic behavior of elliptic differential operators

([**247**], [**227**]). It does, however, involve a new tool, *the Dixmier trace* Tr_ω (cf. Chapter IV.2), which, unlike asymptotic expansions, makes sense in full generality in our context and is the correct operator-theoretic substitute for integration:

Formula 2. *For every* $f \in A$, *we have* $\int_M f \mathrm{d}v = c(d)\ \mathrm{Tr}_\omega(f|D|^{-d})$, *where* $d = \dim M$, $c(d) = 2^{(d-[d/2])}\ \pi^{d/2}\ \Gamma\left(\frac{d}{2}+1\right)$.

By convention we let D^{-1} be equal to 0 on the finite-dimensional subspace Ker$D$.

Let us refer to Section IV.2 for the detailed definition and properties of the Dixmier trace Tr_ω. We can interpret the right-hand side of the equality as the limit of the sequence

$$\frac{1}{\log N}\sum_{j=0}^{N}\lambda_j,$$

where the λ_j are the eigenvalues of the compact operator $f|D|^{-d}$, or, equivalently, as the residue, at the point $s = 1$, of the function

$$\zeta(s) = \mathrm{Trace}(f|D|^{-ds})\ (\Re s > 1).$$

The crucial fact for us is that the Dixmier trace makes sense independently of the context of pseudodifferential operators and that all properties of the integral $\int_M f \mathrm{d}v$, such as positivity, finiteness, covariance, etc., become obvious corollaries of the general properties of the Dixmier trace:

A) *Positivity*: $\mathrm{Tr}_\omega(T) \geq 0$ if T is a positive operator.
B) *Finiteness*: $\mathrm{Tr}_\omega(T) < \infty$ if the eigenvalues of $|T|$ satisfy $\sum_0^N \mu_n(T) = O(\log N)$.
C) *Covariance*: $\mathrm{Tr}_\omega(UTU^*) = \mathrm{Tr}_\omega(T)$ for every unitary U.
D) *Vanishing*: $\mathrm{Tr}_\omega(T) = 0$ if T is of trace class.

Property D is the counterpart of locality in our framework; it shows that the Dixmier trace of an operator is unaffected by a finite-rank perturbation, and allows many identities to hold, as we have seen in Chapter IV.

Now, setting up the integral of functions, i.e., the Riemannian volume form, is a good indication but quite far from the full story. In particular, many distinct Riemannian metrics yield the same volume form. Since our aim is to investigate physical spacetime at the scale of elementary particle physics, we shall now make a deliberate choice: instead of focusing on the intrinsic Riemannian curvature, which would drive us towards general relativity, we shall concentrate on the measurement (using $(\mathfrak{H}, D)$) of the curvature of connections on vector bundles, and on the Yang–Mills functional, which takes us to the theory of matter fields. This line is of course easier since it does not involve derivatives of the $g_{\mu\nu}$.

Let us state our aim clearly: to recover the Yang–Mills functional on connections on vector bundles, making use of only the following data (IV.2.11):

Definition 2. *A* K-cycle $(\mathfrak{H}, D)$, *over an algebra* $\mathcal{A}$ *with involution* $*$, *consists of a* $*$-*representation of* $\mathcal{A}$ *on a Hilbert space* $\mathfrak{H}$ *together with an unbounded selfadjoint operator* D *with compact resolvent, such that* $[D, a]$ *is bounded for every* $a \in \mathcal{A}$.

We shall assume that $\mathcal{A}$ is unital and that the unit $1 \in \mathcal{A}$ acts as the identity on $\mathfrak{H}$ (cf. Remark 12 for the nonunital case).

If the eigenvalues λ_n of $|D|$ are of the order of $n^{1/d}$ as $n \to \infty$, we say that the K-cycle is (d, ∞)-summable (cf. Section 2 of Chapter IV). On the algebra of functions on a compact Riemannian spin manifold, the Dirac operator determines a K-cycle that is (d, ∞)-summable, where $d = \dim M$. Finer regularity of functions, such as infinite differentiability, is easily expressed using the domains of powers of the derivation δ, $\delta(a) = [|D|, a]$.

We shall not be too specific about the choice of regularity; our discussion applies to any degree of regularity higher than Lipschitz.

The value of the following construction is that it will also apply when the $*$-algebra $\mathcal{A}$ is noncommutative, or when D is no longer the Dirac operator (cf. Section 3). The reader can have in mind both the Riemannian case and the slightly more involved case where the algebra $\mathcal{A}$ is the $*$-algebra of matrices of functions on a Riemannian manifold, just to bear in mind that the notion of exterior product no longer makes sense over such an algebra.

We shall begin with the notion of connection on the trivial bundle, i.e., the case of "electrodynamics", and define vector potentials and the Yang–Mills action in that case. We shall then treat the general case of arbitrary Hermitian bundles, i.e., in algebraic terms, of arbitrary Hermitian, finitely generated projective modules over $\mathcal{A}$.

We wish to define k-forms over $\mathcal{A}$ as operators on $\mathfrak{H}$ of the form

$$\omega = \sum a_0^j [D, a_1^j] \cdots [D, a_k^j],$$

where the a_i^j are elements of $\mathcal{A}$ represented as operators on $\mathfrak{H}$. This idea arises because, although the operator D fails to be invariant under the representation on $\mathfrak{H}$ of the unitary group $\mathcal{U}$ of $\mathcal{A}$,

$$\mathcal{U} = \{u \in \mathcal{A};\ u^* u = u u^* = 1\},$$

the following equality shows that the failure of invariance is governed by a 1-form in the above sense: by $\omega_u = u[D, u^*]$, that is,

$$u D u^* = D + \omega_u.$$

Note that ω_u is selfadjoint as an operator on $\mathfrak{H}$. Thus, it is natural to adopt the following definition:

Definition 3. *A* vector potential V *is a selfadjoint element of the space of* 1-*forms* $\sum a_0^j [D, a_1^j]$, *where* $a_k^j \in \mathcal{A}$.

One can immediately check that in the basic example of the Dirac operator on a spin Riemannian manifold, a vector potential in the above sense is exactly a 1-form ω on the manifold M and that this form is imaginary, the corresponding operator in the space of spinors being given by the Clifford multiplication:

$$V = i^{-1}\gamma(\omega) \ (i = \sqrt{-1}).$$

The action of the unitary group $\mathcal{U}$ on vector potentials is such that it replaces the operator $D + V$ by $u(D + V)u^*$; thus it is given by the algebraic formula

$$\gamma_u(V) = u[D, u^*] + uVu^* \ (u \in \mathcal{U}).$$

We now need only define the curvature or field strength θ for a vector potential, and use the analogue of the above Formula 2 to integrate the square of θ: the formula

$$\mathrm{YM}\,(V) = \mathrm{Tr}_\omega(\theta^2|D|^{-d})$$

should give us the Yang–Mills action.

The formula for θ should be of the form $\theta = \mathrm{d}V + V^2$; the only difficulty is in defining properly the "differential" $\mathrm{d}V$ of a vector potential, as an operator on $\mathfrak{H}$.

Let us examine what happens; the naive formulation is

$$\text{If } V = \sum a_0^j[D, a_1^j] \text{ then } \mathrm{d}V = \sum [D, a_0^j][D, a_1^j].$$

Before we point out what the difficulty is, let us check that if we replace V by $\gamma_u(V)$, where

$$\gamma_u(V) = u[D, u^*] + \sum u a_0^j[D, a_1^j]u^*,$$

then the curvature is transformed covariantly:

$$\mathrm{d}(\gamma_u(V)) + \gamma_u(V)^2 = u(\mathrm{d}V + V^2)u^*.$$

As this computation is instructive, we shall carry it out in detail. First, in order to write $\gamma_u(V)$ in the same form as V, we use the equality

$$[D, a_1^j]u^* = [D, a_1^j u^*] - a_1^j[D, u^*].$$

Thus, $\gamma_u(V) = u[D, u^*] + \sum u a_0^j[D, a_1^j u^*] - \sum u a_0^j a_1^j[D, u^*]$, and we have

$$\mathrm{d}\gamma_u(V) = [D, u][D, u^*] + \sum [D, u a_0^j][D, a_1^j u^*] - \sum [D, u a_0^j a_1^j][D, u^*].$$

We now claim that the following operators on $\mathfrak{H}$ are indeed equal:

$$\mathrm{d}\gamma_u(V) + \gamma_u(V)^2 = u(\mathrm{d}V + V^2)u^*.$$

We start with the left-hand side; it is equal to

$$\begin{aligned} & \mathrm{d}\gamma_u(V) + (u[D,u^*] + uVu^*)^2 \\ = \; & \mathrm{d}\gamma_u(V) + u[D,u^*]u[D,u^*] + u[D,u^*]uVu^* \\ & + uVu^*u[D,u^*] + uV^2u^* \\ = \; & \mathrm{d}\gamma_u(V) - [D,u][D,u^*] - [D,u]Vu^* + uV[D,u^*] + uV^2u^* \\ = \; & \sum [D, ua_0^j][D, a_1^j u^*] - \sum [D, ua_0^j a_1^j][D,u^*] \\ & - [D,u]Vu^* + uV[D,u^*] + uV^2u^* \\ = \; & u\mathrm{d}Vu^* + uV^2u^*, \end{aligned}$$

where the last equality follows from

$$\begin{aligned} & \sum [D,u]a_0^j[D,a_1^j u^*] - \sum [D,u]a_0^j a_1^j[D,u^*] = [D,u]Vu^*, \\ & \sum u[D,a_0^j][D,a_1^j u^*] - \sum u[D,a_0^j]a_1^j[D,u^*] = u\mathrm{d}Vu^*, \\ & \sum ua_0^j[D,a_1^j][D,u^*] = uV[D,u^*]. \end{aligned}$$

The difficulty that we overlooked is the following: the same vector potential V might be written in several ways as $V = \sum a_0^j[D,a_1^j]$, so that the definition of $\mathrm{d}V$ as

$$\mathrm{d}V = \sum [D,a_0^j][D,a_1^j]$$

is ambiguous.

To understand the nature of the problem, let us introduce some algebraic notation. We let $\Omega^*\mathcal{A}$ be the reduced universal differential graded algebra over $\mathcal{A}$ (Chapter III.1). It is by definition equal to $\mathcal{A}$ in degree 0 and is generated by symbols $\mathrm{d}a$ ($a \in \mathcal{A}$) of degree 1 with the following presentation:

α) $\mathrm{d}(ab) = (\mathrm{d}a)b + a\mathrm{d}b$ ($\forall a, b \in \mathcal{A}$),
β) $\mathrm{d}1 = 0$.

One can check that $\Omega^1\mathcal{A}$ is isomorphic as an $\mathcal{A}$-bimodule to the kernel $\ker(m)$ of the multiplication mapping $m : \mathcal{A} \otimes \mathcal{A} \to \mathcal{A}$, the isomorphism being given by the mapping

$$\sum a_i \otimes b_i \in \ker(m) \mapsto \sum a_i \mathrm{d}b_i \in \Omega^1\mathcal{A}.$$

The involution $*$ of $\mathcal{A}$ extends uniquely to an involution on Ω^* with the rule

$$(\mathrm{d}a)^* = -\mathrm{d}a^*.$$

The differential d on $\Omega^*\mathcal{A}$ is defined *unambiguously* by

$$\mathrm{d}(a^0\mathrm{d}a^1 \cdots \mathrm{d}a^n) = \mathrm{d}a^0\mathrm{d}a^1 \cdots \mathrm{d}a^n \;\forall a^j \in \mathcal{A},$$

and it satisfies the relations

$\mathrm{d}^2\omega = 0 \ \forall \omega \in \Omega^*\mathcal{A}$,
$\mathrm{d}(\omega_1\omega_2) = (\mathrm{d}\omega_1)\omega_2 + (-1)^{\partial\omega_1}\omega_1\mathrm{d}\omega_2 \ \forall \omega_j \in \Omega^*\mathcal{A}$.

Proposition 4.

1) *The following equality defines a $*$-representation π of the reduced universal algebra $\Omega^*(\mathcal{A})$ on $\mathfrak{H}$:*
$$\pi(a^0\mathrm{d}a^1\cdots\mathrm{d}a^n) = a^0[D,a^1]\cdots[D,a^n] \ \forall a^j \in \mathcal{A}.$$
2) *Let $J_0 = \ker\pi \subset \Omega^*$ be the graded two-sided ideal of Ω^* given by $J_0^{(k)} = \{\omega \in \Omega^k;\ \pi(\omega) = 0\}$; then $J = J_0 + \mathrm{d}J_0$ is a graded differential two-sided ideal of $\Omega^*(\mathcal{A})$.*

The first statement is obvious; let us discuss the second. By construction, J_0 is a two-sided ideal but it is not, in general, a *differential* ideal, i.e., if $\omega \in \Omega^k(\mathcal{A})$ and $\pi(\omega) = 0$, one does not in general have $\pi(\mathrm{d}\omega) = 0$. This is exactly the reason why the above definition of $\sum[D,a_0^j][D,a_1^j]$ as the differential of $\sum a_0^j[D,a_1^j]$ was ambiguous.

Let us show, however, that $J = J_0 + \mathrm{d}J_0$ is still a two-sided ideal. Since $\mathrm{d}^2 = 0$ it is obvious that J is then a differential ideal. Let $\omega \in J^{(k)}$ be a homogeneous element of J; then ω is of the form $\omega = \omega_1 + \mathrm{d}\omega_2$, where $\omega_1 \in J_0 \cap \Omega^k$, $\omega_2 \in J_0 \cap \Omega^{k-1}$. Let $\omega' \in \Omega^{k'}$, and let us show that $\omega\omega' \in J^{(k+k')}$. We have
$$\begin{aligned} \omega\omega' &= \omega_1\omega' + (\mathrm{d}\omega_2)\omega' = \omega_1\omega' + \mathrm{d}(\omega_2\omega') - (-1)^{k-1}\omega_2\mathrm{d}\omega' \\ &= \big(\omega_1\omega' + (-1)^k\omega_2\mathrm{d}\omega'\big) + \mathrm{d}(\omega_2\omega'). \end{aligned}$$
But, the first term belongs to $J_0 \cap \Omega^{k+k'}$ and $\omega_2\omega' \in J_0 \cap \Omega^{k+k'-1}$.

Using 2) of Proposition 4, we can now introduce the graded differential algebra
$$\Omega_D^* = \Omega^*(\mathcal{A})/J.$$
Let us first investigate Ω_D^0, Ω_D^1 and Ω_D^2.

We have $J \cap \Omega^0 = J_0 \cap \Omega^0 = \{0\}$ provided that we assume, as we shall, that $\mathcal{A}$ is a *subalgebra* of $\mathcal{L}(\mathfrak{H})$. Thus, $\Omega_D^0 = \mathcal{A}$.

Next, $J \cap \Omega^1 = J_0 \cap \Omega^1 + \mathrm{d}(J_0 \cap \Omega^0) = J_0 \cap \Omega^1$; thus Ω_D^1 is the quotient of Ω^1 by the kernel of π, and it is thus exactly the $\mathcal{A}$-bimodule $\pi(\Omega^1)$ of operators ω of the form
$$\omega = \sum a_j^0[D,a_j^1] \ (a_j^k \in \mathcal{A}).$$
Finally, $J \cap \Omega^2 = J_0 \cap \Omega^2 + \mathrm{d}(J_0 \cap \Omega^1)$ and the representation π gives an isomorphism
$$(*) \qquad \Omega_D^2 \cong \pi(\Omega^2)/\pi\big(\mathrm{d}(J_0 \cap \Omega^1)\big).$$
More precisely, this means that we can view an element ω of Ω_D^2 as a class of elements ρ of the form
$$\rho = \sum a_j^0[D,a_j^1][D,a_j^2] \ (a_j^k \in \mathcal{A})$$

modulo the sub-bimodule of elements of the form

$$\rho_0 = \sum [D, b_j^0][D, b_j^1] \quad ; \quad b_j^k \in \mathcal{A}, \ \sum b_j^0 [D, b_j^1] = 0.$$

It is now clear that since we work modulo this subspace $\pi\big(\mathrm{d}(J_0 \cap \Omega^1)\big)$, the question of ambiguity in the definition of $\mathrm{d}\omega$ for $\omega \in \pi(\Omega^1)$ no longer arises.

The equality $(*)$ makes sense for all k,

$$(*) \qquad \Omega_D^k \cong \pi(\Omega^k)/\pi\big(\mathrm{d}(J_0 \cap \Omega^{k-1})\big),$$

and allows us to define the following inner product on Ω_D^k: for each k let $\mathfrak{H}_k$ be the Hilbert space completion of $\pi(\Omega^k)$ with the inner product

$$\langle T_1, T_2 \rangle_k = \mathrm{Tr}_\omega(T_2^* T_1 |D|^{-d}) \ \forall T_j \in \pi(\Omega^k).$$

Let P be the orthogonal projection of $\mathfrak{H}_k$ onto the orthogonal complement of the subspace $\pi\big(\mathrm{d}(J_0 \cap \Omega^{k-1})\big)$. By construction, the inner product $\langle P\omega_1, \omega_2 \rangle = \langle P\omega_1, P\omega_2 \rangle$ for $\omega_j \in \pi(\Omega^k)$ depends only on their classes in Ω_D^k. We denote by Λ^k the Hilbert space completion of Ω_D^k for this inner product; it is, of course, equal to $P\mathfrak{H}_k$.

Proposition 5.

1) *The actions of* $\mathcal{A}$ *on* Λ^k *by left and right multiplication define commuting unitary representations of* $\mathcal{A}$ *on* Λ^k.
2) *The functional* $\mathrm{YM}(V) = \langle \mathrm{d}V + V^2, \mathrm{d}V + V^2 \rangle$ *is positive, quartic and invariant under gauge transformations,*

$$\gamma_u(V) = u\mathrm{d}u^* + uVu^* \ \forall u \in \mathcal{U}(\mathcal{A}).$$

3) *The functional* $I(\alpha) = \mathrm{Tr}_\omega(\theta^2 |D|^{-d})$, with $\theta = \pi(\mathrm{d}\alpha + \alpha^2)$, *is positive, quartic and gauge invariant on* $\{\alpha \in \Omega^1(\mathcal{A});\ \alpha = \alpha^*\}$.
4) *One has* $\mathrm{YM}(V) = \inf\{I(\alpha);\ \pi(\alpha) = V\}$.

Let us say a few words about the easy proof. First, the left and right actions of $\mathcal{A}$ on $\mathfrak{H}_k$ are unitary. The unitarity of the right action of $\mathcal{A}$ follows from the equality $\mathrm{Tr}_\omega(Ta|D|^{-d}) = \mathrm{Tr}_\omega(aT|D|^{-d}) \quad \forall T \in \mathcal{L}(\mathcal{H}),\, a \in \mathcal{A}$. Since $\pi\big(\mathrm{d}(J_0 \cap \Omega^{k-1})\big) \subset \pi(\Omega^k)$ is a sub-bimodule of $\pi(\Omega^k)$ it follows that P is a bimodule morphism:

$$P(a\xi b) = aP(\xi)b \ \forall a, b \in \mathcal{A},\ \xi \in \mathfrak{H}_k.$$

Thus 1) follows. As for 2), one merely notes that by the above calculation, with $\mathrm{d}V$ now unambiguous, $\theta = \mathrm{d}V + V^2$ is covariant under gauge transformations, whence the result. For 3), one again uses the above calculation to show that $\mathrm{d}\alpha + \alpha^2$ transforms covariantly under gauge transformations.

Finally, 4) follows from the property of the orthogonal projection P: as an element of Λ^2, $\mathrm{d}V + V^2$ is equal to $P\big(\pi(\mathrm{d}\alpha + \alpha^2)\big)$ for any α with $\pi(\alpha) = V$, and since the ambiguity in $\pi(\mathrm{d}\alpha)$ is exactly $\pi\big(\mathrm{d}(J_0 \cap \Omega^1)\big)$ one gets 4).

Stated in simpler terms, the meaning of Proposition 5 is that the ambiguity that we met above in the definition of the operator curvature $\theta = \mathrm{d}V + V^2$ can be ignored by taking the infimum

$$\mathrm{YM}(V) = \inf \mathrm{Tr}_\omega(\theta^2 |D|^{-d})$$

over all possibilities for $\theta = \mathrm{d}V + V^2$, $\mathrm{d}V = \sum [D, a_j^0][D, a_j^1]$ being ambiguous. The action obtained is nevertheless quartic by 2).

We shall now check that in the case of Riemannian manifolds with the Dirac K-cycle, the graded differential algebra Ω_D^* is canonically isomorphic to the *de Rham algebra of ordinary forms on M with their canonical pre-Hilbert space structure*. The whole point is that Propositions 4 and 5 give us these concepts in far greater generality, and the formula in 4) will allow extending to this generality, in the case $d = 4$, the inequality between the topological action and the Yang–Mills action YM (cf. Section 2). We refer the skeptical reader to the examples of Section 3.

We now specialize to the Riemannian case, where $\mathcal{A}$ is the algebra of functions (with some regularity) on the compact spin manifold M, and $D = \partial_M$ is the Dirac operator in the Hilbert space $L^2(M, S)$ of spinors. We let C be the bundle over M whose fiber at each $p \in M$ is the complexified Clifford algebra $\mathrm{Cliff}_\mathbb{C}(T_p^*(M))$ of the cotangent space at $p \in M$. Any bounded measurable section ρ of C defines a bounded operator $\gamma(\rho)$ on $\mathfrak{H} = L^2(M, S)$. For any $f^0, \dots, f^n \in \mathcal{A}$ one has

$$\pi(f^0 \mathrm{d}f^1 \cdots \mathrm{d}f^n) = i^{-n} \gamma(f^0 \mathrm{d}_\mathrm{c} f^1 \cdot \mathrm{d}_\mathrm{c} f^2 \cdots \mathrm{d}_\mathrm{c} f^n),$$

where the usual differential $\mathrm{d}_\mathrm{c} f$ is regarded as a section of C, and $\cdot$ denotes the product in C.

For each $p \in M$, the Clifford algebra C_p has a $\mathbb{Z}/2$ grading given by the parity of the number of terms ξ_j, $\xi_j \in T_p^*(M)$ in a product $\xi_1 \cdot \xi_2 \cdots \xi_n$, and a filtration, where $C_p^{(k)}$ is the subspace spanned by products of $n \leq k$ elements of $T_p^*(M)$. The associated graded algebra is canonically isomorphic to the complexified exterior algebra $\wedge_\mathbb{C}\big(T_p^*(M)\big)$ and $\sigma_k : C^{(k)} \to \wedge_\mathbb{C}^k(T_p^*)$ is the quotient mapping.

Using the canonical inner product on C given by the trace in the spinor representation, one can also identify $\bigwedge_\mathbb{C}^k$ with the orthogonal complement of $C^{(k-1)}$ in $C^{(k)}$; equivalently, if we let C^k be the subspace of $C^{(k)}$of elements of the same parity as k, then $\bigwedge_\mathbb{C}^k = C^k \ominus C^{k-2}$.

The differential algebra Ω_D^* is determined by the following lemma:

Lemma 6. *Let $(\mathfrak{H}, D)$ be the Dirac K-cycle on the algebra $\mathcal{A}$ of functions on M and let $k \in \mathbb{N}$. Then a pair T_1, T_2 of operators on $\mathfrak{H}$ is of the form $T_1 = \pi(\omega)$, $T_2 = \pi(\mathrm{d}\omega)$ for some $\omega \in \Omega^k(\mathcal{A})$ if and only if there exist sections ρ_1 and ρ_2 of C^k and C^{k+1} such that*

$$T_j = \gamma(\rho_j) \ (j = 1, 2), \ \mathrm{d}_\mathrm{c} \sigma_k(\rho_1) = i \sigma_{k+1}(\rho_2).$$

Here $\sigma_k(\rho_1)$ is an ordinary k-form on M and $\mathrm{d_c}$ is the classical differential. Note that for $k > \dim M$ one has $\sigma_k(\rho) = 0$. The proof is straightforward.

We can now easily determine the graded differential algebra Ω_D^*. First, let us identify $\pi(\Omega^k)$ with the space of sections of C^k; Lemma 6 then shows that

$$\pi\big(\mathrm{d}(J_0 \cap \Omega^{k-1})\big) = \mathrm{Ker}\sigma_k.$$

(If ρ is a section of C^k with $\sigma_k(\rho) = 0$ then the pair of sections $\rho_1 = 0$, $\rho_2 = \rho$ of C^{k-1} and C^k fulfills the condition of Lemma 6, so that $\rho = \pi(\mathrm{d}\omega)$ for some ω, $\pi(\omega) = 0$.) Thus, σ_k is an isomorphism, $\Omega_D^k \cong$ sections of $\bigwedge_{\mathbb{C}}^k(T^*)$, which, again by Lemma 6, commutes with the differential. We can then state:

Formula 3. *The mapping* $a^0\mathrm{d}a^1 \ldots \mathrm{d}a^n \mapsto a^0\mathrm{d_c}a^1 \cdots \mathrm{d_c}a^n$ *for* $a^j \in \mathcal{A}$ *extends to a canonical isomorphism of the differential graded algebra* Ω_D^* *with the de Rham algebra of differential forms on* M*. Under this isomorphism, the inner product on* Ω_D^k *is* $c(d)^{-1}$ *times the Riemannian inner product of* k*-forms*

$$\langle \omega, \omega' \rangle = \int_M \omega \wedge *\omega'.$$

The last equality follows from the computation of the Dixmier trace for the operator on $\mathfrak{H} = L^2(M, S)$ associated with a section ρ of the bundle C of Clifford algebras (cf. Section IV.2):

$$\mathrm{Tr}_\omega(\rho|D|^{-d}) = 2^{-d}\Gamma\left(\tfrac{d}{2}+1\right)^{-1}\ \pi^{-d/2}\int_M \mathrm{trace}\big(\rho(p)\big)\mathrm{d}v(p).$$

As an immediate corollary of Formula 3, we have

$$\mathrm{YM}(V) = c(d)^{-1}\int \|\mathrm{d}V\|^2\mathrm{d}v.$$

Let us now extend the definition of the action YM to connections on arbitrary Hermitian vector bundles.

First of all, we need to express in algebraic terms — i.e., using only the involutive algebra $\mathcal{A}$ — the notion of a Hermitian vector bundle over M. A vector bundle E is entirely characterized by the right $\mathcal{A}$-module $\mathcal{E}$ of sections of E with the same regularity as the elements of $\mathcal{A}$; the local triviality of E and the finite-dimensionality of its fibers translate algebraically into the statement that $\mathcal{E}$ is a direct summand of a free module $\mathcal{A}^N$ for some finite N, or, in fancier terms, that $\mathcal{E}$ is a finitely generated projective module over $\mathcal{A}$.

The Hermitian structure on E, that is, the inner product $\langle \xi, \eta \rangle_p$ on each fiber E_p, yields a sesquilinear map

$$\langle\ ,\ \rangle : \mathcal{E} \times \mathcal{E} \to \mathcal{A},$$

given by $\langle \xi, \eta \rangle(p) = \langle \xi(p), \eta(p) \rangle_p$. The mapping $\langle\ ,\ \rangle$ satisfies the following conditions:

1) $\langle \xi a, \eta b\rangle = a^* \langle \xi, \eta\rangle b$ $(\forall \xi, \eta \in \mathcal{E},\ a, b \in \mathcal{A})$,
2) $\langle \xi, \xi\rangle \geq 0$ $(\forall \xi \in \mathcal{E})$,
3) $\mathcal{E}$ is self-dual for $\langle\ ,\ \rangle$.

Thus, the Hermitian vector bundles over M correspond bijectively to the Hermitian, finitely generated projective modules over $\mathcal{A}$ in the following sense:

Definition 7. *Let $\mathcal{A}$ be a unital $*$-algebra and let $\mathcal{E}$ be a finitely generated projective module over $\mathcal{A}$. A* Hermitian structure *on $\mathcal{E}$ is given by a sesquilinear mapping $\langle\ ,\ \rangle : \mathcal{E} \times \mathcal{E} \to \mathcal{A}$ satisfying the above conditions* 1, 2 *and* 3.

We shall use this notion only in the case where $\mathcal{A}$ is a subalgebra stable under the holomorphic functional calculus in a C^*-algebra, in which case all reasonable notions of positivity coincide in $\mathcal{A}$.

In this case, all Hermitian structures on a given finitely generated projective module $\mathcal{E}$ over $\mathcal{A}$ are isomorphic to each other and are thus obtained as follows: one writes $\mathcal{E}$ as a direct summand $\mathcal{E} = e\mathcal{A}^N$ of a free module $\mathcal{E}_0 = \mathcal{A}^N$, where the idempotent $e \in M_N(\mathcal{A})$ is *self-adjoint*, and one then restricts to $\mathcal{E}$ the Hermitian structure on $\mathcal{A}^N$ given by

$$\langle \xi, \eta\rangle = \sum \xi_i^* \eta_i \in \mathcal{A}\ \forall \xi = (\xi_i), \eta = (\eta_i) \in \mathcal{A}^N.$$

The algebra $\mathrm{End}_{\mathcal{A}}(\mathcal{E})$ of endomorphisms of a Hermitian, finitely generated projective module $\mathcal{E}$ has a natural involution, given by

$$\langle T^* \xi, \eta\rangle = \langle \xi, T\eta\rangle\ \forall \xi, \eta \in \mathcal{E}.$$

With this involution, $\mathrm{End}_{\mathcal{A}}(\mathcal{E})$ is isomorphic to the reduced $*$-algebra $eM_N(\mathcal{A})e$.

As above, we now let $(\mathfrak{H}, D)$ be a K-cycle over $\mathcal{A}$, and Ω_D^1 the $\mathcal{A}$-bimodule of operators in $\mathfrak{H}$ of the form $V = \sum a_i[D, b_i]$, with $a_i, b_i \in \mathcal{A}$.

Definition 8. *Let $\mathcal{E}$ be a Hermitian, finitely generated projective module over $\mathcal{A}$. A* connection *on $\mathcal{E}$ is given by a linear mapping $\nabla : \mathcal{E} \to \mathcal{E} \otimes_{\mathcal{A}} \Omega_D^1$ such that*

$$\nabla(\xi a) = (\nabla \xi)a + \xi \otimes \mathrm{d}a\ \forall \xi \in \mathcal{E},\ a \in \mathcal{A}.$$

A connection ∇ is compatible *(with the metric) if and only if*

$$\langle \xi, \nabla \eta\rangle - \langle \nabla \xi, \eta\rangle = \mathrm{d}\langle \xi, \eta\rangle\ \forall \xi, \eta \in \mathcal{E}.$$

The last equality has a clear meaning in Ω_D^1. In the computations, one should remember that $(\mathrm{d}a)^* = -\mathrm{d}a^*$ $(\forall a \in \mathcal{A})$, and if $\nabla \xi = \sum \xi_i \otimes \omega_i$, $\omega_i \in \Omega_D^1$, then $\langle \nabla \xi, \eta\rangle = \sum \omega_i^* \langle \xi_i, \eta\rangle$.

Such connections always exist; for $\mathcal{E}$ expressed as $e\mathcal{A}^N$ as above, one may take ∇ as the "Grassmannian" connection

$$(\nabla_0 \xi) = e\eta,\ \text{where } \eta_j = \mathrm{d}\xi_j.$$

Two compatible connections ∇ and ∇' on $\mathcal{E}$ can only differ by an element $\Gamma \in \mathrm{Hom}_{\mathcal{A}}(\mathcal{E}, \mathcal{E} \otimes_{\mathcal{A}} \Omega^1_D)$.

As in Proposition 5, we shall now give two equivalent definitions of the action functional $\mathrm{YM}(\nabla)$ on the affine space $C(\mathcal{E})$ of compatible connections.

The group $\mathcal{U}(\mathcal{E})$ of unitary automorphisms of $\mathcal{E}$, $\mathcal{U}(\mathcal{E}) = \{u \in \mathrm{End}_{\mathcal{A}}(\mathcal{E});\ uu^* = u^*u = 1\}$, acts by conjugation $\gamma_u(\nabla) = u\nabla u^*$ on the space $C(\mathcal{E})$. To define the curvature θ of a connection ∇, one first extends ∇ to a unique linear mapping $\widetilde{\nabla}$ from $\widetilde{\mathcal{E}}$ to $\widetilde{\mathcal{E}}$, $\widetilde{\mathcal{E}} = \mathcal{E} \otimes_{\mathcal{A}} \Omega^*_D$, such that

$$\widetilde{\nabla}(\xi \otimes \omega) = (\nabla\xi)\omega + \xi \otimes \mathrm{d}\omega \ \forall \xi \in \mathcal{E},\ \omega \in \Omega^*_D,$$

and one checks that this mapping satisfies

$$\tilde{\nabla}(\eta\omega) = (\widetilde{\nabla}\eta)\omega + (-1)^{\partial\eta}\eta\mathrm{d}\omega$$

for every homogeneous $\eta \in \widetilde{\mathcal{E}}$ and $\omega \in \Omega^*_D$. It then follows that $\theta = \widetilde{\nabla}^2$ is an endomorphism of the right Ω^*_D-module $\widetilde{\mathcal{E}}$; it is determined by its restriction to $\mathcal{E}$, again denoted θ,

$$\theta \in \mathrm{Hom}_{\mathcal{A}}(\mathcal{E}, \mathcal{E} \otimes_{\mathcal{A}} \Omega^2_D).$$

Next, using the inner product on Ω^2_D and the Hermitian structure on $\mathcal{E}$, one has a natural inner product on

$$\mathrm{Hom}_{\mathcal{A}}(\mathcal{E}, \mathcal{E} \otimes_{\mathcal{A}} \Omega^2_D).$$

Using this, we make the following definition.

Definition 9. $\mathrm{YM}(\nabla) = \langle \theta, \theta \rangle$.

By construction, this action is gauge invariant, positive and quartic. It is moreover obvious from the above Formula 3 in the case of the Dirac K-cycle on a Riemannian spin manifold that one has:

Formula 4. *Let M be a Riemannian spin manifold with its Dirac K-cycle $(\mathfrak{H}, D)$. Then, the notion of connection* (Definition 8) *is the usual one, and*

$$\mathrm{YM}(\nabla) = c(d)^{-1} \int_M \|\theta\|^2_{\mathrm{HS}} \mathrm{d}v,$$

where θ is the usual curvature of ∇.

Thus, we recover in this case the usual Yang–Mills action. For computational purposes, and also to see the curvature as an operator in $\mathfrak{H}$, we shall now mention the easy adaptation of Proposition 5, 4) to the general case.

First of all, any compatible connection in the sense of Definition 8 is the composition with π of a *universal compatible connection*,

Definition 10. *Let $\mathcal{E}$ be a Hermitian, finitely generated projective module over $\mathcal{A}$. Then a* universal compatible connection *on $\mathcal{E}$ is a linear mapping ∇ of $\mathcal{E}$ to $\mathcal{E} \otimes_{\mathcal{A}} \Omega^1$ such that:*

a) $\nabla(\xi a) = (\nabla\xi)a + \xi \otimes \mathrm{d}a \ (\forall \xi \in \mathcal{E},\ a \in \mathcal{A})$,

b) $\langle \xi, \nabla\eta\rangle - \langle \nabla\xi, \eta\rangle = \mathrm{d}\langle \xi, \eta\rangle \ (\forall \xi, \eta \in \mathcal{E})$.

To see the surjectivity of the mapping $\pi : CC(\mathcal{E}) \to C(\mathcal{E})$, where $CC(\mathcal{E})$ is the space of universal compatible connections, it is enough to check that the special Grassmannian connection ∇_0 is of this form and that π is a surjection of Ω^1 onto $\pi(\Omega^1)$. Next (cf. Chapter III Section 3), a universal compatible connection extends uniquely as a linear mapping

$$\widetilde{\nabla} : \mathcal{E} \otimes_{\mathcal{A}} \Omega^* \to \mathcal{E} \otimes_{\mathcal{A}} \Omega^*$$

such that $\widetilde{\nabla}$ is equal to ∇ on $\mathcal{E} \otimes 1$ and such that

$$\widetilde{\nabla}(\eta\omega) = (\widetilde{\nabla}\eta)\omega + (-1)^{\deg \eta}\eta \mathrm{d}\omega$$

for every homogeneous η in $\mathcal{E} \otimes_{\mathcal{A}} \Omega^*$ and $\omega \in \Omega^*$.

The curvature $\theta = \tilde{\nabla}^2$ is then an endomorphism of the induced module $\tilde{\mathcal{E}} = \mathcal{E} \otimes_{\mathcal{A}} \Omega^*$ over Ω^*, and $\pi(\theta)$ makes sense as a bounded operator in the Hilbert space $\mathcal{E} \otimes_{\mathcal{A}} \mathfrak{H}$, as does the following operator D_∇ (cf. Section 3):

$$D_\nabla(\xi \otimes \eta) = \xi \otimes D\eta + \big((1 \otimes \pi)\nabla\xi\big)\eta \ \forall \xi \in \mathcal{E},\ \eta \in \mathfrak{H};$$

the analogue of the action I of Proposition 5 3) is then given by

$$I(\nabla) = \mathrm{Tr}_\omega\big(\pi(\theta)^2 |D_\nabla|^{-d}\big).$$

One then proves in the same way that

Proposition 11. *For any compatible connection $\nabla \in C(\mathcal{E})$, one has*

$$\mathrm{YM}(\nabla) = \inf\{I(\nabla_1);\ \pi(\nabla_1) = \nabla\}.$$

Remark 12. All the above considerations apply to noncompact spaces as well, i.e. the $*$-algebra $\mathcal{A}$ is no longer unital. The summability hypothesis $(D-\lambda)^{-1} \in \mathcal{L}^{(d,\infty)}$ $\forall \lambda \notin \mathbb{R}$ is being replaced by $a(D-\lambda)^{-1} \in \mathcal{L}^{(d,\infty)}$ $\forall \lambda \notin \mathbb{R}, a \in \mathcal{A}$.

Definition 10. *Let $\mathcal{E}$ be a Hermitian, finitely generated projective module over $\mathcal{A}$. Then a* universal compatible connection *on $\mathcal{E}$ is a linear mapping ∇ of $\mathcal{E}$ to $\mathcal{E} \otimes_{\mathcal{A}} \Omega^1$ such that:*

a) $\nabla(\xi a) = (\nabla\xi)a + \xi \otimes \mathrm{d}a \ (\forall \xi \in \mathcal{E},\ a \in \mathcal{A})$,
b) $\langle \xi, \nabla\eta\rangle - \langle \nabla\xi, \eta\rangle = \mathrm{d}\langle \xi, \eta\rangle \ (\forall \xi, \eta \in \mathcal{E})$.

To see the surjectivity of the mapping $\pi : CC(\mathcal{E}) \to C(\mathcal{E})$, where $CC(\mathcal{E})$ is the space of universal compatible connections, it is enough to check that the special Grassmannian connection ∇_0 is of this form and that π is a surjection of Ω^1 onto $\pi(\Omega^1)$. Next (cf. Chapter III Section 3), a universal compatible connection extends uniquely as a linear mapping

$$\widetilde{\nabla} : \mathcal{E} \otimes_{\mathcal{A}} \Omega^* \to \mathcal{E} \otimes_{\mathcal{A}} \Omega^*$$

such that $\widetilde{\nabla}$ is equal to ∇ on $\mathcal{E} \otimes 1$ and such that

$$\widetilde{\nabla}(\eta\omega) = (\widetilde{\nabla}\eta)\omega + (-1)^{\deg \eta}\eta \mathrm{d}\omega$$

for every homogeneous η in $\mathcal{E} \otimes_{\mathcal{A}} \Omega^*$ and $\omega \in \Omega^*$.

The curvature $\theta = \tilde{\nabla}^2$ is then an endomorphism of the induced module $\tilde{\mathcal{E}} = \mathcal{E} \otimes_{\mathcal{A}} \Omega^*$ over Ω^*, and $\pi(\theta)$ makes sense as a bounded operator in the Hilbert space $\mathcal{E} \otimes_{\mathcal{A}} \mathfrak{H}$, as does the following operator D_∇ (cf. Section 3):

$$D_\nabla(\xi \otimes \eta) = \xi \otimes D\eta + \big((1 \otimes \pi)\nabla\xi\big)\eta \ \forall \xi \in \mathcal{E},\ \eta \in \mathfrak{H};$$

the analogue of the action I of Proposition 5 3) is then given by

$$I(\nabla) = \mathrm{Tr}_\omega\big(\pi(\theta)^2 |D_\nabla|^{-d}\big).$$

One then proves in the same way that

Proposition 11. *For any compatible connection $\nabla \in C(\mathcal{E})$, one has*

$$\mathrm{YM}(\nabla) = \inf\{I(\nabla_1);\ \pi(\nabla_1) = \nabla\}.$$

Remark 12. All the above considerations apply to noncompact spaces as well, i.e. the $*$-algebra $\mathcal{A}$ is no longer unital. The summability hypothesis $(D-\lambda)^{-1} \in \mathcal{L}^{(d,\infty)}\ \forall \lambda \notin \mathbb{R}$ is being replaced by $a(D-\lambda)^{-1} \in \mathcal{L}^{(d,\infty)}\ \ \forall \lambda \notin \mathbb{R}, a \in \mathcal{A}$.

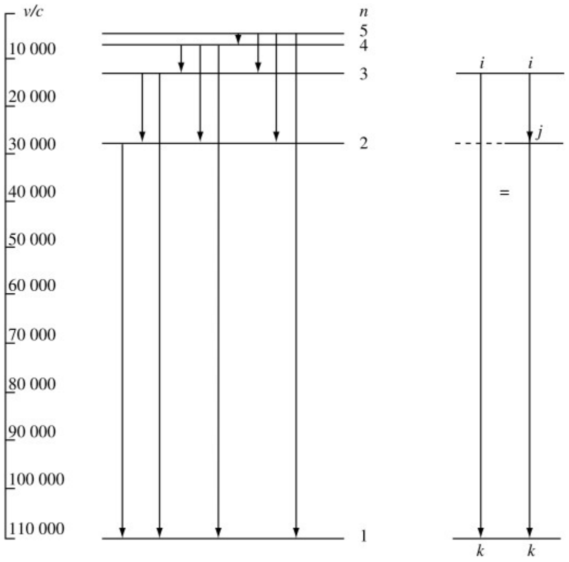

FIGURE 2. The vertical arrows represent the transitions. They are indexed by a pair of indices (i, j).

thus essential to find the regularities that appear in these configurations or *atomic spectra*. It is hydrogen that, in conformity with Mendeleev's table, has the simplest spectrum.

The numerical expression of the regularity of the lines $H_\alpha, H_\beta, H_\gamma, \ldots$ was obtained by Balmer in 1885 in the form

$$H_\alpha = \frac{9}{5}L,\ H_\beta = \frac{16}{12}L,\ H_\gamma = \frac{25}{21}L,\ H_\delta = \frac{36}{32}L,$$

where the value of the length L is approximately 3645.6×10^{-8} cm. In other words, the wavelengths of the lines in Figure 1 are of the form

$$\lambda = \frac{n^2}{n^2 - 4}\,L\,, \text{ where } n \text{ is an integer equal to 3, 4, 5 or 6.}$$

Around 1890, Rydberg showed that for a complex atom the lines of the spectrum can be classified into series, each of them being of the form

$$1/\lambda = R/m^2 - R/n^2 \text{ with } n \text{ and } m \text{ integers, } m \text{ fixed.}$$

Here $R = 4/L$ is Rydberg's constant. From this experimental discovery one deduces that, on the one hand, the frequency $\nu = c/\lambda$ is a more natural parameter than the wavelength λ for indexing the lines of the spectrum and, on the other hand, the

spectrum is a set of differences of frequencies, that is, there exists a set I of frequencies such that the spectrum is the set of differences $\nu_{ij} = \nu_i - \nu_j$ of arbitrary pairs of elements of I. This property shows that one can combine two frequencies ν_{ij} and ν_{jk} to obtain a third, $\nu_{ik} = \nu_{ij} + \nu_{jk}$. This important corollary is the Ritz-Rydberg combination principle: the spectrum is naturally endowed with a partially defined law of composition; the sum of certain frequencies of the spectrum is again a frequency of the spectrum (Figure 2).
Now, these experimental results could not be explained in the framework of the theoretical physics of the 19th century, based as it was on Newton's mechanics and Maxwell's electromagnetism. If one applies the classical conception of mechanics to the microscopic level, then an atom is described mathematically by the phase space and the Hamiltonian, and its interaction with radiation is described by Maxwell's theory. As we shall see, this theory predicts that the set of frequencies forms a subgroup Γ of $\mathbb{R}$.

Let us begin with the phase space. In the model of classical mechanics, to determine the later trajectory of a particle it is necessary to know both its initial position and its velocity. The initial data thus forms a set with six parameters, which are the three coordinates of position and the three coordinates of velocity, or rather of the momentum $p = mv$. If one is interested in a number n of particles, it is necessary to know the position and momentum of each of them. One is thus dealing with a set with $6n$ parameters, called the phase space of the mechanical system under consideration.

Starting with a function on this space which is called the Hamiltonian and which measures energy, classical mechanics prescribes the differential equations that determine the trajectory from the initial data. The natural structure of the phase space is that of a symplectic manifold X whose points are the "states" of the system. The Hamiltonian H is a function on X that intervenes to specify the evolution of every observable physical quantity, that is, of every function f on X, by the equation

$$\dot{f} = \{H, f\},$$

where $\{\ ,\ \}$ denotes the Poisson bracket and $\dot{f} = \mathrm{d}f/\mathrm{d}t$.

In the good cases such as, for example, the planetary model of the hydrogen atom, the dynamical system obtained is totally integrable. This means that there are sufficiently many "constants of motion" so that, on specifying them, the system is reduced to an almost periodic motion. The description of such a system is very simple. For, on the one hand, the algebra of observable quantities is the commutative algebra of almost periodic series

$$q(t) = \sum q_{n_1 \dots n_k} \exp(2\pi \mathrm{i} \langle n, \nu \rangle t),$$

where the n_i are integers, the ν_i are positive real numbers called the fundamental frequencies, and $\langle n, \nu \rangle = \sum n_i \nu_i$. On the other hand, the evolution in time is given by translation of the variable t.

The interaction between a classical atom and the electromagnetic field is described by Maxwell's theory. Such an atom emits an electromagnetic wave whose radiative part is calculated by superposing the plane waves W_n, $n = (n_1, \ldots, n_k)$, with frequencies $\langle n, \nu \rangle = \sum n_i \nu_i$, and whose amplitude and polarization are calculated simply from the fundamental observable that is the dipole moment. The dipole moment Q has three components Q_x, Q_y and Q_z, each of which is an observable quantity,

$$Q_x(t) = \sum q_{x,n} \exp(2\pi \mathrm{i} \langle n, \nu \rangle t)\,,$$

and which give the intensity of the emitted radiation of frequency $\langle n, \nu \rangle$ by the equation

$$I = \frac{\mathrm{d}E}{\mathrm{d}t} = \frac{2}{3c^3}(2\pi \langle n, \nu \rangle)^4 (|q_{x,n}|^2 + |q_{y,n}|^2 + |q_{z,n}|^2)\,,$$

where c denotes the speed of light. It follows, in particular, that the set of frequencies of the emitted radiations is an additive subgroup, $\Gamma \subset \mathbb{R}$, of the real numbers. Thus, to each frequency emitted there are associated all of its integral multiples or harmonics.

In fact, spectroscopy and its numerous experimental results show that this last theoretical result is contradicted by experiment. The set of frequencies emitted by an atom does not form a group, and it is false that the sum of two frequencies of the spectrum is again one. What experiment dictates is the Ritz-Rydberg combination principle, which permits indexing the spectral lines by the set Δ of all pairs (i, j) of elements of a set I of indices. The frequencies ν_{ij} and $\nu_{k\ell}$ only combine when $j = k$ to yield $\nu_{i\ell} = \nu_{ij} + \nu_{j\ell}$. The theory of Bohr, by artificially discretizing the angular momentum of the electron, succeeds in predicting the frequencies of the radiations emitted by the hydrogen atom, but it is unable to predict their intensities and polarizations.

It is by a fundamental calling into question of classical mechanics that Heisenberg arrived at this goal and went well beyond his predecessors. This questioning of classical mechanics runs approximately as follows: in the classical model, the algebra of observable physical quantities can be directly read from the *group* Γ of emitted frequencies; it is the convolution algebra of this group of frequencies. Since Γ is a commutative group, the convolution algebra is commutative. Now, in reality one is not dealing with a group of frequencies but rather, due to the Ritz-Rydberg combination principle, with a groupoid $\Delta = \{(i, j);\ i, j \in I\}$ having the composition rule $(i, j) \cdot (j, k) = (i, k)$. The convolution algebra still has meaning when one passes from a group to a groupoid, and the convolution algebra of the groupoid Δ is none other than *the algebra of matrices* since the convolution product may be written

$$(ab)_{(i,k)} = \sum_j a_{(i,j)} b_{(j,k)}\,,$$

which is identical with the product rule for matrices. On replacing the commutative convolution algebra of the group Γ by the noncommutative convolution algebra of the groupoid Δ dictated by experimental results, Heisenberg replaced classical mechanics, in which the observable quantities commute pairwise, by *matrix mechanics*, in which observable quantities as important as position and momentum no longer commute. Heisenberg's rules of algebraic calculation were imposed on him by the experimental results of spectroscopy. However, Heisenberg did not understand right away that the algebra he was working with was already known to mathematicians and was called the algebra of matrices. It was Jordan and Born who noticed this. In fact, Jordan had remarked that the conditions which, in Heisenberg's formalism, correspond to the Bohr-Sommerfeld quantization rules, signified that the diagonal elements of the matrix $[p,q]$ were equal to $-i\hbar$. In Heisenberg's matrix mechanics, an observable physical quantity is given by its coefficients $q_{(i,j)}$, indexed by elements $(i,j) \in \Delta$ of the groupoid Δ. The time evolution of an observable is given by the homomorphism $(i,j) \in \Delta \mapsto \nu_{ij} \in \mathbb{R}$ of Δ into $\mathbb{R}$ which associates with each spectral line its frequency. One has

$$q_{(i,j)}(t) = q_{(i,j)} \exp(2\pi \mathrm{i} \nu_{ij} t) \,. \tag{1}$$

This formula is the analogue of the classical formula

$$q_{n_1 \dots n_k}(t) = q_{n_1 \dots n_k} \exp(2\pi \mathrm{i} \langle n, \nu \rangle t) \,.$$

To obtain the analogue of Hamilton's law of evolution

$$\frac{dq}{dt} = \{H, q\} \,,$$

one defines a particular physical quantity H that plays the role of the classical energy and is given by its coefficients $H_{(i,j)}$, with

$$H_{(i,j)} = 0 \text{ if } i \neq j \,,\ H_{(i,i)} = h\nu_i \,, \text{ where } \nu_i - \nu_j = \nu_{ij} \ \forall\, i,j \in I,$$

where h is Planck's constant, a factor that converts frequencies into energies. One sees that H is defined uniquely, up to the addition of a multiple of the identity matrix. Moreover, the above formula (1) is equivalent to

$$\frac{dq}{dt} = \frac{2\pi i}{h}(Hq - qH) \,. \tag{2}$$

This equation is similar to the one of Hamilton that uses the Poisson brackets. It is in fact simpler, since it only uses the product of the observables, and more precisely the commutator $[A,B] = AB - BA$, which plays the role that the Poisson bracket plays in Hamiltonian mechanics. By analogy with classical mechanics, one requires the observables q of position and p of momentum to satisfy $[p,q] = -i\hbar$, where $\hbar = h/2\pi$. The simple algebraic form of the classical energy as a function of p and q then gives the equation of Schrödinger for determining the set $\{\nu_i;\ i \in I\}$, or the spectrum of H.

The quantum system thus described is much simpler and more rigid than its classical analogue. One thus obtains a nonnegligible payoff for abandoning the commutativity of classical mechanics. Though less intuitive, quantum mechanics is more directly accessible by virtue of its simplicity and its contact with spectroscopy.

In fact, the results of the theory of $*$-products show that a *symplectic* structure on a manifold such as the phase space is none other than the indication of the existence of a deformation with one parameter (h here) of the algebra of functions into a noncommutative algebra. I refer the reader to the literature ([**13**], [**37**], [**38**], [**169**], [**182**], [**220**], [**368**], [**474**], [**570**]) for a description of the results of this theory.

2. Statistical State of a Macroscopic System and Quantum Statistical Mechanics

A cubic centimeter of water contains on the order of $N = 3\times 10^{22}$ molecules of water agitated by an incessant movement. The detailed description of the motion of each molecule is not necessary, any more than is the precise knowledge of the microscopic state of the system, to determine the results of macroscopic observations. In classical statistical mechanics, a microscopic state of the system is represented by a point of the phase space, which is of dimension $6N$ for N point molecules. A statistical state is described not by a point of the phase space but by a measure μ on that space, a measure that associates with each observable f its mean value

$$\int f\,\mathrm{d}\mu\,.$$

For a system that is maintained at fixed temperature by means of a thermostat, the measure μ is called the Gibbs canonical ensemble; it is given by a formula that involves the Hamiltonian H of the system and the Liouville measure that arises from the symplectic structure of the phase space. One sets

$$\mathrm{d}\mu = \frac{1}{Z}\,e^{-\beta H}\cdot \text{Liouville measure}\,, \tag{3}$$

where $\beta = 1/kT$, T being the absolute temperature and k the Boltzmann constant, whose value is approximately 1.38×10^{-23} joules per degree Kelvin, and where Z is a normalization factor.

The thermodynamic quantities, such as the entropy or the free energy, are calculated as functions of β and a small number of macroscopic parameters introduced in the formula that gives the Hamiltonian H. For a finite system, the free energy is an analytic function of these parameters. For an infinite system, some discontinuities appear that correspond to the phenomenon of phase transition. The image of $[M;G/PL]$ in $[M;G/TOP]$ is a subgroup of index 2 (see Section 15 of [Si71]). It follows that if M is the total space of an S^2-bundle over RP^2 any homotopy equivalence $f : N \to M$ where N is also PL is homotopic to a homeomorphism. (For then $S_{TOP}(M) \cong (Z/2Z)^2$, and the nontrivial element of the image of $S_{PL}(M)$ is represented by a self homotopy equivalence of M. The case $M = S^2 \times RP^2$ was treated in [Ma79]. See also [Te97] for the cases with $\pi = Z/2Z$ and $w_1(M) = 0$.) This is also true if $M = S^4$, RP^4, CP^2, $S^2 \times S^2$ or $S^2 \tilde{\times} S^2$.

If $\pi \cong Z/4Z$ or $(Z/2Z)^2$ then $\chi(M) = 1$, and so M is nonorientable. As the $\mathbb{F}_2$-Hurewicz homomorphism is 0 in these cases Lemma 6.5 does not apply to give any exotic self homotopy equivalences.

If $\pi \cong (Z/2Z)^2$ then $[M;G/TOP] \cong (Z/2Z)^4$ and the surgery obstruction groups are $L_5((Z/2Z)^2,-) = 0$ and $L_4((Z/2Z)^2,-) = Z/2Z$, by Theorem 3.5.1 of [Wl76]. Since $w_1(M)$ is a split epimorphism $L_4(w_1(M))$ is an isomorphism, so the surgery obstruction is detected by the Kervaire-Arf invariant. As $w_1(M)^2 \neq 0$ we find that $S_{TOP}(M) \cong (Z/2Z)^3$. Thus there are between six and 56 homeomorphism classes of closed 4-manifolds with $\pi \cong (Z/2Z)^2$ and $\chi = 1$, of which half are not stably smoothable.

If $\pi \cong Z/4Z$ then $[M;G/TOP] \cong (Z/2Z)^2$ and the surgery obstruction groups $L_4(Z/4Z,-)$ and $L_5(Z/4Z,-)$ are both 0, by Theorem 3.4.5 of [Wl76]. Hence $S_{TOP}(M) \cong (Z/2Z)^2$. In the next section we show that self homotopy equivalences of $S^2 \times S^2/\langle\tau(I,-I)\rangle$ are homotopic to homeomorphisms. Hence there are four homeomorphism classes of closed 4-manifolds with $\pi \cong Z/4Z$ and $\chi = 1$. In all cases the orientable double covering space has trivial Kirby-Siebenmann invariant and so is homeomorphic to $(S^2 \times S^2)/(-I,-I)$. In the final section we give a candidate for another PL 4-manifold in this homotopy type. (This is from [HH17].)

12.8 The case $\pi = Z/4Z$

Let X be a connected cell complex, and let $G_\#(X)$ be the group of based self homotopy equivalences of X which induce the identity on all homotopy groups. Let $P_n(X)$ be the n^{th} stage of the Postnikov tower for X. This may be constructed by adjoining cells of dimension $\geq n+2$ to X. Then $G_\#(P_2(X)) \cong H^2(\pi;\pi_2(X))$, and there are exact sequences

$$H^n(P_{n-1}(X);\pi_n(X)) \to G_\#(P_n(X)) \to G_\#(P_{n-1}(X)),$$

for $n > 2$, by Theorem 2.2 and Proposition 1.5 of [Ts80], respectively. (The image on the right is the stabilizer in $G_\#(P_{n-1}(X))$ of the n^{th} k-invariant.)

In particular, if $H^k(P_{k-1}(X);\pi_k(X)) = 0$ for $2 \leq k \leq n$ then self homotopy equivalences of $P_n(X)$ are detected by their actions on the homotopy groups.

Let $M = S^2 \times S^2/\langle \tau(I,-I)\rangle$ be the geometric manifold with $\pi = \pi_1(M) \cong Z/4Z$ and $\chi = 1$. Since $\widetilde{M} = S^2 \times S^2$, $\pi_k(M) = \pi_k(S^2) \oplus \pi_k(S^2)$, for all $k \geq 2$. Let $\Pi = \pi_2(M)$, considered as a $\mathbb{Z}[\pi]$-module. Fix a basepoint $e = R_1(e)$ on the equator of S^2 and let $[s,t]$ be the image in M of $(s,t) \in S^2 \times S^2$. We shall take (e,e) and $[e,e]$ as basepoints for $S^2 \times S^2$ and M, respectively.

Theorem 12.6 *Let $M = S^2 \times S^2/\langle \tau(I,-I)\rangle$. Then the natural map from π to $Aut_\pi(\Pi)$ is an isomorphism, while $G_\#(M)$ has order ≤ 2.*

Proof The group $\pi = Z/4Z$ acts on $\Pi = \mathbb{Z}^2$ via $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$, and so $\Pi \cong \Lambda/(t^2+1) = \mathbb{Z}[i]$. Hence the natural map from π to $Aut_\pi(\Pi) \cong \mathbb{Z}[i]^\times = \langle i \rangle$ is an isomorphism. Similarly, π acts on $\pi_4(M) = (Z/2Z)^2$ via swapping the summands.

The Hopf maps corresponding to the factors of $\widetilde{M}$ generate $\pi_3(M) \cong \mathbb{Z}^2$. Hence $\pi = Z/4Z$ acts on $\pi_3(M)$ via $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. Simple calculations using the standard periodic resolution of the augmentation module $\mathbb{Z}$ give $H^0(\pi;\Pi) \cong H^0(\pi;\pi_3(M)) \cong \mathbb{Z}$, while $H^{2k-1}(\pi;\Pi) = H^{2k}(\pi;\pi_3(M)) = Z/2Z$ and $H^{2k}(\pi;\Pi) = H^{2k-1}(\pi;\pi_3(M)) = 0$, for all $k > 0$.

The homotopy fibre of the classifying map from $P_2(M)$ to $K(\pi,1)$ is $K(\Pi,2)$. Since $K(\Pi,2)$ has no cohomology in odd degrees, while $H^2(K(\Pi,2);\pi_3(M)) \cong \pi_3(M)^2$, all the terms with $p+q$ odd in the Leray-Serre spectral sequence

$$H^p(\pi;H^q(K(\Pi,2);\pi_3(M)) \Rightarrow H^{p+q}(P_2(M);\pi_3(M))$$

are 0. Hence the spectral sequence collapses, so $H^3(P_2(M);\pi_3(M)) = 0$ and $H^4(P_2(M);\pi_3(M)) \cong \mathbb{Z} \oplus T$, where T has order 4. Therefore $G_\#(P_2(M)) = G_\#(P_3(M)) = 0$.

We may assume that $P_3(M)$ has a single 5-cell, attached along a map which factors through one of the S^2 factors of $\widetilde{M}$. Therefore the connecting homomorphism from $H^4(M;\pi_4(M))$ to $H^5(P_3(M),M;\pi_4(M))$ is 0, and restriction from $H^4(P_3(M);\pi_4(M))$ to $H^4(M;\pi_4(M))$ is an isomorphism. Since $H^4(M;\pi_4(M)) \cong \overline{H_0(M;\pi_4(M))} = Z/2Z$, by Poincaré duality, we see that $G_\#(P_4(M))$ has order at most 2.

Every self homotopy equivalence of M extends to a self-homotopy equivalence of $P_n(M)$, for all $n > 0$. Conversely, if $n \geq 3$ then every self-map f of $P_n(M)$ restricts to a self-map of M, by cellular approximation, and if f is a self-homotopy equivalence then so is the restriction, by duality in the universal cover $\widetilde{M} = S^2 \times S^2$ and the Whitehead theorems. If, moreover, $n \geq 4$ then homotopies of self maps of $P_n(M)$ restrict to homotopies of self-maps of M. Thus $G_\#(M) = G_\#(P_4(M))$, and so has order ≤ 2. □

Is $G_\#(M)$ trivial? We may circumvent our ignorance of the answer to this question by the argument of the next lemma.

Let $M_o = \overline{M \setminus D^4}$, and let $j_o : M_o \to M$ be the natural inclusion.

Lemma 12.7 *Let h be a based self homotopy equivalence of M which induces the identity on π and Π. Then h is based homotopic to a self-homeomorphism of M.*

Proof The map h induces the identity on all homotopy groups, since $\pi_k(M) = \pi_k(S^2) \oplus \pi_k(S^2)$, for all $k \geq 2$. Let $P_j(h)$ be the extension of h to a self-homotopy equivalence of $P_j(M)$. Since $P_3(h)$ induces the identity on π, Π and $\pi_3(M)$, there is a homotopy H_t from $P_3(h)$ to the identity, by Theorem 12.6 and the exact sequences of [Ts80]. We may assume that $H(M_o \times [0,1])$ has image in M. Thus $h|_{M_o} \sim j_o$, and so we may assume that $h|_{M_o} = j_o$, by the HEP. We then see that h may be obtained by the pinch construction; $h = id_M \vee \gamma$ for some $\gamma \in \pi_4(M)$. Now $\gamma = \mu\eta^2$ for some $\mu \in \Pi$, since $\pi_4(S^2) = Z/2Z$ is generated by η^2. Since $H_2(M;\mathbb{F}_2) = H_2(\pi;\mathbb{F}_2)$, the Hurewicz homomorphism from Π to $H_2(M;\mathbb{F}_2)$ is 0. Therefore $kerv(h) = 0$. Hence h has trivial normal invariant, by Theorem 5.1 of [CH90]. Thus h is homotopic to a self-homeomorphism of M. □

Theorem 12.8 *Every based self-homotopy equivalence of M is based homotopy equivalent to a homeomorphism.*

Proof Interchange of factors and reflection across the equator of S^2 may be used to define basepoint preserving homeomorphisms r and s of M, with $r([x,y]) = [y,x]$ and $s([x,y]) = [R_1x, R_1y]$, for all $[x,y] \in M$. Let c be the equatorial arc from $c(0) = e$ to $c(1) = -e$ in S^2. Then $\gamma(t) = [c(t), e]$ represents a generator of π, while $r\gamma(t) = \gamma(1-t)$ and $s\gamma(t) = \gamma(t)$, for all $0 \leq t \leq 1$. Therefore $\pi_1(r) = -1$ and $\pi_1(s) = 1$. Clearly $\pi_2(r)$ and $\pi_2(s)$ have matrices $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ and $-I$, respectively.

Let h be the homeomorphism which drags the basepoint $\star$ around a loop representing a generator g of π. Then $\pi_1(h) = id_\pi$, since π is abelian, while $\pi_2(h)$

acts through g, and so has matrix $\left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ or its inverse. It is now clear that if f is a based self-homotopy equivalence of M there is a based self-homeomorphism F such that $\pi_i(f) = \pi_i(F)$, for $i = 1$ and 2. Since $F^{-1}f$ induces the identity on π and Π, the theorem follows from Lemma 12.7. □

Corollary 12.8.1 *There are four homeomorphism types of manifolds homotopy equivalent to* M*.* □

12.9 A smooth fake version of $S^2 \times S^2/\langle\tau(I,-I)\rangle$?

Let $M = S^2 \times S^2/\langle\tau(I,-I)\rangle$, as in the previous section, and let M^+ be its orientable double cover. Let $\Delta = \{(s,s) \mid s \in S^2\}$ be the diagonal in $S^2 \times S^2$. We may isotope Δ to a nearby sphere which meets Δ transversely in two points, by rotating the first factor, and so Δ has self-intersection ± 2. The diagonal is invariant under $(-I,-I)$, and so $\delta = \Delta/\langle\sigma^2\rangle \cong RP^2$ embeds in $M^+ = S^2 \times S^2/\langle(-I,-I)\rangle$ with an orientable regular neighbourhood. Since $\sigma(\Delta) \cap \Delta = \emptyset$ this also embeds in M. We shall see that the complementary region also has a simple description.

We shall view S^2 here as the unit sphere in the space of purely imaginary quaternions. The standard inner product on this space is given by $v \bullet w = \mathfrak{Re}(v\bar{w})$, for v, w purely imaginary quaternions. We shall also identify S^3 with the unit quaternions $\mathbb{H}_1$. Let $C_x = \{(s,t) \in S^2 \times S^2 \mid s \bullet t = x\}$, for all $x \in [-1,1]$. Then $C_1 = \Delta$ and $C_{-1} = \tau(I,-I)(\Delta)$, while $C_x \cong C_0$ for all $|x| < 1$. The map $p : S^3 \to C_0$ given by $p(q) = (q\mathbf{i}q^{-1}, q\mathbf{j}q^{-1})$ for all $q \in S^3$ is a 2-fold covering projection, and so $C_0 \cong RP^3$.

It is easily seen that $N = \cup_{x \geq \varepsilon} C_x$ and $\tau(I,-I)(N)$ are regular neighbourhoods of Δ and $\tau(I,-I)(\Delta)$, respectively, while $C = \cup_{x \in [-\varepsilon,\varepsilon]} C_x \cong C_0 \times [-\varepsilon,\varepsilon]$. In particular, N and $\tau(I,-I)(N)$ are each homeomorphic to the total space of the unit disc bundle in T_{S^2}, and $\partial N \cong C_0 \cong RP^3$. The subsets C_x are invariant under $(-I,-I)$. Hence $N(\delta) = N/\langle(-I,-I)\rangle$ is the total space of the tangent disc bundle of RP^2. In particular, $\partial N(\delta) \cong L(4,1)$ and δ represents the nonzero element of $H_2(M;\mathbb{F}_2)$, since it has self-intersection 1 in $\mathbb{F}_2$. (It is not hard to show that any embedded surface representing the nonzero element of $H_2(M;\mathbb{F}_2)$ is non-orientable but lifts to M^+, and so has an orientable regular neighbourhood.)

We also see that $C/\langle(-I,-I)\rangle \cong L(4,1) \times [-\varepsilon,\varepsilon]$. The self map of S^3 defined by right multiplication by $\frac{1}{\sqrt{2}}(\mathbf{1}+\mathbf{k})$ lifts $\tau(I,-I)$, since $p(q.\frac{1}{\sqrt{2}}(\mathbf{1}+\mathbf{k})) = \tau(I,-I)(p(q))$. Hence $C_0/\langle\tau(I,-I)\rangle = S^3/\langle\frac{1}{\sqrt{2}}(\mathbf{1}+\mathbf{k})\rangle = L(8,1)$, and so $MC =$

$C/\langle\sigma\rangle$ is the mapping cylinder of the double cover $L(4,1)\to L(8,1)$. Since $S^2\times S^2=N\cup C\cup\tau(I,-I)(N)$ it follows that $M=N(\delta)\cup MC$.

This construction suggests a candidate for another smooth 4-manifold in the same (simple) homotopy type. Let $M'=N(\delta)\cup MC'$, where MC' is the mapping cylinder of the double cover $L(4,1)\to L(8,5)$. Then $\pi_1(M')\cong Z/4Z$ and $\chi(M')=1$, and so there is a homotopy equivalence $h:M'\simeq M$. In this case, $kerv(h)$ is a complete invariant. The difficulty is in finding an easily analyzed explicit choice for h, for which we can compute $kerv(h)$.

Is there a computable homeomorphism (or diffeomorphism) invariant that can be applied here? Most readily computable invariants are invariants of homotopy type. These manifolds have $w_2\neq 0$ but $w_1^2=0$ and $w_1w_2=0$, so admit Pin^c-structures. Is it possible to distinguish them by consideration of the associated Arf invariants?

If M and M' are not homeomorphic then every closed 4-manifold with $\pi\cong Z/4Z$ and $\chi=1$ is homeomorphic to one of M, M', $*M$ or $*M'$.

THE DIFFERENTIAL TOPOLOGY OF ALGEBRAIC SURFACES

Let us now review our position with regard to the overall aims of this book. In Chapter 1 we set up the twin problems in four-manifold theory: deciding the existence and uniqueness of manifolds with given intersection forms. In Chapter 8 we have shown how arguments with Yang–Mills moduli spaces give strong non-existence results, and in Chapter 9 we have developed invariants of four-manifolds aimed at the complementary question of uniqueness. However we have not yet given any full-blooded example of the application of these invariants, i.e. shown that they can distinguish differentiable four-manifolds with the same intersection form, and this is the purpose of the present chapter. We will describe the main ideas in the proof of the general Theorem (1.3.5), and give a complete proof of the special result (1.3.6).

We have seen in Chapter 9 that for most four-manifolds which admit connected sum decompositions the new invariants are trivial. We can construct connected sums which realize many homotopy types, so finding an example of the kind we want is essentially equivalent to showing that the invariants are not always trivial. In this chapter we shall see that, for rather basic reasons, the invariants are indeed non-trivial for complex algebraic surfaces. This general theory is explained in Section 10.1.

Another problem taken up in this chapter is that of the calculation of the invariants in any kind of generality. While we have defined invariants for a large class of four-manifolds, we have given little indication as to how they may be calculated in practice. The definition involves the solution of the non-linear ASD partial differential equations, and this can certainly not be done in general in any explicit form. However, for the particular class of complex surfaces, we have seen in Chapter 6 that the ASD connections can be identified with stable holomorphic bundles, and in this chapter we continue the same line of ideas by describing techniques which can be applied fairly generally to analyse moduli spaces of stable bundles. The basic construction is reviewed, within a differential-geometric framework in Section 10.2, and in Section 10.3 we illustrate its application in a particular case: moduli spaces of bundles over a ‘double plane’ (branched cover). These geometric calculations are then applied in Section 10.4 to calculate some of the Yang–Mills invariants for this four-manifold.

10.1 General theory

10.1.1 Statement of results

Let S be a smooth, simply connected, complex algebraic surface. As we have seen in Section 1.1.7, the underlying differentiable four-manifold has a standard orientation and $b^+(S) = 1 + 2p_g(S)$. We will henceforth assume that $p_g(S) > 0$, so $b^+ \geq 3$ and the various different polynomial invariants on $H_2(S)$ of Chapter 9 are defined. Moreover the complex structure fixes a natural orientation on the moduli space and so there are no ambiguities of sign (see Section 6.4.2). Here we want to have in mind primarily $SU(2)$-bundles, but our results apply equally to $SO(3)$-bundles where w_2 is the reduction of the first Chern class of a holomorphic line bundle over S (i.e. an integral (1, 1) class). In particular we can consider bundles with $w_2 = c_1(K_S) \bmod 2$. (The point of this condition is that we can then lift up to rank-two vector bundles over S, as explained in Section 6.1.4.)

The surface S can be holomorphically embedded in projective space. Such an embedding defines a 'hyperplane class' h in $H^2(S)$, the restriction of the standard generator for $H^2(\mathbb{CP}^N)$. Geometrically, this is the class realized by the intersecton of S with a general hyperplane or, in other language, a complex curve C in the linear system $|\mathcal{O}(1)|$ over S. The main general theorem we have is then:

Theorem (10.1.1). *For any simply connected complex algebraic surface S with $p_g(S) > 0$ and any hyperplane class h in $H_2(S)$ there is a $k_0 = k_0(S, h)$ such that for $k \geq k_0$ and any Stiefel–Whitney class α which is the reduction of a (1, 1) class $\hat{\alpha}$, we have $q_{k,\hat{\alpha}}(h) > 0$.*

This obviously implies Theorem (1.3.5), and combined with the results of Chapter 9 gives

Corollary (10.1.2). *No simply connected complex algebraic surface S can be written as a smooth connected sum $X_1 \# X_2$ with $b^+(X_1)$ and $b^+(X_2)$ both positive.*

From this we immediately obtain many examples of distinct smooth four-manifolds with the same intersection forms. Indeed we have:

Corollary (10.1.3) {= (1.3.7)}. *For any simply connected complex algebraic surface S with $b^+(S) \geq 5$, there is a smooth four-manifold $X(S)$, homotopy equivalent to S but not diffeomorphic to S, nor to any complex surface.*

For manifolds with odd forms this is immediate; by the classification of forms we can take

$$X(S) = \mathbb{CP}^2 \# \mathbb{CP}^2 \# \mathbb{CP}^2 \# \ldots \# \mathbb{CP}^2 \# \overline{\mathbb{CP}}^2 \# \ldots \# \overline{\mathbb{CP}}^2 \# \overline{\mathbb{CP}}^2$$

(and we need only assume $b^+ \geq 3$). In the other case, we consider a connected sum of the form $X = lK \# m(S^2 \times S^2)$ or $l\bar{K} \# m(S^2 \times S^2)$, where K is the $K3$ surface and $\bar{K}$ is the same manifold with reversed orientation. By Rohlin's theorem and the classification of even forms we can arrange X to have the same homotopy type as S so long as S satisfies the '11/8 inequality',

$$b^+ + b^- \leq (11/8)|b^+ - b^-|.$$

This inequality can be deduced from standard results about surfaces (an observation of Moishezon). One easily reduces to minimal surfaces of general type, for which $c_1^2 \geq 0$, and $c_1^2 \leq 3c_2$. These give $b^+ - 2b^- \leq 1$ and $5b^+ - b^- \geq -4$ (using the formulae of Section 1.1.7) which, together with the special consideration of small values of b^+, b^-, imply the result.

In any case, S cannot be diffeomorphic to $X(S)$, by Corollary (10.1.3). Of course, as well as these general results we have many explicit examples, for example the hypersurfaces S_d ($d \geq 5$) and the branched covers R_p ($p \geq 4$) of Section 1.1.7.

Notice that, combining (10.1.2) with the non-existence results of Chapter 8, in any smooth connected sum splitting of a simply connected algebraic surface one of the summands must have intersection form $\mathrm{diag}(-1, -1, -1, \ldots, -1)$, i.e. the intersection form of a connected sum of $\overline{\mathbb{CP}}^2$s. Conversely, this situation certainly can occur: we can take S to be the multiple blow up of another complex surface S'; then, as we have seen in Chapter 1:

$$S = S' \# \overline{\mathbb{CP}}^2 \# \overline{\mathbb{CP}}^2 \ldots \# \overline{\mathbb{CP}}^2.$$

Now let us go back to our remarks about Wall's theorem on the stable classification of four-manifolds from Chapter 1. We know that for any simply connected complex surface S and sufficiently large integers m, n, the manifold $S \# m\mathbb{CP}^2 \# n\overline{\mathbb{CP}}^2$ is diffeomorphic to $X(S) \# m\mathbb{CP}^2 \# n\overline{\mathbb{CP}}^2$. But we see now that we cannot take $m = 0$, however large n may be, since the connected sum of S with $n\overline{\mathbb{CP}}^2$ is still an algebraic surface. In the reverse direction it has been shown by Mandelbaum (1980) and Moishezon (1977) that for many surfaces S, for example the hypersurfaces in $\mathbb{CP}^3$, we can take $n = 0$ and $m = 1$; i.e. adding a single $\mathbb{CP}^2$ kills the 'exotic' property of the differentiable structure on S. (Such surfaces are called 'almost completely decomposable' by Mandelbaum and Moishezon, and they conjecture that in fact all surfaces have this property.) Thus we see that there is a radical difference between the differential-topological effect of the addition of $\mathbb{CP}^2$s and $\overline{\mathbb{CP}}^2$s. Of course this is quite in line with our methods, based on the ASD equation which involves a definite choice of orientation. Indeed we see that for almost completely decomposable surfaces S with b^+, b^- both odd the ASD Yang–Mills invariants of $\bar{S}$ are all zero (by (9.3.14)) while those of S are not.

10.1.2 The main idea

Let S be a complex algebraic surface as above and fix a Kähler metric on S, for simplicity a 'Hodge metric', compatible with a projective embedding. Thus the de Rham cohomology class of the metric 2-form ω is Poincaré dual to the hyperplane section class ω. (For example we could take the pull-back of the Fubini–Study metric on $\mathbb{CP}^N$.) We shall now explain why (10.1.1) is true in a favourable (but rare) case when we have a moduli space M of ASD connections, defined relative to this Kähler metric, which is non-empty, compact and regular, i.e. $H_A^2 = 0$ for all points in M. The argument is very simple: the number $q(h)$ is defined by pairing the relevant power of the cohomology class $\mu(h)$ with the fundamental cycle of M:

$$q(h) = \langle \mu(h)^d, [M] \rangle. \tag{10.1.4}$$

Now we know on the one hand, from (5.2.19), that $\mu(h)$ can be represented by the 2-form on M,

$$\Omega(a, b) = \frac{1}{8\pi^2} \int_S \operatorname{Tr}(a \wedge b) \wedge \omega,$$

since the metric form ω is self-dual. Thus, using de Rham cohomology,

$$q(h) = \int_M \Omega^d. \tag{10.1.5}$$

On the other hand we know that M is a complex manifold and that Ω is the two-form of the natural Kähler metric on M (see Section 6.5.3). It follows then that Ω^d is $(d-1)!$ times the Riemannian volume element on M, so

$$q(h) = (d-1)! \operatorname{Vol}(M) > 0,$$

as required.

This proof does not use the fact that the metric is a Hodge metric; it applies to any Kähler surface. However in the algebraic case we can carry through a parallel algebro-geometric argument. We know that $-2\pi i\Omega$ is the curvature form of a line bundle $\mathscr{L}$ over M, the determinant line bundle of the restriction of the connections to a (real) surface representing h. Now since $\mathscr{L}$ is a 'positive' line bundle, we know by Kodaira's embedding theorem that the holomorphic sections of some positive power $\mathscr{L}^{\otimes n}$ give a projective embedding $j: M \to \mathbb{CP}^r$. So the image $j(M)$ is a complex algebraic subvariety of $\mathbb{CP}^r$, and the restriction of the Hopf line bundle on $\mathbb{CP}^r$ to $j(M)$ is isomorphic to $\mathscr{L}^n$. It follows then that $q(h)$ is $1/n^d$ times the *degree* of $j(M)$: the degree being the number of points in the intersection of $j(M)$ with d general hyperplanes in $\mathbb{CP}^r$. Since the degree of a non-empty variety is always positive we reach the same conclusion. Notice that if we can construct the projective embedding directly, without recourse to Kodaira's theorem, we obtain an independent algebro-geometric proof, and we shall use this approach in Section 10.1.4 to handle the technical difficulties of singularities and non-compact moduli spaces which occur in realistic problems. First we digress to describe projective embeddings of moduli spaces of bundles, beginning with bundles over curves.

10.1.3 Gieseker's projective embedding

Let C be an algebraic curve (compact Riemann surface) of genus g and fix a line bundle $\mathcal{O}(1)$ of degree one over C. Let p be a positive integer, to be fixed below, and consider two moduli spaces W_0, W_1 of rank-two stable holomorphic bundles $\mathcal{E}$ over C with determinant $\mathcal{O}(2p)$ (the tensor power $\mathcal{O}(1)^{2p}$) and $\mathcal{O}(2p+1)$ respectively. The operation of tensoring with $\mathcal{O}(1)$ shows that these are independent of p. Each can be described in terms of projectively flat unitary connections; the space W_0 is the same as the space denoted W_C in Section 6.1.4. Both W_0 and W_1 are complex manifolds of complex dimension $3g-3$, and W_1 is also compact. We want to construct projective embeddings of W_0 and W_1 by sections of the determinant line bundle $\mathcal{L}$. In the case of W_1 we get such an embedding by Kodaira's theorem, since we know that $\mathcal{L}$ is a positive line bundle, but as it stands this does not cover the non-compact space W_0. We will describe here an algebro-geometric construction due to Gieseker which is rather more explicit and has the advantage that it works equally well in the non-compact case. In this construction we shall see another way in which the notion of stability for bundles can be fitted into the general theory described in Section 6.5, involving quotients by linear actions. As in the case of the ADHM construction of instantons, the relevant symmetry group is the automorphism group of the cohomology of a bundle.

Recall that, topologically, any bundle can be induced from a universal bundle U over a Grassman manifold by a suitable map. Gieseker's construction takes as starting point the analogue of this for holomorphic bundles. Suppose a rank-two bundle $\mathcal{E}$ over C is *generated by its global sections*, i.e. for each point x in C the evaluation map $e_x\colon H^0(\mathcal{E}) \to \mathcal{E}_x$ is surjective. If we write H for $H^0(\mathcal{E})$ and $\underline{H}$ for the corresponding trivial bundle over C we get a surjective bundle map

$$e\colon \underline{H} \longrightarrow \mathcal{E}.$$

Thus the bundle $\mathcal{E}$ is completely described by giving a family of two-dimensional quotients of the fixed vector space H, or equivalently by a family of two-dimensional subspaces of the dual space H^*. We get a canonical map to the Grassmannian of two-planes:

$$f\colon C \longrightarrow \mathrm{Gr}_2(H^*), \tag{10.1.6}$$

with $f(x)$ the annihilator of $\ker e_x$. The universal bundle U over the

Grassmannian (the dual of the tautological bundle) is holomorphic, and $\mathscr{E}$ is canonically isomorphic to the pull-back $f^*(U)$.

We next give a rather different description of f. First we apply the standard Plücker embedding i of a Grassmannian. This maps $\mathrm{Gr}_2(H^*)$ to the projective space $\mathbb{P}(\Lambda^2 H^*)$, with

$$i(\mathrm{Span}(\varepsilon_1, \varepsilon_2)) = [\varepsilon_1 \wedge \varepsilon_2].$$

Thus we have a composite map

$$g = if : C \longrightarrow \mathbb{P}(\Lambda^2 H^*).$$

Now, maps to a projective space correspond to linear systems of sections of line bundles. The pull back by g of the Hopf line bundle over the projective space is canonically isomorphic to the line bundle $\Lambda^2\mathscr{E}$ over C. The map g must therefore be induced from the universal map,

$$u : C \longrightarrow \mathbb{P}(H^0(\Lambda^2\mathscr{E})^*)$$

by a linear mapping:

$$\sigma^T : H^0(\Lambda^2\mathscr{E})^* \longrightarrow (\Lambda^2 H)^*.$$

More precisely, any such linear map induces a rational map on the projective spaces and this becomes a well-defined mapping on the one-dimensional curve C (provided σ^T is not identically zero). So we have a commutative diagram:

$$\begin{tikzcd}
C \arrow[r, "f"] \arrow[dr, "u"'] & \mathrm{Gr}_2(H^*) \arrow[r, "i"] & \mathbb{P}(\Lambda^2 H^*) \\
& \mathbb{P}(H^0(\Lambda^2\mathscr{E}))^* \arrow[ur, "\mathbb{P}(\sigma^T)"'] &
\end{tikzcd}$$

Lemma (10.1.7). *The map* σ^T *is the transpose of the tautological map* $\sigma : \Lambda^2 H = \Lambda^2(H^0(\mathscr{E})) \to H^0(\Lambda^2\mathscr{E})$.

This is just a matter of checking definitions, and we can safely omit the proof.

It follows then that our bundle is completely determined by the associated map σ. To apply this to moduli problems we consider families of bundles $\mathscr{E}$ with the same determinant $\Lambda^2\mathscr{E}$, and with a fixed dimension, N say, of $H^0(\mathscr{E})$. Then to each bundle we can associate an orbit in the vector space $\mathrm{Hom}(\Lambda^2\mathbb{C}^N, H^0(\Lambda^2\mathscr{E}))$ under the natural action of $GL(N, \mathbb{C})$. For bundles which are generated by their global sections, this orbit determines the bundle up to isomorphism.

Lemma (10.1.8). *A stable bundle* $\mathscr{E}$ *over* C *with* $\deg(\mathscr{E}) \geq 4g + 2$ *is generated by its global sections and has* $\dim H^0(\mathscr{E}) = \deg(\mathscr{E}) - 2(g - 1)$.

Proof. For any point x in C we have an exact sequence:

$$0 \longrightarrow \mathscr{E} \otimes [-x] \longrightarrow \mathscr{E} \underset{e_x}{\longrightarrow} \mathscr{E}_x \longrightarrow 0,$$

where $[-x]$ denotes the line bundle of degree -1 defined by x. The long exact cohomology sequence shows that e_x is surjective if $H^1(\mathscr{E} \otimes [-x]) = 0$. But this space is dual to $H^0(\mathscr{E}^* \otimes K_C \otimes [x])$, i.e. to the maps from $\mathscr{E}$ to the line bundle $K_C \otimes [x]$, which has degree $2(g-1)+1$. By the definition of stability, such maps exist only if $\frac{1}{2}\deg \mathscr{E} < 2(g-1)+1$. Similarly, when $\deg \mathscr{E} \geq 4g-4$ we have $H^1(\mathscr{E}) = 0$ and $\dim H$ is given by the Riemann–Roch formula.

We thus obtain the following proposition, in which we let W denote either of the moduli spaces W_0, W_1, we write $\mathbb{C}^q$ for $H^0(\mathcal{O}(2p))$, $H^0(\mathcal{O}(2p+1))$ and put $N = 2p - 2(g-1)$, $(2p+1) - 2(g-1)$ respectively, where p is any integer bigger than $2g-1$.

Proposition (10.1.9). *There is a natural injection γ of W into the set of orbits of $SL(N, \mathbb{C})$ in the projective space $\mathbb{P}(\mathrm{Hom}(\Lambda^2\mathbb{C}^N, \mathbb{C}^q))$.*

Gieseker's approach thus arrives squarely in the class of problems we discussed in Section 6.5.2. If we restrict the $SL(N, \mathbb{C})$ action to the open set of stable orbits in the projective space, the quotient U^* becomes a complex manifold (or orbifold) and the invariant polynomials, of fixed large degree s say, induce an embedding of U^* into a projective space $\mathbb{CP}^r$. What needs to be shown is that the injection γ maps W to the subset U^*, i.e. that stable bundles $\mathscr{E}$ have stable maps $\sigma_{\mathscr{E}}$. We omit the proof of this and refer to the very readable account by Gieseker (1977). In outline, one applies the Hilbert criterion to show that if $\sigma_{\mathscr{E}}$ is not stable and is destabilized by the one-parameter subgroup associated with weights w_i and a basis s_i for $H^0(\mathscr{E})$, then for all pairs with $w_i + w_j > 0$, s_i and s_j lie in a common line sub-bundle. Then the Riemann–Roch formula can be used to show that the sub-line bundle associated to the largest weight destabilizes $\mathscr{E}$ as a bundle. The conclusion is that there is a projective embedding j: $W \to \mathbb{CP}^r$ obtained by composing γ with the embedding of U^*. (Similarly one finds that semi-stable bundles $\mathscr{E}$ have semi-stable maps $\sigma_{\mathscr{E}}$.)

We want now to show that the line bundle associated to this Gieseker embedding j can be identified with the power $\mathscr{L}^s$ of the determinant line bundle over W. We consider the even case for simplicity. Recall that we defined the determinant line bundle over the moduli space of bundles V with $\Lambda^2 V$ trivial by the index of the Dirac operator, which could be identified with the $\bar{\partial}$ operator after twisting by a square root of the canonical bundle. We will now clarify the role of this twisting. Observe first that the moduli space of bundles with $\Lambda^2 V$ trivial, up to bundle isomorphism, is identical with the moduli space of pairs (V, ψ) where ψ is an isomorphism from $\Lambda^2 V$ to $\mathcal{O}$. This is because the scalars act transitively on the maps ψ. So when classifying such bundles we may suppose we have a definite trivialization of Λ^2. Now for any line bundle θ over C we can assign to the pair (V, ψ) the line obtained from the cohomology of $V \otimes \theta$. If V is stable, say, the only automorphisms of (V, ψ) are ± 1, and since the numerical Euler characteristic of V is even this acts trivially on the determinant line. So, as in Chapter 5, we obtain a line bundle, $\mathscr{L}_\theta$ say, over the moduli space of stable holomorphic bundles with a trivialization of Λ^2. At first sight it may seem that we are obtaining different line bundles in this way, since the cohomology groups of $V \otimes \theta$ are not isomorphic for different θ. In reality, however, all these line bundles are isomorphic. To see this we represent line bundles by divisors on C. Suppose for example that $\theta = [P]$ is the line bundle associated with a point P in C. Then we have an exact sequence:

$$0 \longrightarrow V \longrightarrow V \otimes \theta \longrightarrow V \otimes \theta|_P \longrightarrow 0. \qquad (10.1.10)$$

The resulting long exact cohomology sequence, and the usual property of the 'multiplicative Euler characteristic' in exact sequences, gives a natural isomorphism between the determinant line of the cohomology of $V \otimes \theta$ and the tensor product of the determinant line of the cohomology of V and $\Lambda^2(V \otimes \theta)_P$. Fix a trivialization of the fibre of θ over P. Then the trivialization of $\Lambda^2 V$ gives us an isomorphism between the two determinant lines, and hence an isomorphism between $\mathscr{L}_\theta$ and $\mathscr{L}_0$. Repeating this procedure, we see that all the line bundles $\mathscr{L}_\theta$ are isomorphic. So we can use any twist to describe our basic line bundle $\mathscr{L}$ over the moduli space W_0.

With this preliminary observation we return to the line bundle induced by Gieseker's embedding—the pull-back by j of L_U, the quotient of the Hopf line bundle over $\mathbb{P}(\mathrm{Hom}(\Lambda^2\mathbb{C}^N, \mathbb{C}^q))$. We let $\mathscr{E} = V \otimes \mathscr{O}(p)$, and by the remarks above we suppose we have a fixed isomorphism between $\Lambda^2\mathscr{E}$ and $\mathscr{O}(2p)$. Now we introduce the moduli space of triples (V, ψ, f) where ψ is a trivialization of $\Lambda^2 V$ and f is an isomorphism:

$$f: H^0(V \otimes \mathscr{O}(p)) \longrightarrow \mathbb{C}^N.$$

Given such a triple we get a point $\sigma_{V,\psi,f}$ in $\mathrm{Hom}(\Lambda^2\mathbb{C}^N, \mathbb{C}^q)$ whose orbit is $j([V])$. Changing f to ζf, where ζ is in $\mathbb{C}^*$, changes $\sigma_{V,\psi,f}$ to $\zeta^{-1}\sigma_{V,\psi,f}$. Here we come to a point which we hurried past in Section 6.5. The centre $\mathbb{Z}/N$ of $SL(N, \mathbb{C})$ acts trivially on the projective space, so the Hopf line bundle need not descend to the quotient. However its N'th power will do, i.e. the line bundle L_U over the quotient lifts to this power of the Hopf bundle. So, by the discussion above, the choice of f gives a basis element in the fibre of the pull-back of L_U, and multiplication of f by ζ multiplies this basis element by ζ^N. On the other hand, the choice of f gives a basis element in the determinant line $\det H^0(V \otimes \mathscr{O}(p))$, and multiplication of f by ζ changes this by ζ^{-N}.

We deduce that there is a natural isomorphism between the line bundles $j^*(L_U)$ and the $\mathscr{L}_{\mathscr{O}(p)}$, the latter being the bundle with fibres $\det H^0(V \otimes \mathscr{O}(p))$ (since the other cohomology group is zero). In sum then we obtain a projective embedding j of W_0 by holomorphic sections of some high power sN of the determinant line bundle $\mathscr{L}$ over W_0.

There is one last fact to mention. The points of W_0 represent stable bundles and the holomorphic sections which give Gieseker's projective embedding can be viewed as holomorphic sections of a line bundle $\mathscr{L}$ over an open subset $\mathscr{A}_s$ of the space of connections ($\bar{\partial}$ operators) over C, invariant under the natural action of the complexified gauge group $\mathscr{G}^c$. However, these sections can all be extended holomorphically over the whole space $\mathscr{A}$. One can see this by examining the definition of the sections carefully or, more directly, by using the fact that (if $g > 0$) the complement of $\mathscr{A}_s$ has complex co-dimension two or more. We know then that for any stable point in $\mathscr{A}$ there is a holomorphic, invariant, section which does not vanish at that point. The last fact we need is that the same is true for the trivial connection or, more generally, for any connection which defines a semi-stable holomorphic bundle over C. The point $\sigma_{V \otimes \mathcal{O}(p)}$ defined by such a connection is semi-stable for the $SL(N, \mathbb{C})$ action, so this follows from the corresponding piece of theory for the finite-dimensional quotient.

10.1.4 Technical facts about moduli spaces

We will now begin our description of the detailed proof of (10.1.1) which will rely on a number of general facts about moduli spaces, which we will marshall in this section. The first point is that the ASD moduli spaces are *non-empty* when k is sufficiently large. This is true for any Riemannian four-manifold and was proved by Taubes (1984) for $SU(2)$-bundles and (as a special application of the results) by Taubes (1989) for $SO(3)$-bundles. In the algebro-geometric context the existence of stable holomorphic $SL(2, \mathbb{C})$ bundles was proved by Gieseker (1988); results on general two-plane bundles can be obtained using the Serre construction discussed in Section 10.2.

The next point concerns the dimension of the moduli space of stable bundles, i.e. the ASD connections relative to a Kähler metric. We know that for *generic* Riemannian metrics the moduli space of irreducible connections is regular, and is therefore smooth and of the proper 'virtual' dimension. But the Kähler metrics are not generic and it certainly may happen that we encounter moduli spaces with singularities of various kinds, or with components which have dimension larger than the virtual dimension. In the latter case the argument we have given above for the positivity of $q(h)$ is certainly not valid. The situation is quite analogous to the familiar intersection theory of subvarieties: if P, Q are complex subvarieties of an ambient compact complex manifold V, with $\dim V = \dim P + \dim Q$, and if the intersection of P and Q consists of isolated points, then the topological intersection number $[P].[Q]$ is positive. In fact $[P].[Q]$ is at least the number of intersection points. But if $P \cap Q$ has dimension one or more it may be that $[P].[Q]$ is negative. For example, we could take $P = Q$ to be an 'exceptional curve' on a surface, with self-intersection -1.

To avoid this difficulty we look at bundles with k large. Then it can be proved that each component of the moduli space has the proper dimension.

Precisely, let us define for the fixed Hodge metric:

$$\Sigma_{k,\alpha} = \{[A] \in M_{k,\alpha} | H_A^2 \neq 0\}.$$

Σ is a complex-analytic subspace of the complex space M_k and we have:

Proposition (10.1.11). *There are constants B_1, B_2 such that for all k and all reductions α of* (1, 1) *classes:*

$$\dim \Sigma_{k,\alpha} \leq 3k + B_1 k^{1/2} + B_2.$$

This is proved by Donaldson (1990*a*) for $SU(2)$ bundles, but the argument extends easily to the general case.

Thus the dimension of Σ grows more slowly than the virtual complex dimension $4k - 3(1 + p_g)$ of M_k. On the other hand, if the dimension of a component of M exceeds the virtual dimension, then this component is contained in Σ. It follows that for large k the moduli space does indeed have the proper dimension. Moreover the singular set has large codimension in M_k.

The third fact we want is that the moduli spaces, viewed as moduli spaces of stable bundles on our projective algebraic surface S, are themselves naturally complex varieties, in the sense of abstract algebraic geometry. This is the algebro-geometric analogue of the theory we studied from the transcendental point of view in Section 6.4, that the moduli spaces are Hausdorff complex spaces. It is a generalization of the theorem that holomorphic bundles over S are necessarily algebraic. What is asserted is, first, that the local versal deformations of algebraic vector bundles over S can be realized as algebraic vector bundles over $S \times V_\lambda$, where V_λ is a 'quasi-affine' variety (the difference $V \backslash W$ of affine varieties), and that the gluing maps

$$\begin{tikzcd}
\phi_{\lambda\mu}: V_{\lambda\mu} \arrow[r] \arrow[d, phantom, "\cap" rotate=0] & V_{\mu\lambda} \arrow[d, phantom, "\cap"] \\
V_\lambda & V_\mu
\end{tikzcd}$$

are represented by rational functions. Second, the statement that M_k is a complex variety asserts that M_k has 'finite type', i.e. that it can be covered by a finite number of quasi-affine patches V_α. This is closely related to our compactness theorem for moduli spaces of ASD connections. For proofs of these assertions see Maruyama (1977) and Gieseker (1977).

Next we want to study the restriction of stable holomorphic bundles on S to curves. The main theorem we need is the following result from Mehta and Ramanathan (1984).

Proposition (10.1.12) (Mehta and Ramanathan). *For any stable bundle $\mathscr{E}$ on S there is an integer p_0 such that, for $p \geq p_0$ and generic curves C in the linear system $|\mathscr{O}(p)|$ on S, the restriction of $\mathscr{E}$ to C is also stable.*

Now the stability condition is itself open, so for each (smooth) curve C in a linear system $|\mathcal{O}(p)|$ we have a Zariski open subset $U_C \subset M_k$ consisting of bundles whose restriction to C is stable. The proposition asserts that the union of the U_C, over all p and C, is the whole of M_k. But the finite type condition asserts that M_k is compact in the Zariski topology, so we can find a finite cover:

$$M = \bigcup_{i=1}^{R} U_i, \quad U_i = U_{C_i}. \qquad (10.1.13)$$

Moreover we can suppose that the curves C_i are in the same linear system $|\mathcal{O}(p)|$ and are in general position, with all triple intersections empty. Similarly we can suppose that for all pairs $[\mathcal{E}]$, $[\mathcal{F}]$ in M_k the cohomology group $H^1(\mathrm{Hom}(\mathcal{E}, \mathcal{F})(-p))$ is zero. Finally, replacing the given projective embedding by that defined by $|\mathcal{O}(p)|$, we may as well suppose that $p = 1$ and the curves C_i are hyperplane sections.

10.1.5 Restriction to curves

We can now construct a projective embedding of M_k, using restriction to complex curves in the surface S. We first consider the situation from the point of view of determinant line bundles. Suppose first that S is spin, so there is a square root $K_S^{1/2}$ of the canonical bundle. Let C be a curve in the linear system $|\mathcal{O}(2d)|$. There is an induced square root of K_C and an exact sequence:

$$0 \longrightarrow \mathcal{O}(-d) \otimes K_S^{1/2} \longrightarrow \mathcal{O}(d) \otimes K_S^{1/2} \longrightarrow K_C^{1/2} \longrightarrow 0. \qquad (10.1.14)$$

For any bundle $\mathcal{E}$ over S we get, just as for (10.1.10), an induced isomorphism of determinant lines:

$$\{\det H^*(\mathcal{E} \otimes K_S^{1/2} \otimes \mathcal{O}(d))\}\{\det H^*(\mathcal{E} \otimes K_S^{1/2} \otimes \mathcal{O}(-d))\}^{-1}$$
$$= \det H^*(\mathcal{E}|_C \otimes K_C^{1/2}).$$

The term on the right is the fibre of the determinant line bundle defined by restriction to C, whereas the expression on the left is independent of C. We deduce that restriction to different curves gives isomorphic line bundles over the ASD moduli space. This is an algebro-geometric version of Proposition (7.1.16). It is easy to remove the spin condition, and the requirement that the homology class of C be even, by introducing twisting factors just as in Section 10.1.3.

To sum up then, for each i we have a smooth moduli space $W_i = W(C_i)$, a determinant line bundle $\mathcal{L}_i$ over W_i and a projective embedding:

$$J_i \colon W_i \longrightarrow \mathbb{P}_i = \mathbb{P}(G_i^*)$$

associated with a vector space G_i of sections of $\mathcal{L}_i^N$. Now the restriction map

$$r_i \colon U_i \longrightarrow W_i$$
$$r_i(\mathcal{E}) = \mathcal{E}|_{C_i}$$

is regular, so we get composite maps $J_i r_i \colon U_i \to \mathbb{P}_i$. On M_k we have the fixed line bundle $\mathscr{L}$, and a holomorphic isomorphism from $\mathscr{L}$ to $\mathscr{L}_i$. So we can regard the G_i as spaces of sections of $\mathscr{L}^N$ over U_i, and these extend holomorphically over M_k by the remark at the end of Section 10.1.3. Hence we now have a space $G = \oplus\, G_i$ of sections of $\mathscr{L}^N$ over M_k, and for each point $\mathscr{E}$ in M_k there is a section in G not vanishing at $\mathscr{E}$. But this just means that we have an induced map,

$$J \colon M_k \longrightarrow \mathbb{P}(G^*) \quad \text{with } J^*(\mathcal{O}(l)) = \mathscr{L}^N.$$

This also holds with $k = 0$, when we have the moduli space with one point representing the trivial bundle, by the remark at the end of Section 10.1.3. The maps $J_i r_i$ are of course the composites of J with the projection maps to the individual factors. They are rational maps on M_k, regular on U_i.

To see that J is an embedding we use the vanishing of the cohomology groups $H^1(\mathrm{Hom}(\mathscr{E}, \mathscr{F})(-1))$. This implies that any two bundles $\mathscr{E}, \mathscr{F}$ which become isomorphic when restricted to some C_i are already isomorphic over S. Then the fact that J is injective follows from the corresponding property of the J_i. Similarly, taking $\mathscr{E} = \mathscr{F}$, we see that J is an immersion. As a final technicality, we can arrange the given set of surfaces to have the desired properties for all the finite number of moduli spaces M_j for $j \leq k$. So we have embeddings, which we will still denote by J, of M_j in the same projective space, and similarly $J_i \colon M_j \to \mathbb{P}_i$.

10.1.6 The detailed argument

By examining Gieseker's algebraic construction one sees that the embedding J of the algebraic variety is defined by a rational map. It is a general fact that the image of an abstract complex variety under a projective embedding by a rational map is a *quasi-projective* variety, i.e. the difference $V_1 \setminus V_2$ of projective varieties. For any quasi-projective variety $Y \subset \mathbb{CP}^r$ we define the degree $\deg(Y)$ to be the degree of the projective variety $\bar{Y}$; it is the number of intersection points of a generic $\overline{\mathbb{CP}^q}$ $(q = r - \dim \Omega)$ with Y, and if Y is non-empty the degree is always strictly positive. So the proof of our main theorem (10.1.1) is completed by the next lemma:

Lemma (10.1.15).

(i) *Let* $J \colon M_k \to \mathbb{P}(G)$ *be the projective embedding, defined by sections of* $\mathscr{L}^N$, *constructed above. Then the degree of the image* $J(M_k)$ *is independent of the choice of curves* C_i.

(ii) *For sufficiently large* k, $q_k([C_i]) = (1/N^d)\deg(J(M_k))$.

Proof. To prove (i) it suffices to show that if we extend a given collection of curves $C_1, \ldots, C_L$ by another one C_{L+1} then the degree of the resulting projective embeddings is unchanged. But this follows immediately from the general fact that if a projection $\mathbb{P}^{n+s} \to \mathbb{P}^n$ (a rational map) restricts to a subvariety $Q \subset \mathbb{P}^{n+s}$ to give an embedding $\pi: Q \to \mathbb{P}^n$, then the degrees of Q and its image $\pi(Q)$ are equal. To prove (ii) we trace through the definition of our polynomial invariant q_k using restriction to surfaces, and make an appropriate choice of the curves C_i. Let us suppose inductively that we have chosen curves C_i ($i = 1, \ldots, l$) in general position, and sections g_i in G_i so that the common zero set

$$Z_l^{(k)} = Z(g_1, \ldots, g_l) = \{[\mathscr{E}] \in M_k \,|\, g_i(\mathscr{E}) = 0, \quad i = 1, \ldots, l\}$$

has the following good properties:

(i) $Z_l^{(k)}$ has the correct dimension $d - l$,

(ii) $Z_l^{(k)} \cap \Sigma$ has the correct dimension $\dim \Sigma - l$.

(iii) On a dense open subset of $(M_k \backslash \Sigma) \cap Z_l^{(k)}$ the zeros of g_i are transverse.

(iv) For all the lower moduli spaces M_i the zero sets

$$Z_l^{(i)} = \{[\mathscr{E}] \in M_i \mid g_j(\mathscr{E}) = 0, \quad j = 1, \ldots, l\}$$

have dimension $\dim M_i - l$.

To pass from l to $l + 1$ we note that, as quasi-projective varieties, all of the $Z_l^{(i)}$ and $Z_l^{(k)} \cap \Sigma$ have finitely many components. We choose a point in each component, i.e. a finite set of bundles $\mathscr{E}_\lambda$. Then we can, by (10.1.12), choose a curve C_{l+1} such that all the $\mathscr{E}_\lambda$ are stable on C_{l+1}. Thus the generic hyperplane section of $\mathbb{P}_{l+1}$ induces a section g_{l+1} which does not vanish at any of the $\mathscr{E}_\lambda$; then the zero sets $Z_{l+1}^{(i)}$ do not contain any component of the $Z_l^{(i)}$ and it follows that they have the proper dimension. So, inductively, we can choose a set of curves $C_1, \ldots, C_d$ and sections $g_1, \ldots, g_d$ such that the common zero set in M_k is a finite set of points $\{E_\mu\}$, none contained in Σ, and with the general position properties (i)–(iv) with respect to the lower moduli spaces.

Now on the one hand we can extend this collection of curves, if necessary, to get a projective embedding of M_k. The g_i represent hyperplane sections of $J(M_k)$ and the number of points in the intersection, counted with appropriate multiplicities, represents the degree of $J(M_k)$ *provided* there are no 'zeros at infinity', i.e. no common zeros of all the g_i in $\overline{J(M_k)} \backslash J(M_k)$. On the other hand, from the point of view of the general set-up in Chapters 5 and 9, each g_i represents a section of the determinant line bundle $\mathscr{L}_i$, and its zero set represents a codimension-two submanifold V_{C_i} in the space of connections. The intersection $M_k \cap V_{C_1} \cap \ldots \cap V_{C_d}$ is by construction a finite set of points $\{A_\mu\}$. To prove the equality of $q_k(\alpha)$ and $\deg(J(M_k))$ we have to check three things:

(*a*) That the multiplicities with which we count the points, regarded either as intersections in the projective space P or in the space of connections, agree. That is, if we perturb the Kähler metric to a nearby generic metric and perturb the V_{C_i} to be transverse, as in the definition of Section 9.2.1, the intersections A_μ split up into the correct number of nearby transverse intersection points.

(*b*) That when we perturb the metric and V_{C_i} as in Section 10.1.1, all the new intersection points are close to the A_μ.

(*c*) That in the projective space $\mathbb{P}$ there are no common zeros of the g_i in $\overline{J(M_k)}\backslash J(M_k)$.

Of these (*a*) is quite straightforward; it is just the assertion that the local multiplicity of the zero set equals the multiplicity of any transverse deformation. Points (*b*) and (*c*) are more interesting and the proof is much the same in each case. We begin with (*c*), and suppose that on the contrary there is a zero in $\overline{J(M_k)}\backslash J(M_k)$. Then we can find a sequence of holomorphic bundles $\mathscr{E}_\alpha$ over S without convergent subsequences but with all $g_i(\mathscr{E}_\alpha)$ tending to zero as α tends to ∞. Regarded as ASD connections A_α we can apply our compactness theorem and, without loss of generality, suppose that A_α tends to a limiting connection A_∞ on the complement of a finite set of points $\{x_\nu\}$. The limiting connection has Chern class $l < k$ say, and there are at most $k - l$ points x_ν. We now apply our familiar argument: for any curve C_i which does not contain any of the points x_ν the restriction of the connections converges in C^∞; it follows that for any such i, $g_i(A_\infty)$ is zero. But we have arranged that all the multiple zeros of the g_i in the lower moduli spaces are of the appropriate dimension (property (iv) above), so if d_l is the complex dimension of M_l we must have:

$$d_l + 2(k - l) \geq d = 4k - 3(1 + p_g). \tag{10.1.16}$$

In the present situation we do not know that all the lower moduli spaces have the correct (virtual) dimension. But we do know that this holds for large enough values, $j \geq k_0$, of the Chern class, by (10.1.11). We put

$$D = \max_{j \leq k_0} \dim_{\mathbf{C}} M_j.$$

Then if $2k > D + 3(1 + p_g)$ (say) the inequality (10.1.16) cannot hold, thus verifying property (*c*). Precisely the same argument shows that for a sequence of metrics $g^{(\alpha)} \to g$ and sections $g_i^{(\alpha)} \to g_i$, the common zeros in the perturbed moduli space $M_k(g^{(\alpha)})$ converge to the A_μ, verifying property (*b*).

10.2 Construction of holomorphic bundles

10.2.1 Extensions

In this section we will describe general techniques for constructing holomorphic bundles out of linear data. Consider first a complex manifold Z and

Relativistic Mass

As the relative speed between two inertial reference frames gets closer to the speed of light, the effects of special relativity—including time dilation and length contraction—become more pronounced. In the limit that the relative speed approaches the speed of light, time slows down to a complete stop and length contracts to zero. However, you **can't** actually reach this limit. An object that has mass can be accelerated to nearly light speed (like 0.99c or 0.999c), but can never reach the speed of light exactly.

In Galilean relativity, it would be very easy to accelerate an object faster than the speed of light. According to **Newton's second law** of motion, the net force acting on an object equals the object's mass times its acceleration:

$$\sum \vec{\mathbf{F}} = m\vec{\mathbf{a}}.$$

(This equation applies to objects that have constant mass, but that's not a problem for Galilean relativity, where ordinarily an object's mass isn't expected to change while it accelerates.) The mass of an electron is 9.1×10^{-31} kg. If you applied a force of just 1 N (one Newton) to an electron, according to Galilean relativity, the electron would experience an acceleration of

$$a = \frac{F}{m} = \frac{1\ \mathrm{N}}{9.1\times10^{-31}\mathrm{kg}} = 1.1 \times 10^{30}\mathrm{m/s^2}.$$

What does this **acceleration** mean? It means that starting from rest, after a just 1 s (one second), an electron would have a speed of $v = 1.1 \times 10^{30}$ m/s (since acceleration describes the rate at which velocity increases). That's way, way faster than the speed of light in vacuum, which is $c = 2.9979 \times 10^{8}$ m/s.

In the laboratory, it doesn't happen that way. Although it is very easy to accelerate electrons to very high speeds, once the speed of an electron reaches the neighborhood of the speed of light in vacuum, it becomes increasingly harder to accelerate the electron. We can accelerate electrons up to 0.9c or even 0.99c, but trying to reach 0.99999c is extremely difficult. Why? According to Einstein's theory of relativity, mass isn't constant: The faster an electron travels, the more mass the electron has (relative to the laboratory). We call this **relativistic mass**.

Recall that mass is a measure of **inertia** in the following sense: The more mass an object has, the more difficult it is to overcome the object's inertia in order to accelerate the object. The relativistic mass of an object describes the object's inertia. As the object travels closer to the speed of light (relative to an inertial reference frame), the greater its relativistic mass (and relativistic inertia): It becomes harder and harder to accelerate the object.

There are two types of mass:

* 1= > / " 1= ?
1 ? 1 ? " 1= 1
@ * 1= > ? / " 1= ?

i.e. points so that all chords through them have constant length. The problem is studied extensively in note 6.3, chapter 6 of Gardner 1995 [548]. Do not miss the recent revolution in the theory of plane curves: see the end of §1.4.

1.3.2 Curvature

We now look at the outer geometry of plane curves. The inner geometry of curves does not differ from that of straight lines, but the geometry is radically different if we look at the way a curve sits in the plane. We are going to introduce a concept of *curvature* which measures how much a curve differs from a straight line. For a curve seen as a kinematic motion, curvature is directly linked with the *acceleration* vector $c''(t)$. For a geometric curve, we can introduce it by looking at the variation of the length of the curves drawn at a constant distance, called the *parallel curves* (recall the first variation equation 1.2 on page 4). If the absolute value of the infinitesimal change of length of these equidistant curves, close to a point $m = c(t)$, is the same as for a circle of radius r we say that the curve c has *radius of curvature* r at $m = c(t)$, and that its curvature is $K = 1/r$. The formula to compute curvature is

$$K(t) = \frac{1}{r(t)} = \frac{|\det(c'(t), c''(t))|}{\|c'(t)\|^3}$$

where t is any parameter, and boils down to

$$K(t) = \frac{1}{r(t)} = \|c''(t)\|$$

when t is a unit speed parameterization (i.e. arc length parameterization). Of course a circle of radius R has constant curvature equal to $1/R$. Another way to look at it is the following: the circle $C(t)$ which is defined as tangent to the curve at the point $c(t)$ and has radius $r(t)$ is the circle which has the most intimate contact with the curve (technically, the contact is third order, meaning that the curve and the circle have the same first three derivatives at that point). This circle is called the *osculating circle* to the curve at $m = c(t)$.

To rest a little, we mention an interesting fact rarely found in textbooks. When at a point m of the curve c, the curvature varies, that is to say $dK/dt(m) \neq 0$, then the osculating circle at m crosses the curve (guess where it is inside, and where outside). A baffling consequence is that the osculating circles of of a curve whose curvature is never critical never intersect one another. See the picture in figure 1.15. This picture gives two counterexamples. First, consider the unit tangent vectors to this family of circles. We get a continuous vector field, alias a differential equation in the plane. Now at every point of the curve there are at least *two* different integral curves of that vector field: namely the curve and the circle. The moral is that uniqueness of solutions of ordinary differential equations does not follow only from continuity. Second, consider the envelope of this family of circles. In many books it

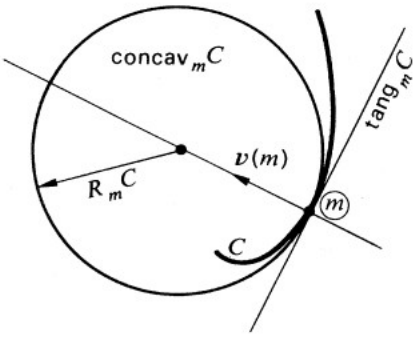

Fig. 1.15. Finding tangent line, concavity and curvature

is "proven" that the envelope is the limit of the so-called characteristic point, the point of intersection of close-by curves. This is wrong (unless we invoke "complex circles").

There is another geometric definition of the curvature. Parameterize the curve by arc length, so that $\|c'(t)\| = 1$ identically. Then $c'(t)$ is a unit vector, running through the unit circle of the plane. The curvature is the speed of its rotation. More precisely, one needs first to orient the plane, and choose an oriented direction in the plane. Then one can define an angle $\alpha(t)$ for $c'(t)$ which is a real number, defined only up to integer multiples of 2π. The curvature is $K(t) = d\alpha/dt$.

To get rid of the 2π ambiguity, there is an important fact which we are going to use below. For regular curves, when t runs through the interval of definition, one can follow $\alpha(t)$ by continuity and then define a map $t \mapsto \alpha(t)$ into $\mathbb{R}$. Note that if the curve is closed with period T then $\alpha(t+T)$ will in general differ from $\alpha(t)$ by an integral multiple of 2π.

We saw above that straight lines are the shortest paths between two points. Let us look at this again, now in a more sophisticated way. We start with a curve c with ends $p = c(a)$ and $q = c(b)$. Suppose it is as short as any curve can be with these extremities. Consider any one parameter family of curves c_μ with the same ends, with $c = c_0$, and compute their lengths. The fact that the length should be a minimum implies in particular that the first derivative of the length as a function of the parameter μ has to vanish. Computation yields

$$\left.\frac{d\,\mathrm{length}\,(c_\mu)}{d\mu}\right|_{\mu=0} = -\int_a^b \langle f(s), c''(s)\rangle \; ds \tag{1.3}$$

where the vector valued function $f(s)$ (which we can choose to be orthogonal to the curve everywhere) estimates the derivative of the normal displacement of the family of curves. This is also a first variation formula. Note that this formula is nothing but the integrated version of the definition we previously gave for curvature. A classical calculus trick (which is not obvious) proves that if we want all of these derivatives to vanish, namely the above integral

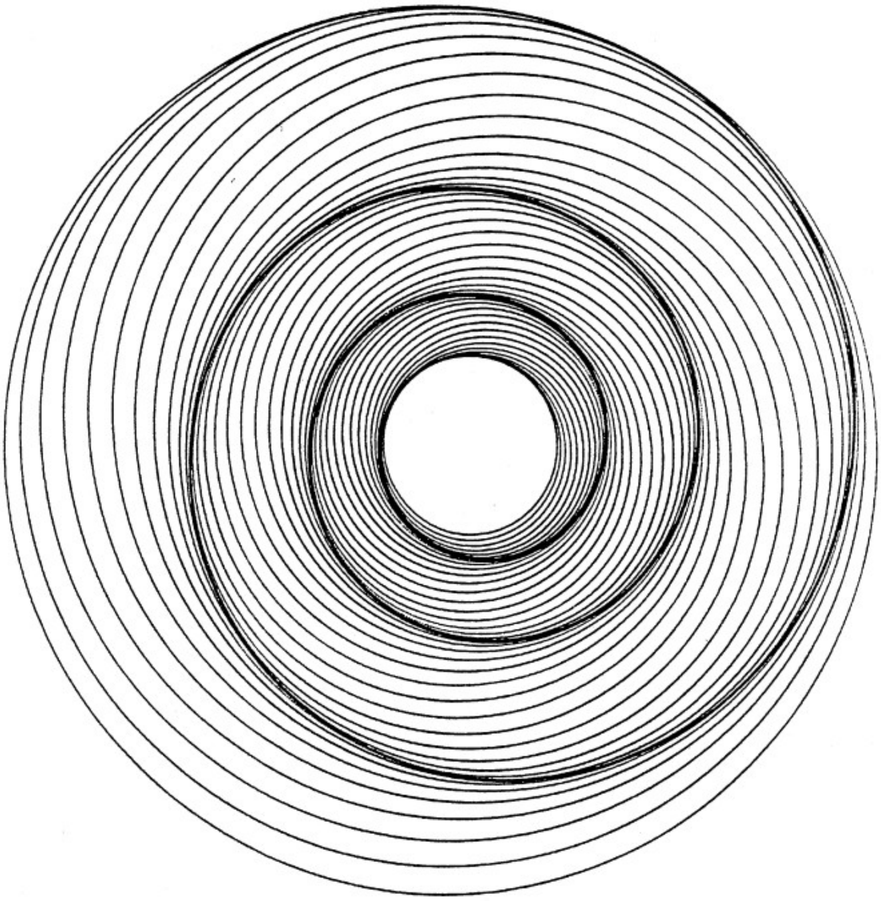

Fig. 1.16. Picture drawn for us by Etienne Ghys

to be 0 whatever the function f vanishing at $s = a$ and $s = b$, then $c''(t) = 0$ identically, and in particular our curve should have everywhere vanishing curvature. Curves with everywhere vanishing curvature are, of course, straight lines. Beware: what we have proven up to now by this method is that shortest paths can only be found among straight lines. Not every zero of the derivative of a function is a minimum. For a local minimum, a sufficient condition is to have positive second derivative. But we still have to search for an absolute minimum. The above proof is interesting because it is the simplest model of a field called *the calculus of variations*, and gives a general scheme to start searching for shortest paths. We will use it soon in §1.6 but principally in chapter 6. To conclude this story for the Euclidean plane, we know that if shortest paths exist, they should be straight lines. Then we check directly as above.

Fig. 1.17. Different definitions of curvature

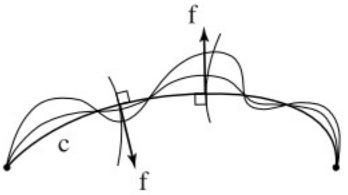

Fig. 1.18. Planar calculus of variations

There is a notion of *algebraic curvature* k as opposed to the scalar curvature K, linked by $K = |k|$. This is defined as soon as the curve is regular and oriented and the plane is also oriented, or (equivalently) if one side of the geometric curve is chosen, or (equivalently) if one of the two possible unit normal vectors is chosen. This side need not be the concavity side. Denote by $n(t)$ the unit normal vector you have chosen. Remember now that $c''(t)$ is an invariant. The algebraic curvature of c at t is the real number $k(t)$ so that

$$c''(t) = k(t)n(t)$$

A nice theorem about algebraic curvature:

Theorem 1 (More tightly curved curves) *If two curves c_1, c_2 are arc length parameterized, and have respective curvatures satisfying $k_1(t) \geq k_2(t)$ and start at the same initial point in the same direction, then the curve c_1 lies entirely inside the curve c_2.*

(because it is "more curved" as intuition tells you). For a proof see Chern 1989 [366] and exercise 7, section 5-7 of do Carmo 1976 [451]. Beware that you need simple curves if you want a global result. If not, you just get a local one. The

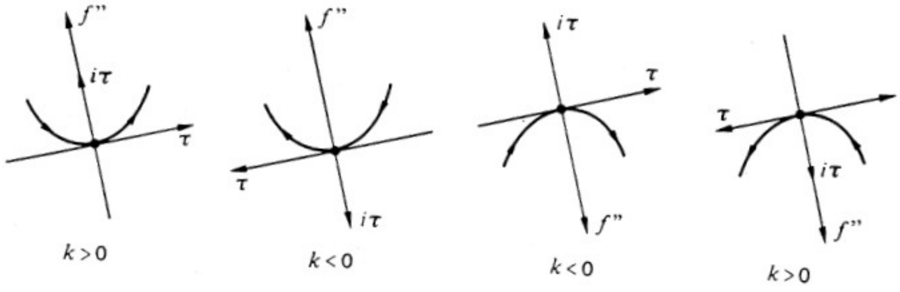

Fig. 1.19. Picturing algebraic curvatures

above theorem is one of the simplest ones in *control theory*. You will see many, many others later on. Note the following amusing consequences. Consider a simple closed plane curve, and the point where the curvature is maximum. Then the osculating circle at that point can keep rolling inside the curve all the way around. Similarly, the curve itself can roll inside its osculating circle of minimum curvature.

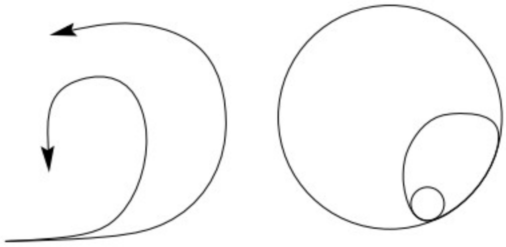

Fig. 1.20. (a) One is more curved than the other **(b)** The little circle can roll inside the closed curve, and the closed curve can roll inside the big circle

Let us make more precise our claim above that curvature is the only invariant of plane curves. More precisely the algebraic curvature is a characteristic invariant: if in the above inequality for curvatures we have equality ($k_1(t) = k_2(t)$ for every t) then the curves c_1 and c_2 are the same. Moral: if you know the value of the curvature as a function of the arc length then you know the curve completely. If the curves do not have the same initial point and direction, this just means that they are deduced one from the other by a Euclidean motion. The simplest example: a curve with non-zero constant curvature is part (or the whole) of a circle.

A spectacular application of this property of arcs of circle is the manufacture of a perfect straightedge. Take two pieces (of anything suitable for the job) and rub one against the other. The above theorem tells you that such a rubbing will eventually carve the two bounding curves into perfect circles. Now take three pieces, and rub them two by two. The boundaries will be circles, but the pieces will have to exhibit opposite convexity, i.e. equal algebraic curvature with opposite sign. For three, this is not possible unless the common curvature is zero. Naively, one might imagine that a laser can draw straight lines, but this is impractical. Today, lasers are used only to check the accuracy of the straightedge, after it is manufactured following the above recipe; once the laser has reported its evaluation of the straightedge, corrections are carried out by skilled hands using emery powder. Before the invention of the laser, accuracy was tested with interferences.

The same technique is still the only one available to make "perfect" planes: rub three surfaces against one another, and the result has to be a plane. To prove it, use the fact which we will quote on page 47 that pieces of a surface, all of whose points are umbilics, are pieces of spheres. To check accuracy, one doesn't use a laser, but drags a straightedge around on the surface, or a comparison plane, or applies an interferometer.[3] Rubbing only two pieces will yield pieces of a sphere, and is still the only method to sculpt spherical lenses.

In the same spirit, to fashion "perfect" balls, (which have thousands of practical applications, for example as ball bearings), one method was to put approximate balls inside a box, and stir them. Proof that the limit object is a sphere is not as elementary as proofs of the efficacy of the previous production methods, and was only recently established in Andrews 1999 [52]. Since 1907, balls for ball bearings have been produced by rolling rough balls between two plates with toroidal concentric groves and random indentations. See Berger 2003 [173] or technical books for more details.

For the story of curves in $\mathbb{E}^3$ see Berger and Gostiaux 1988 [175], do Carmo 1976 [451], or Stoker 1989 [1160]. We will just mention briefly what happens there. This time there are two characteristic invariants, curvature and torsion, but the curves need to be biregular, i.e. the acceleration should never vanish. Things also extend similarly to any $\mathbb{E}^d$, this time with $d-1$ invariants: see Spivak 1979 [1155]. But the first invariant is always the curvature and is defined simply as the norm $\|c''(t)\|$ for any arc-length parameterization. Only straight lines have everywhere zero curvature. For the kinematician this is the old fact that points with no force applied to them move along straight lines and at constant speed.

Take helices for example. They can be characterized as the curves with constant curvature and torsion. A practical application, in the spirit of the one just above: graduate a straightedge to make ruler; this is equivalent to making a protractor, dividing a circle in equal parts, etc. It is clear that you can do it if you can produce a screw (a helix). This is even simpler than a straightedge. Just start with an approximately good pair of a bolt and a nut and rub one against the other. At the end we will get a perfect bolt, and a perfect nut, because the common boundary will be made up of a union of curves with necessarily constant metric invariants, hence easily seen to be helices.

---

[3] An *interferometer* is a device which uses the interference of two waves (radio, acoustic, or light waves will do) to make very precise distance measurements.

Chapter 8
Coulomb Collisions in Astrophysical Plasma

Abstract Binary collisions of particles with the Coulomb potential of interaction are typical for physics of collisional plasmas in space and especially for gravitational systems. Coulomb collisions of fast particles with plasma particles determine momentum and energy losses of fast particles, the relaxation processes in astrophysical plasma.

8.1 Close and Distant Collisions

8.1.1 The Collision Parameters

Binary interactions of particles, described by the Coulomb potential

$$\varphi(r) = \frac{e}{r}\,, \tag{8.1}$$

have been studied in mechanics (see Landau and Lifshitz (1976), Chap. 4, Sect. 19). Considering binary interactions as *collisions*, we are interested only in their final result, the duration of the interaction and the actual form of particle trajectories being neglected. Thus in the centre-of-mass system, each particle is deflected through an angle χ defined by the relation

$$\tan\frac{\chi}{2} = \frac{e_1 e_2}{m v^2\, l} \tag{8.2}$$

or

$$l\,(\chi) = \frac{e_1 e_2}{m v^2}\,\cot\frac{\chi}{2}\,. \tag{8.3}$$

Here

$$m = \frac{m_1 m_2}{m_1 + m_2} \tag{8.4}$$

On the other hand, in the *Bastille day flare* on 2000 July 14 (see Chaps. 6 and 7) as well as in some other large solar flares, it was possible to detect the real changes in the sunspot structure just after a flare.

> The outer penumber fields became more vertical due to magnetic reconnection in the corona during a flare

(Liu et al. 2005; Wang et al. 2005). One can easily imagine such changes by considering, for example, Fig. 4.1 between sunspots N and s.

Sudol and Harvey (2005) have used the *Global Oscillation Network Group* (GONG) magnetograms to characterize the changes in the photospheric vertical component of magnetic field during 15 large solar flares. An abrupt, significant, and persistent change in the magnetic field occurred in at least one location within the flaring active region during each event after its start. Among several possible interpretations for these observations, Sudoh and Harvey favor one in which

> the magnetic field changes result from the penumber field relaxing upward by reconnecting magnetic field above the photosphere.

This interpretation is very similar to than one given by Liu et al. (2005) and Wang et al. (2005).

The topological model (Somov et al. 2008) self-consistently explains the following observational effects in the photosphere during and after the large flare on 2000 July 14 (see Chap. 6): (a) the enhancement of the horizontal and vertical magnetic fields at the center of an active region (AR) and the weakening of the horizontal field on the AR periphery; (b) the decrease in the AR magnetic flux as a whole; and (c) the convergence of the center-of-mass positions of opposite magnetic polarities. Therefore the entire set of these observations can be interpreted as the result of a magnetic-field restructuring in the corona caused by magnetic reconnection.

As for the second objection (2) to the hypothesis of accumulation of energy in the form of magnetic field of *slowly-reconnecting* current layers in the solar atmosphere, the rapid dissipation of the field necessary for the flare is naturally explained by the theory of current layers presented in what follows, especially in Chaps. 8 and 9).

4.2 The Simple Topological Model of an Active Region

4.2.1 The Potential Magnetic Field Approximation

Gorbachev and Somov (1989, 1990) have developed a three-dimensional (3D) model for a *potential* magnetic field in the active region AR 2776 with an extended solar flare on 1980 November 5. Before discussing the active region and the flare (see Sect. 4.3.1), let us consider, at first, the general properties of this class of models called *topological*.

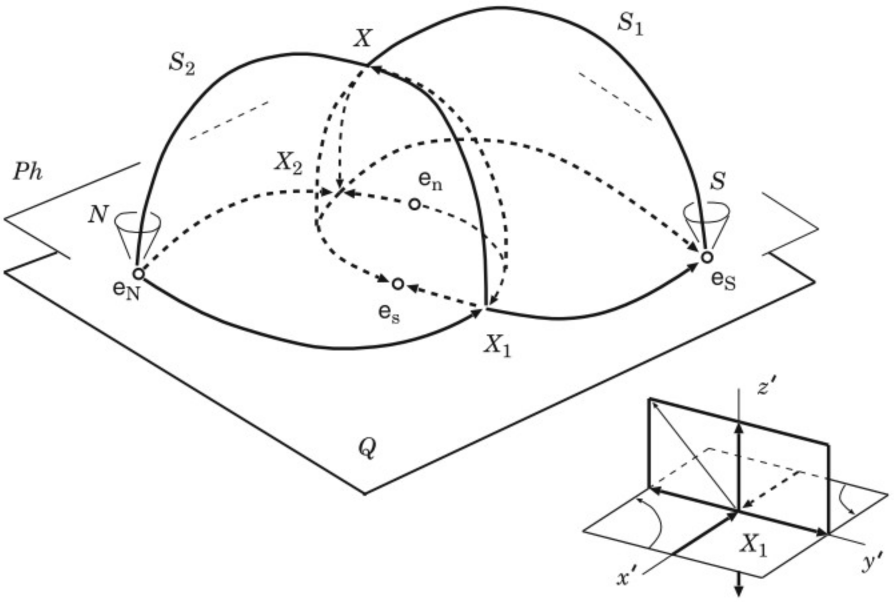

Fig. 4.2 The model for the magnetic field of four sunspots of pairwise opposite polarity. The sunspots N and S in the photospheric plane Ph. The separatrices S_1 and S_2 cross at the separator X_1XX_2 above the plane Q of the effective magnetic 'charges' e_{N}, e_{S}, etc

In the simplest variant of the model (Gorbachev and Somov1988), four magnetic field sources – the magnetic 'charges' e_{N} and e_{S}, e_{n} and e_{s}, located in the plane Q under the photosphere Ph (Fig. 4.2) – are used to reproduce the main features of the observed field in the photosphere related to the four most important sunspots: N, S, n and s. As a consequence, the *quadrupole* model reproduces only the large-scale features of the actual field in the corona related to these sunspots. As a minimum, the four sources are necessarily to describe two interacting magnetic fluxes having the two sources per each. The larger number of sources are not necessarily much better.

The main features are two magnetic surfaces, the boundary surfaces called the *separatrices* S_1 and S_2 (Fig. 4.2). They divide the whole space above the under-photospheric plane Q into four regions and, correspondingly, the whole magnetic field into four magnetic fluxes having different linkages. The field lines are grouped into four regions according to their termini. The separatrices of the potential magnetic field are formed from field lines beginning or ending at magnetic zeroth points X_1 and X_2. For example, the field lines originating at the point X_1 form a separatrix surface S_1 (for more detail see Gorbachev et al. 1988).

There is a topologically singular field line X_1XX_2 lying at the intersection of the two separatrices, it belongs to all four fluxes (two reconnecting and two reconnected fluxes) that interact at this line – the 3D magnetic *separator*. So

> the separator separates the interacting magnetic fluxes by the separatrices above the plane of magnetic sources

(cf. Fig. 1.4a; see also Sweet 1969; Lau 1993). Detection of a separator, as a field line that connects two zeroth points in the Earth magnetotail, by the four *Cluster* spacecraft (Xiao et al. 2007) provides an important step towards establishing an observational framework of 3D reconnection.

4.2.2 Classification of Zeroth Points

Let us clarify the basic properties of the zeroth points of the magnetic field discussed above. In the vicinity of a zeroth point X_i located at $\mathbf{r} = \mathbf{r}_i$ in the plane Q, the vector of magnetic field can be represented in the form

$$B_\alpha(\mathbf{r}) = \frac{\partial \psi}{\partial r_\alpha} = M_{\alpha\beta}(\mathbf{r}_i)\,\xi_\beta\,. \tag{4.2}$$

Here $\psi(\mathbf{r})$ is the potential of the field, the vector $\xi = \mathbf{r} - \mathbf{r}_i$, the index $i = 1, 2$; the Greek indices $\alpha, \beta = 1, 2, 3$ or x, y, z. The symmetric matrix

$$M_{\alpha\beta}(\mathbf{r}_i) = \frac{\partial^2 \psi\,(\mathbf{r}_i)}{\partial r_\alpha\, \partial r_\beta} = \begin{vmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{vmatrix} \tag{4.3}$$

in the frame of coordinates r'_α related to the eigenvectors $\mathbf{e}'_\alpha$, λ_α are the eigenvalues of the matrix. Because the magnetic field is potential, all the λ_α are real numbers (e.g., Dubrovin et al. 1986). Positive eigenvalues λ_α correspond to the magnetic-field lines emerging from a zeroth point and negative λ_α correspond to the field lines arriving at a point $\mathbf{r}_i$.

If the determinant

$$\det M_{\alpha\beta}(\mathbf{r}_i) = \lambda_1 \lambda_2 \lambda_3 \neq 0\,, \tag{4.4}$$

then the zeroth point is called *non-degenerate*. Such a point is *isolated*, i.e., the magnetic field in its vicinity does not vanish.

Since div $\mathbf{B} = 0$, we obtain a condition

$$\lambda_1 + \lambda_2 + \lambda_3 = 0\,. \tag{4.5}$$

Therefore there exist only three following classes of zeroth points of magnetic field (see Gorbachev et al. 1988).

Type A. All eigenvalues $\lambda_\alpha \neq 0$. This corresponds to two zeroth points shown in Fig. 4.2. At the first point X_1

$$\lambda_1 < 0\,, \quad \lambda_2 > 0\,, \quad \lambda_3 > 0\,. \tag{4.6}$$

METRIC CONNECTIONS IN PROJECTIVE DIFFERENTIAL GEOMETRY*

MICHAEL EASTWOOD† AND VLADIMIR MATVEEV‡

(In memory of Thomas Branson)

Abstract. We search for Riemannian metrics whose Levi-Civita connection belongs to a given projective class. Following Sinjukov and Mikeš, we show that such metrics correspond precisely to suitably positive solutions of a certain projectively invariant finite-type linear system of partial differential equations. Prolonging this system, we may reformulate these equations as defining covariant constant sections of a certain vector bundle with connection. This vector bundle and its connection are derived from the Cartan connection of the underlying projective structure.

Key words. Projective differential geometry, metric connection, tractor.

AMS(MOS) subject classifications. Primary 53A20; Secondary 58J70.

1. Introduction. We shall always work on a smooth oriented manifold M of dimension n. Suppose that ∇ is a torsion-free connection on the tangent bundle of M. We may ask whether there is a Riemannian metric on M whose geodesics coincide with the geodesics of ∇ as unparameterised curves. We shall show that there is a linear system of partial differential equations that precisely controls this question.

To state our results, we shall need some terminology, notation, and preliminary observations. Two torsion-free connections ∇ and $\hat{\nabla}$ are said to be projectively equivalent if they have the same geodesics as unparameterised curves. A projective structure on M is a projective equivalence class of connections. In these terms, we are given a projective structure on M and we ask whether it may be represented by a metric connection. Questions such as this have been addressed by many authors. Starting with a metric connection, Sinjukov [9] considered the existence of other metrics with the same geodesics. He found a system of equations that controls this question and Mikeš [7] observed that essentially the same system pertains when starting with an arbitrary projective structure.

We shall use Penrose's abstract index notation [8] in which indices act as markers to specify the type of a tensor. Thus, ω_a denotes a 1-form whilst X^a denotes a vector field. Repeated indices denote the canonical

---

*This work was undertaken during the 2006 Summer Program at the Institute for Mathematics and its Applications at the University of Minnesota. The authors would like to thank the IMA for hospitality during this time. The first author is supported by the Australian Research Council.

pairing between vectors and co-vectors. Thus, we shall write $X^a\omega_a$ instead of $X \lrcorner\, \omega$. The tautological 1-form with values in the tangent bundle is denoted by the Kronecker delta $\delta_a{}^b$.

As is well-known [5], the geometric formulation of projective equivalence may be re-expressed as

$$\hat{\nabla}_a X^b = \nabla_a X^b + \Upsilon_a X^b + \delta_a{}^b \Upsilon_c X^c \tag{1.1}$$

for an arbitrary 1-form Υ_a. We shall also adopt the curvature conventions of [5]. In particular, it is convenient to write

$$(\nabla_b\nabla_a - \nabla_a\nabla_b)X^b = R_{ab}X^b,$$

where R_{ab} is the usual Ricci tensor, as

$$(\nabla_b\nabla_a - \nabla_a\nabla_b)X^b = (n-1)\mathrm{P}_{ab}X^b - \beta_{ab}X^b \quad \text{where } \beta_{ab} = \mathrm{P}_{ba} - \mathrm{P}_{ab}.$$

If a different connection is chosen in the projective class according to (1.1), then

$$\hat{\beta}_{ab} = \beta_{ab} + \nabla_a\Upsilon_b - \nabla_b\Upsilon_a.$$

Therefore, as a 2-form β_{ab} changes by an exact form. On the other hand, the Bianchi identity implies that β_{ab} is closed. Thus, there is a well-defined de Rham cohomology class $[\beta] \in H^2(M, \mathbb{R})$ associated to any projective structure.

PROPOSITION 1.1. *The class $[\beta] \in H^2(M, \mathbb{R})$ is an obstruction to the existence of a metric connection in the given projective class.*

Proof. The Ricci tensor is symmetric for a metric connection. □

In searching for a metric connection in a given projective class, we may as well suppose that the obstruction $[\beta]$ vanishes. For the remainder of this article we suppose that this is the case and we shall consider only representative connections with symmetric Ricci tensor. In other words, all connections from now on enjoy

$$(\nabla_b\nabla_a - \nabla_a\nabla_b)X^b = (n-1)\mathrm{P}_{ab}X^b \quad \text{where } \mathrm{P}_{ab} = \mathrm{P}_{ba}. \tag{1.2}$$

A convenient alternative characterisation of such connections as follows.

PROPOSITION 1.2. *A torsion-free affine connection has symmetric Ricci tensor if and only if it induces the flat connection on the bundle of n-forms.*

Proof. If $\epsilon^{pqr\cdots s}$ has n indices and is totally skew then

$$(\nabla_a\nabla_b - \nabla_b\nabla_a)\epsilon^{pqr\cdots s} = \kappa_{ab}\epsilon^{pqr\cdots s}$$

for some 2-form κ_{ab}. But, by the Bianchi symmetry,

$$(\nabla_a\nabla_b - \nabla_b\nabla_a)\epsilon^{abr\cdots s} = -2R_{ab}\epsilon^{abr\cdots s},$$

which vanishes if and only if R_{ab} is symmetric. □

Having restricted our attention to affine connections that are flat on the bundle of n-forms, we may as well further restrict to connections ∇_a for which there is a volume form $\epsilon_{bc\cdots d}$ (necessarily unique up to scale) with $\nabla_a\epsilon_{bc\cdots d} = 0$. We shall refer to such connections as special. The freedom in special connections within a given projective class is given by (1.1) where $\Upsilon_a = \nabla_a f$ for an arbitrary smooth function f. Following [5], the full curvature of a special connection may be conveniently decomposed:

$$(\nabla_a\nabla_b - \nabla_b\nabla_a)X^c = W_{ab}{}^c{}_dX^d + \delta_a{}^c\mathrm{P}_{bd}X^d - \delta_b{}^c\mathrm{P}_{ad}X^d, \qquad (1.3)$$

where $W_{ab}{}^c{}_d$ is totally trace-free and P_{ab} is symmetric. The tensor $W_{ab}{}^c{}_d$ is known as the Weyl curvature and is projectively invariant.

2. A linear system of equations. In this section we present, as Proposition 2.1, an alternative characterisation of the Levi-Civita connection. The advantage of this characterisation is that it leads, almost immediately, to a system of linear equations that controls the metric connections within a given projective class. The precise results are Theorems 2.1 and 2.2.

PROPOSITION 2.1. *Suppose g^{ab} is a metric on M with volume form $\epsilon_{bc\cdots d}$. Then a torsion-free connection ∇_a is the metric connection for g^{ab} if and only if*

- $\nabla_a g^{bc} = \delta_a{}^b\mu^c + \delta_a{}^c\mu^b$ *for some vector field μ^a*
- $\nabla_a\epsilon_{bc\cdots d} = 0$.

Proof. Write D_a for the metric connection of g^{ab}. Then

$$\nabla_a\omega_b = D_a\omega_b - \Gamma_{ab}{}^c\omega_c \qquad (2.1)$$

for some tensor $\Gamma_{ab}{}^c = \Gamma_{ba}{}^c$. We compute

$$\epsilon^{bc\cdots d}\nabla_a\epsilon_{bc\cdots d} = -n\epsilon^{bc\cdots d}\Gamma_{ab}{}^e\epsilon_{ec\cdots d} = -n!\,\Gamma_{ab}{}^b$$

and so $\Gamma_{ab}{}^b = 0$. Similarly,

$$\nabla_a g^{bc} = \Gamma_{ad}{}^b g^{dc} + \Gamma_{ad}{}^c g^{bd}$$

and so

$$\Gamma_{ad}{}^b g^{dc} + \Gamma_{ad}{}^c g^{bd} = \delta_a{}^b\mu^c + \delta_a{}^c\mu^b. \qquad (2.2)$$

Let g_{ab} denote the inverse of g^{ab} and contract (2.2) with g_{bc} to conclude that

$$2\Gamma_{ab}{}^b = 2\mu_a \quad \text{where } \mu_a = g_{ab}\mu^b$$

and hence that $\mu^a = 0$. If we let $\Gamma_{abc} = \Gamma_{ab}{}^d g_{cd}$, then (2.2) now reads

$$\Gamma_{acb} + \Gamma_{abc} = 0.$$

Together with $\Gamma_{abc} = \Gamma_{bac}$, this implies that $\Gamma_{abc} = 0$. From (2.1) we see that $\nabla_a = D_a$, which is what we wanted to show. □

THEOREM 2.1. *Suppose ∇_a is a special torsion-free connection and there is a metric tensor σ^{ab} such that*

$$\nabla_a\sigma^{bc} = \delta_a{}^b\mu^c + \delta_a{}^c\mu^b \quad \text{for some vector field } \mu^a. \tag{2.3}$$

Then ∇_a is projectively equivalent to a metric connection.

Proof. Consider the projectively equivalent connection

$$\hat\nabla_a X^b = \nabla_a X^b + \Upsilon_a X^b + \delta_a{}^b\Upsilon_c X^c \quad \text{where } \Upsilon_a = \nabla_a f$$

for some function f. If we let $\hat\sigma^{ab} \equiv e^{-2f}\sigma^{ab}$, then

$$\begin{aligned}\hat\nabla_a\hat\sigma^{bc} &= e^{-2f}\left(-2\Upsilon_a\sigma^{bc} + \nabla_a\sigma^{bc} + 2\Upsilon_a\sigma^{bc} + \delta_a{}^b\Upsilon_d\sigma^{dc} + \delta_a{}^c\Upsilon_d\sigma^{bd}\right)\\ &= e^{-2f}\left(\delta_a{}^b\mu^c + \delta_a{}^c\mu^b + \delta_a{}^b\Upsilon_d\sigma^{dc} + \delta_a{}^c\Upsilon_d\sigma^{bd}\right)\end{aligned}$$

and so

$$\hat\nabla_a\hat\sigma^{bc} = \delta_a{}^b\hat\mu^c + \delta_a{}^c\hat\mu^b \quad \text{where } \hat\mu^a = e^{-2f}\left(\mu^a + \Upsilon_b\sigma^{ab}\right). \tag{2.4}$$

Similarly, if we choose a volume form $\epsilon_{bc\cdots d}$ killed by ∇_a and let $\hat\epsilon_{bc\cdots d} \equiv e^{(n+1)f}\epsilon_{bc\cdots d}$, then

$$\hat\nabla_a\hat\epsilon_{bc\cdots d} = e^{(n+1)f}\left(\nabla_a\epsilon_{bc\cdots d} + \Upsilon_{[a}\epsilon_{bc\cdots d]}\right) = e^{(n+1)f}\nabla_a\epsilon_{bc\cdots d} = 0. \tag{2.5}$$

Define

$$\det(\sigma) \equiv \epsilon_{a\cdots b}\epsilon_{c\cdots d}\sigma^{ac}\cdots\sigma^{bd}$$

and compute

$$\begin{aligned}\widehat{\det}(\hat\sigma) &= \hat\epsilon_{a\cdots b}\hat\epsilon_{c\cdots d}\hat\sigma^{ac}\cdots\hat\sigma^{bd}\\ &= e^{2(n+1)f}e^{-2nf}\epsilon_{a\cdots b}\epsilon_{c\cdots d}\sigma^{ac}\cdots\sigma^{bd} = e^{2f}\det(\sigma).\end{aligned}$$

Therefore, if we take

$$f = -\tfrac{1}{2}\log\det(\sigma),$$

then we have arranged that $\widehat{\det}(\hat\sigma) = 1$. This is precisely the condition that $\hat\epsilon_{bc\cdots d}$ be the volume form for the metric $\hat\sigma^{ab}$. With (2.4) and (2.5) we are now in a position to use Proposition 2.1 to conclude that $\hat\nabla_a$ is the metric connection for $\hat\sigma^{ab}$. We have shown that our original connection ∇_a is projectively equivalent to the Levi-Civita connection for the metric $g^{ab} \equiv \det(\sigma)\,\sigma^{ab}$. □

Evidently, the equations (2.3) precisely control the metric connections within a given special projective class. Precisely, if g_{ab} is a Riemannian metric with associated Levi-Civita connection ∇_a, then

$$\hat\nabla_a\hat g^{bc} = \delta_a{}^b\hat\mu^c + \delta_a{}^c\hat\mu^b,$$

where $\hat{\nabla}_a$ is projectively equivalent to ∇_a according to (1.1) with $\Upsilon_a = \nabla_a f$ and where $\hat{g}^{bc} = e^{-2f} g^{bc}$. In other words, we have shown (cf. [7, 9]):–

THEOREM 2.2. *There is a one-to-one correspondence between solutions of* (2.3) *for positive definite* σ^{bc} *and metric connections that are projectively equivalent to* ∇_a.

3. Prolongation. Let us consider the system of equations (2.3) in more detail. It is a linear system for any symmetric contravariant 2-tensor σ^{bc}. Specifically, we may write (2.3) as

$$\text{the trace-free part of } (\nabla_a \sigma^{bc}) = 0 \tag{3.1}$$

or, more explicitly, as

$$\nabla_a \sigma^{bc} - \tfrac{1}{n+1} \delta_a{}^b \nabla_d \sigma^{cd} - \tfrac{1}{n+1} \delta_a{}^c \nabla_d \sigma^{bd} = 0.$$

According to [2], this equation is of finite-type and may be prolonged to a closed system as follows. According to (1.2) and (1.3) we have

$$(\nabla_a \nabla_b - \nabla_b \nabla_a) \sigma^{bc} = W_{ab}{}^c{}_d \sigma^{bd} + \delta_a{}^c \mathrm{P}_{bd} \sigma^{bd} - n \mathrm{P}_{ad} \sigma^{cd}.$$

On the other hand, from (2.3) we have

$$(\nabla_a \nabla_b - \nabla_b \nabla_a) \sigma^{bc} = (n+1) \nabla_a \mu^c - \nabla_b (\delta_a{}^b \mu^c + \delta_a{}^c \mu^b) = n \nabla_a \mu^c - \delta_a{}^c \nabla_b \mu^b.$$

We conclude that

$$n \nabla_a \mu^c = \delta_a{}^c \left(\nabla_b \mu^b + \mathrm{P}_{bd} \sigma^{bd} \right) - n \mathrm{P}_{ad} \sigma^{cd} + W_{ab}{}^c{}_d \sigma^{bd}$$

or, equivalently, that

$$\nabla_a \mu^c = \delta_a{}^c \rho - \mathrm{P}_{ad} \sigma^{cd} + \tfrac{1}{n} W_{ab}{}^c{}_d \sigma^{bd}, \tag{3.2}$$

for some function ρ. To complete the prolongation, we use (1.2) to write

$$(\nabla_c \nabla_a - \nabla_a \nabla_c) \mu^c = (n-1) \mathrm{P}_{ac} \mu^c$$

whereas from (3.2) we also have

$$\begin{aligned}(\nabla_c \nabla_a - \nabla_a \nabla_c) \mu^c = {} & \nabla_c \left(\delta_a{}^c \rho - \mathrm{P}_{ad} \sigma^{cd} + \tfrac{1}{n} W_{ab}{}^c{}_d \sigma^{bd} \right) \\ & - \nabla_a \left(n\rho - \mathrm{P}_{cd} \sigma^{cd} \right).\end{aligned}$$

Therefore,

$$\begin{aligned}(n-1) \mathrm{P}_{ac} \mu^c = {} & \nabla_c \left(-\mathrm{P}_{ad} \sigma^{cd} + \tfrac{1}{n} W_{ab}{}^c{}_d \sigma^{bd} \right) \\ & -(n-1) \nabla_a \rho + \nabla_a (\mathrm{P}_{cd} \sigma^{cd}).\end{aligned} \tag{3.3}$$

The terms involving Weyl curvature

$$\nabla_c(W_{ab}{}^c{}_d\sigma^{bd}) = (\nabla_c W_{ab}{}^c{}_d)\sigma^{bd} + W_{ab}{}^c{}_d\nabla_c\sigma^{bd}$$

may be dealt with by (2.3) and a Bianchi identity

$$\nabla_c W_{ab}{}^c{}_d = (n-2)(\nabla_a \mathrm{P}_{bd} - \nabla_b \mathrm{P}_{ad}).$$

We see that

$$\nabla_c(W_{ab}{}^c{}_d\sigma^{bd}) = (n-2)(\nabla_a \mathrm{P}_{bd} - \nabla_b \mathrm{P}_{ad})\sigma^{bd}$$

and (3.3) becomes

$$\begin{aligned}(n-1)\mathrm{P}_{ac}\mu^c = {} & \tfrac{n-2}{n}(\nabla_a \mathrm{P}_{bd} - \nabla_b \mathrm{P}_{ad})\sigma^{bd} - \nabla_c(\mathrm{P}_{ad}\sigma^{cd}) \\ & -(n-1)\nabla_a\rho + \nabla_a(\mathrm{P}_{cd}\sigma^{cd})\end{aligned}$$

or, equivalently,

$$\begin{aligned}\mathrm{P}_{ac}\mu^c = {} & \tfrac{2}{n}(\nabla_a \mathrm{P}_{bd} - \nabla_b \mathrm{P}_{ad})\sigma^{bd} - \tfrac{1}{n-1}\mathrm{P}_{ad}\nabla_c\sigma^{cd} \\ & -\nabla_a\rho + \tfrac{1}{n-1}\mathrm{P}_{cd}\nabla_a\sigma^{cd}.\end{aligned} \tag{3.4}$$

Again, we substitute from (2.3) to rewrite

$$\mathrm{P}_{cd}\nabla_a\sigma^{cd} - \mathrm{P}_{ad}\nabla_c\sigma^{cd} = \mathrm{P}_{cd}(\delta_a{}^c\mu^d + \delta_a{}^d\mu^c) - (n+1)\mathrm{P}_{ad}\mu^d = -(n-1)\mathrm{P}_{ad}\mu^d$$

and (3.4) becomes

$$\mathrm{P}_{ac}\mu^c = \tfrac{2}{n}(\nabla_a \mathrm{P}_{bd} - \nabla_b \mathrm{P}_{ad})\sigma^{bd} - \mathrm{P}_{ad}\mu^d - \nabla_a\rho,$$

which we may rearrange as

$$\nabla_a\rho = -2\mathrm{P}_{ab}\mu^b + \tfrac{2}{n}(\nabla_a \mathrm{P}_{bd} - \nabla_b \mathrm{P}_{ad})\sigma^{bd}.$$

Together with (2.3) and (3.2), we have a closed system, essentially as in [7, 9]:

$$\begin{aligned}\nabla_a\sigma^{bc} &= \delta_a{}^b\mu^c + \delta_a{}^c\mu^b \\ \nabla_a\mu^b &= \delta_a{}^b\rho - \mathrm{P}_{ac}\sigma^{bc} + \tfrac{1}{n}W_{ac}{}^b{}_d\sigma^{cd} \\ \nabla_a\rho &= -2\mathrm{P}_{ab}\mu^b + \tfrac{4}{n}Y_{abc}\sigma^{bc}\end{aligned} \tag{3.5}$$

where $Y_{abc} = \frac{1}{2}(\nabla_a \mathrm{P}_{bc} - \nabla_b \mathrm{P}_{ac})$, the Cotton-York tensor. The three tensors σ^{bc}, μ^b, and ρ may be regarded together as a section of the vector bundle

$$\mathcal{T} = \bigodot^2 TM \oplus TM \oplus \mathbb{R}$$

where $\bigodot$ denotes symmetric tensor product and $\mathbb{R}$ denotes the trivial bundle. We have proved:

THEOREM 3.1. *If we endow $\mathcal{T}$ with the connection*

$$\begin{pmatrix} \sigma^{bc} \\ \mu^b \\ \rho \end{pmatrix} \longmapsto \begin{pmatrix} \nabla_a\sigma^{bc} - \delta_a{}^b\mu^c - \delta_a{}^c\mu^b \\ \nabla_a\mu^b - \delta_a{}^b\rho + \mathrm{P}_{ac}\sigma^{bc} - \frac{1}{n}W_{ac}{}^b{}_d\sigma^{cd} \\ \nabla_a\rho + 2\mathrm{P}_{ab}\mu^b - \frac{4}{n}Y_{abc}\sigma^{bc} \end{pmatrix} \tag{3.6}$$

then there is a one-to-one correspondence between covariant constant sections of $\mathcal{T}$ and solutions σ^{bc} of (2.3).

4. Projective invariance. The equation (2.3) is projectively invariant in the following sense. Following [5], let $\mathcal{E}^{(ab)}(w)$ denote the bundle of symmetric contravariant 2-tensors of projective weight w. Thus, in the presence of a volume form $\epsilon_{bc\cdots d}$, a section $\sigma^{ab} \in \Gamma(M, \mathcal{E}^{(ab)}(w))$ is an ordinary symmetric contravariant 2-tensor but if we change volume form

$$\epsilon_{bc\cdots d} \mapsto \hat{\epsilon}_{bc\cdots d} = e^{(n+1)f}\epsilon_{bc\cdots d} \quad \text{for any smooth function } f,$$

then we are obliged to rescale σ^{ab} according to $\hat{\sigma}^{ab} = e^{wf}\sigma^{ab}$. Equivalently, we are saying that $\mathcal{E}^{(ab)}(w) = \bigodot^2 TM \otimes (\Lambda^n)^{-w/(n+1)}$, where Λ^n is the line-bundle of n-forms on M. The projectively weighted irreducible tensor bundles are fundamental objects on a manifold with projective structure.

PROPOSITION 4.1. *The differential operator*

$$\mathcal{E}^{(ab)}(-2) \longrightarrow \text{the trace-free part of } \mathcal{E}_a{}^{(bc)}(-2) \tag{4.1}$$

defined by (3.1) *is projectively invariant.*

Proof. This is already implicit in the proof of Theorem 2.1. Explicitly, however, we just compute from (1.1):

$$\hat{\nabla}_a\hat{\sigma}^{bc} = \nabla_a\hat{\sigma}^{bc} + 2\Upsilon_a\hat{\sigma}^{bc} + \delta_a{}^b\Upsilon_d\hat{\sigma}^{dc} + \delta_a{}^c\Upsilon_d\hat{\sigma}^{bd},$$

where $\Upsilon_a = \nabla_a f$ whilst

$$\nabla_a\hat{\sigma}^{bc} = \nabla_a(e^{-2f}\sigma^{bc}) = e^{-2f}\left(\nabla_a\sigma^{bc} - 2\Upsilon_a\sigma^{bc}\right) = \widehat{\nabla_a\sigma^{bc}} - 2\Upsilon_a\hat{\sigma}^{bc}.$$

It follows that

$$\hat{\nabla}_a\hat{\sigma}^{bc} = \widehat{\nabla_a\sigma^{bc}} + \text{trace terms},$$

which is what we wanted to show. □

In hindsight, it is not too difficult to believe that (3.1) should control the metric connections within a given projective class. There are very few projectively invariant operators. In fact, there are precisely two finite-type first order invariant linear operators on symmetric 2-tensors. One of them is (4.1) and the other is

$$\mathcal{E}_{(ab)}(4) \to \mathcal{E}_{(abc)}(4) \quad \text{given by} \quad \sigma_{ab} \mapsto \nabla_{(a}\sigma_{bc)}. \tag{4.2}$$

In two dimensions, (4.2) and (4.1) coincide. In higher dimensions, however, being in the kernel of (4.2) for positive definite σ_{ab} corresponds to having a metric g_{ab} and a totally trace-free tensor Γ_{abc} with

$$\Gamma_{abc} = \Gamma_{bac} \quad \text{and} \quad \Gamma_{abc} + \Gamma_{bca} + \Gamma_{cab} = 0$$

such that the connection

$$\omega_b \longmapsto D_a\omega_b - \Gamma_{ab}{}^c\omega_c$$

belongs to the projective class of ∇_a, where D_a is the Levi-Civita connection of g_{ab}. The available tensors Γ_{abc} for a given metric have dimension $n(n+2)(n-2)/3$.

5. Relationship to the Cartan connection. On a manifold with projective structure, it is shown in [5] how to associate vector bundles with connection to any irreducible representation of $\mathrm{SL}(n+1,\mathbb{R})$. These are the tractor bundles following their construction by Thomas [10]. Equivalently, they are induced by the Cartan connection [4] of the projective structure. The relevant tractor bundle in our case is induced by $\bigodot^2\mathbb{R}^{n+1}$ where $\mathbb{R}^{n+1}$ is the defining representation of $\mathrm{SL}(n+1,\mathbb{R})$. It has a composition series

$$\mathcal{E}^{(BC)} = \mathcal{E}^{(bc)}(-2) + \mathcal{E}^b(-2) + \mathcal{E}(-2)$$

and in the presence of a connection is simply the direct sum of these bundles. Under projective change of connection according to (1.1), however, we decree that

$$\widehat{\begin{pmatrix} \sigma^{bc} \\ \mu^b \\ \rho \end{pmatrix}} = \begin{pmatrix} \sigma^{bc} \\ \mu^b + \Upsilon_c\sigma^{bc} \\ \rho + 2\Upsilon_b\mu^b + \Upsilon_b\Upsilon_c\sigma^{bc} \end{pmatrix}. \tag{5.1}$$

Following [5], the tractor connection on $\mathcal{E}^{(AB)}$ is given by

$$\nabla_a \begin{pmatrix} \sigma^{bc} \\ \mu^b \\ \rho \end{pmatrix} = \begin{pmatrix} \nabla_a\sigma^{bc} - \delta_a{}^b\mu^c - \delta_a{}^c\mu^b \\ \nabla_a\mu^b - \delta_a{}^b\rho + \mathrm{P}_{ac}\sigma^{bc} \\ \nabla_a\rho + 2\mathrm{P}_{ab}\mu^b \end{pmatrix}.$$

Therefore, we have proved:

THEOREM 5.1. *The solutions of* (2.3) *are in one-to-one correspondence with solutions of the following system:*

$$\nabla_a \begin{pmatrix} \sigma^{bc} \\ \mu^b \\ \rho \end{pmatrix} - \frac{1}{n}\begin{pmatrix} 0 \\ W_{ac}{}^b{}_d\sigma^{cd} \\ 4Y_{abc}\sigma^{bc} \end{pmatrix} = 0. \tag{5.2}$$

COROLLARY 5.1. *There is a one-to-one correspondence between solutions of* (5.2) *for positive definite* σ^{bc} *and metric connections that are projectively equivalent to* ∇_a.
Notice that the extra terms in (5.2) are projectively invariant as they should be. Specifically, it is observed in [5] that

$$\hat{Y}_{abc} = Y_{abc} + \tfrac{1}{2} W_{ab}{}^{d}{}_{c} \Upsilon_d$$

and so

$$4\hat{Y}_{abc}\sigma^{bc} = 4Y_{abc}\sigma^{bc} + 2\Upsilon_b W_{ac}{}^{b}{}_{d}\sigma^{cd}$$

in accordance with (5.1).

It is clear from Theorem 3.1 that, generically, (2.3) has no solutions. Indeed, this is one reason why the prolonged from is so helpful. More generally, we should compute the curvature of the connection (3.6) and the form (5.2) is useful for this task. A model computation along these lines is given in [5]. In our case, the tractor curvature is given by

$$(\nabla_a\nabla_b - \nabla_b\nabla_a)\begin{pmatrix} \sigma^{cd} \\ \mu^c \\ \rho \end{pmatrix} = \begin{pmatrix} W_{ab}{}^{c}{}_{e}\sigma^{de} + W_{ab}{}^{d}{}_{e}\sigma^{ce} \\ W_{ab}{}^{c}{}_{d}\mu^d + 2Y_{abd}\sigma^{cd} \\ 4Y_{abc}\mu^c \end{pmatrix}$$

and we obtain:

PROPOSITION 5.1. *The curvature of the connection* (3.6) *is given by*

$$\begin{pmatrix} \sigma^{cd} \\ \mu^c \\ \rho \end{pmatrix} \mapsto \begin{pmatrix} W_{ab}{}^{c}{}_{e}\sigma^{de} + W_{ab}{}^{d}{}_{e}\sigma^{ce} \\ W_{ab}{}^{c}{}_{d}\mu^d + 2Y_{abd}\sigma^{cd} \\ 4Y_{abc}\mu^c \end{pmatrix} + \frac{1}{n}\begin{pmatrix} \delta_a{}^{c}U_b{}^{d} + \delta_a{}^{d}U_b{}^{c} - \delta_b{}^{c}U_a{}^{d} - \delta_b{}^{d}U_a{}^{c} \\ * \\ * \end{pmatrix},$$

where $U_b{}^d = W_{be}{}^{d}{}_{f}\sigma^{ef}$ *and* $*$ *denotes expressions that we shall not need.*

COROLLARY 5.2. *The curvature of the connection* (3.6) *vanishes if and only if the projective structure is flat.*

Proof. Let us suppose that $n \geq 3$. The uppermost entry of the curvature is given by

$$\sigma^{cd} \longmapsto \text{the trace-free part of } (W_{ab}{}^{c}{}_{e}\sigma^{de} + W_{ab}{}^{d}{}_{e}\sigma^{ce})$$

and it is a matter of elementary representation theory to show that if this expression is zero for a fixed $W_{ab}{}^{c}{}_{d}$ and for all σ^{cd}, then $W_{ab}{}^{c}{}_{d} = 0$. Specifically, the symmetries of $W_{ab}{}^{c}{}_{d}$, namely

$$W_{ab}{}^{c}{}_{d} + W_{ba}{}^{c}{}_{d} = 0, \qquad W_{ab}{}^{c}{}_{d} + W_{bd}{}^{c}{}_{a} + W_{da}{}^{c}{}_{b} = 0, \qquad W_{ab}{}^{a}{}_{d} = 0, \quad (5.3)$$

constitute an irreducible representation of $\mathrm{SL}(n,\mathbb{R})$. Hence, the submodule

$$\{W_{ab}{}^c{}_d \text{ s.t. the trace-free part of } (W_{ab}{}^c{}_e\sigma^{de} + W_{ab}{}^d{}_e\sigma^{ce}) = 0,\ \forall\, \sigma^{cd}\}$$

must be zero since it is not the whole space. We have shown that if the curvature of the connection (3.6) vanishes, then $W_{ab}{}^c{}_d = 0$. For $n \geq 3$ this is exactly the condition that the projective structure be flat. For $n = 2$, the Weyl curvature $W_{ab}{}^c{}_d$ vanishes automatically since the symmetries (5.3) are too severe a constraint. Instead, a similar calculation shows that $Y_{abc} = 0$ and this is the condition that the projective structure be flat. □

Following Mikeš [7], the dimension of the space of solutions of (2.3) is called the degree of mobility of the projective structure. Theorem 3.1 implies that the degree of mobility is bounded by $(n+1)(n+2)/2$ and Corollary 5.2 implies that this bound is achieved only for the flat projective structure. Of course, the flat projective structure may as well be represented by the flat connection $\nabla_a = \partial/\partial x^a$ on $\mathbb{R}^n$, which is the Levi-Civita connection for the standard Euclidean metric. In this case, we may use (3.5) find the general solution of (2.3):

$$\sigma^{ab} = s^{ab} + x^a m^b + x^b m^a + x^a x^b r. \tag{5.4}$$

This form is positive definite near the origin if and only if s^{ab} is positive definite. We conclude that the general projectively flat metric near the origin in $\mathbb{R}^n$ is

$$g^{ab} = \det(\sigma)\,\sigma^{ab},$$

where σ^{ab} is as in (5.4) for some positive definite quadratic form s^{ab}. In fact, these metrics are constant curvature. Rather than prove this by calculation, there is an alternative as follows. As already observed, the Weyl curvature $W_{ab}{}^c{}_d$ corresponds to an irreducible representation of $\mathrm{SL}(n,\mathbb{R})$ characterised by (5.3). In the presence of a metric g_{ab}, however, we should decompose $W_{ab}{}^c{}_d$ further under $\mathrm{SO}(n)$.

PROPOSITION 5.2. *In the presence of a metric* g_{ab}

$$\begin{aligned} W_{ab}{}^c{}_d = C_{ab}{}^c{}_d &+ \tfrac{1}{(n-1)(n-2)}\left(\delta_a{}^c\Phi_{bd} - \delta_b{}^c\Phi_{ad}\right) \\ &+ \tfrac{1}{n-2}\left(\Phi_a{}^c g_{bd} - \Phi_b{}^c g_{ad}\right) \end{aligned} \tag{5.5}$$

where $C_{ab}{}^c{}_d$ *is the Weyl part of the Riemann curvature tensor and* Φ_{ab} *is the trace-free part of the Ricci tensor.*

Proof. According to (1.3),

$$R_{ab}{}^c{}_d = W_{ab}{}^c{}_d + \delta_a{}^c\mathrm{P}_{bd} - \delta_b{}^c\mathrm{P}_{ad} \tag{5.6}$$

but the Riemann curvature decomposes according to

$$R_{abcd} = C_{abcd} + g_{ac}Q_{bd} - g_{bc}Q_{ad} + Q_{ac}g_{bd} - Q_{bc}g_{ad}, \tag{5.7}$$

where Q_{ab} is the Schouten tensor

$$Q_{ab} = \tfrac{1}{n-2}\Phi_{ab} + \tfrac{1}{2n(n-1)}Rg_{ab}.$$

Comparing (5.6) and (5.7) leads, after a short computation, to (5.5). □

COROLLARY 5.3. *A projectively flat metric is constant curvature.*

Proof. If $n \geq 3$ and the projective Weyl tensor vanishes then the only remaining part of the Riemann curvature tensor is the scalar curvature. As usual, a separate proof based on Y_{abc} is needed for the case $n = 2$. □

This corollary is usually stated as follows. If a local diffeomorphism between two Riemannian manifolds preserves geodesics and one of them is constant curvature, then so is the other. This is a classical result due to Beltrami [1].

6. Concluding remarks. Results such as Theorem 2.2 and Theorem 5.1 are quite common in projective, conformal, and other parabolic geometries. It is shown in [5], for example, that the Killing equation in Riemannian geometry is projectively invariant and its solutions are in one-to-one correspondence with covariant constant sections of the tractor bundle $\mathcal{E}_{[AB]}$ equipped with a connection that is derived from (but not quite equal to) the tractor connection. The situation is completely parallel for conformal Killing vectors in conformal geometry and, more generally, for the infinitesimal automorphisms of parabolic geometries [3]. It is well-known that having an Einstein metric in a given conformal class is equivalent to having a suitably positive covariant constant section of the standard tractor bundle $\mathcal{E}^A$ equipped with its usual tractor connection. Gover and Nurowski [6] use this observation systematically to find obstructions to the existence of an Einstein metric within a given conformal class. We anticipate a similar use for Theorem 5.1 in establishing obstructions to the existence of a metric connection within a given projective class.

Chapter 2
Sphere

"The description of right lines and circles, upon which geometry is founded, belongs to mechanics. Geometry does not teach us to draw these lines, but requires them to be drawn."

Isaac Newton (1642–1727)

"Geometry is the art of correct reasoning from incorrectly drawn figures."

Henri Poincaré (1854–1912)

Spherical geometry is almost as old as Euclidean geometry. In fact, the word geometry means 'measurement of the Earth', and the Earth is (more or less) a sphere. The ancient Greek geometers knew that the Earth was spherical. Navigation motivated the study of spherical geometry because, even 2000 years ago, the fact that the earth is curved had a noticeable effect on cartography. In spherical geometry, the 'points' are points on the surface of the sphere. We are not concerned with the 'inside' of the sphere.

2.1 The Sphere $\mathbb{S}^2$ in $\mathbb{R}^3$

The (unit) sphere is

$$\mathbb{S}^2 = \{(x, y, z) \in \mathbb{R}^3 \mid x^2 + y^2 + z^2 = 1\}.$$

N.-H. Lee, *Geometry: from Isometries to Special Relativity*, Undergraduate Texts in Mathematics, https://doi.org/10.1007/978-3-030-42101-4_2

A *great circle* is a circle on the sphere that divides the sphere into two equal hemispheres. A great circle can also be defined as the intersection of the sphere and a plane that goes through the origin **0**. Two points that are diametrically opposite on the sphere are called *antipodal points*. In spherical geometry, two points determine a great circle unless they are antipodal points, in which case there are infinitely many great circles joining them.

For two points $p_1 = (x_1, y_1, z_1)$ and $p_2 = (x_2, y_2, z_2)$ in $\mathbb{S}^2$, the distance between them in $\mathbb{R}^3$ is

$$d(p_1, p_2) = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2}.$$

The *spherical distance* $d_{\mathbb{S}^2}(p_1, p_2)$ is the arc length of the shortest path on $\mathbb{S}^2$ from p_1 to p_2, which is a segment of the great circle through the points p_1 and p_2 (Figure 2.1).

Note that

$$d_{\mathbb{S}^2}(p_1, p_2) = \angle p_1 \mathbf{0} p_2 = 2\theta = 2 \arcsin\left(\frac{1}{2} d(p_1, p_2)\right), \tag{2.1}$$

where $\theta = \frac{1}{2}\angle p_1 \mathbf{0} p_2$ (Figure 2.2).

A plane in $\mathbb{R}^3$ is a set of points defined by a linear equation,

$$ax + by + cz = d,$$

where a, b, c, and d are constants with $(a, b, c) \neq (0, 0, 0)$. Similar to a line in the Euclidean plane, a plane in $\mathbb{R}^3$ can be regarded as the set of points equidistant from two distinct points p_1 and p_2 in $\mathbb{R}^3$:

$$P_{p_1, p_2} = \{p \in \mathbb{R}^3 \mid d(p_1, p) = d(p_2, p)\}.$$

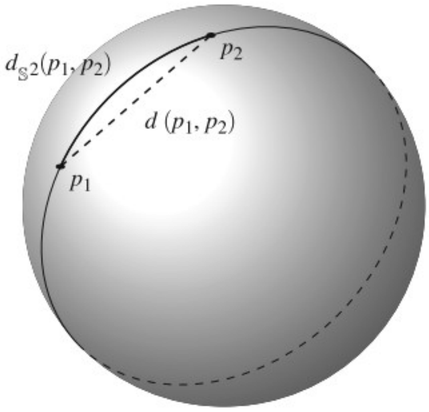

Fig. 2.1 Spherical distance $d_{\mathbb{S}^2}(p_1, p_2)$ between the two points p_1 and p_2 on $\mathbb{S}^2$

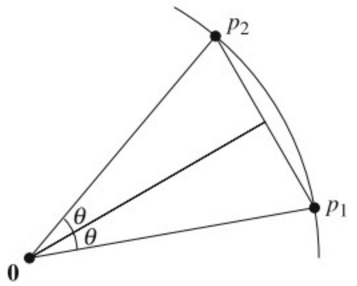

Fig. 2.2 $d_{\mathbb{S}^2}(p_1, p_2) = \angle p_1 \mathbf{0} p_2 = 2\theta = 2 \arcsin\left(\frac{1}{2} d(p_1, p_2)\right)$

Let

$$p_1 = (a_1, b_1, c_1) \text{ and } p_2 = (a_2, b_2, c_2).$$

A point $p = (x, y, z)$ belongs to P_{p_1, p_2} if and only if $d(p_1, p) = d(p_2, p)$, i.e.,

$$\sqrt{(a_1 - x)^2 + (b_1 - y)^2 + (c_1 - z)^2} = \sqrt{(a_2 - x)^2 + (b_2 - y)^2 + (c_2 - z)^2}$$

or

$$(a_1 - a_2)x + (b_1 - b_2)y + (c_1 - c_2)z - d = 0,$$

which is a linear equation, where $d = \frac{1}{2}((a_1^2 + b_1^2 + c_1^2) - (a_2^2 + b_2^2 + c_2^2))$. For a point $p = (x, y, z)$ in $\mathbb{R}^3$, the norm of p is defined by

$$\|p\| = \sqrt{x^2 + y^2 + z^2}.$$

Then, we obviously have $d(p, q) = \|p - q\|$.

Now let us define the notion of maps that preserve the geometric properties of figures on the sphere.

Definition 2.1. A bijective map $\phi : \mathbb{S}^2 \to \mathbb{S}^2$ is called an *isometry* of $\mathbb{S}^2$ if it preserves the spherical distance, i.e.,

$$d_{\mathbb{S}^2}(\phi(p_1), \phi(p_2)) = d_{\mathbb{S}^2}(p_1, p_2)$$

for any two points $p_1, p_2 \in \mathbb{S}^2$.

The main purpose of this chapter is to classify the isometries of the sphere as we did for the Euclidean plane in the previous chapter. In doing so, we will be able to gain considerable knowledge about the spherical geometry.

A bijective map $\phi : \mathbb{R}^3 \to \mathbb{R}^3$ is called an *isometry* of $\mathbb{R}^3$ if the distance is preserved, i.e.,

$$d(\phi(p_1), \phi(p_2)) = d(p_1, p_2)$$

for any two points $p_1, p_2 \in \mathbb{R}^3$.

According to (2.1),

$$d_{\mathbb{S}^2}(\phi(p_1), \phi(p_2)) = d_{\mathbb{S}^2}(p_1, p_2)$$

if and only if

$$2 \arcsin\left(\frac{1}{2} d(\phi(p_1), \phi(p_2))\right) = 2 \arcsin\left(\frac{1}{2} d(p_1, p_2)\right),$$

i.e.,

$$d(\phi(p_1), \phi(p_2)) = d(p_1, p_2).$$

In summary,

$$d_{\mathbb{S}^2}(\phi(p_1), \phi(p_2)) = d_{\mathbb{S}^2}(p_1, p_2) \quad \Leftrightarrow \quad d(\phi(p_1), \phi(p_2)) = d(p_1, p_2). \tag{2.2}$$

Therefore, isometries of the sphere and isometries of $\mathbb{R}^3$ are closely related.

Proposition 2.2. *If an isometry of $\mathbb{R}^3$ fixes the origin $\mathbf{0}$, then it induces an isometry of $\mathbb{S}^2$. In other words, if an isometry ϕ of $\mathbb{R}^3$ satisfies*

$$\phi(\mathbf{0}) = \mathbf{0},$$

then the map $\psi : \mathbb{S}^2 \to \mathbb{S}^2$, given by $\psi(p) = \phi(p)$, is well defined and an isometry of the sphere.

Proof. First, we must verify that $\psi(p)$ belongs to the sphere if the point p does. This is shown by the following:

$$d(\psi(p), \mathbf{0}) = d(\phi(p), \mathbf{0}) = d(\phi(p), \phi(\mathbf{0})) = d(p, \mathbf{0}) = 1.$$

Since ϕ^{-1} is also an isometry of $\mathbb{R}^3$, the map $\psi' : \mathbb{S}^2 \to \mathbb{S}^2$ by $\psi'(p) = \phi^{-1}(p)$ is also well defined. Then, ψ' is the inverse map of ψ, and so ψ is bijective. Finally, by (2.2), ψ preserves the spherical distance because ϕ preserves the distance. □

We denote the set of all the isometries of $\mathbb{S}^2$ by $\mathrm{Iso}(\mathbb{S}^2)$. In Chapter 1, we saw that reflections in lines play important roles when studying isometries. We define a *spherical line* for two distinct points p_1 and p_2 in $\mathbb{S}^2$ (Figure 2.3) as follows:

$$G_{p_1,p_2} = \{p \in \mathbb{S}^2 \mid d_{\mathbb{S}^2}(p_1, p) = d_{\mathbb{S}^2}(p_2, p)\}.$$

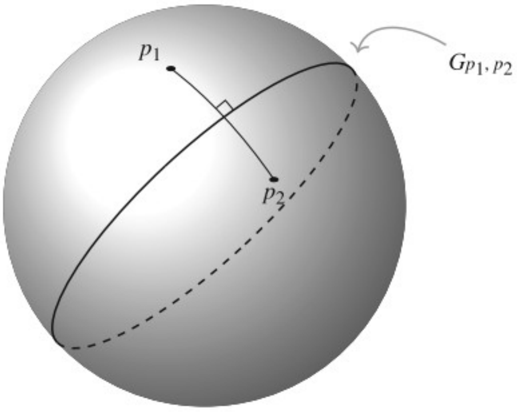

Fig. 2.3 Spherical line G_{p_1,p_2} with respect to points p_1 and p_2 on $\mathbb{S}^2$

Proposition 2.3. *A spherical line is a great circle.*

Proof. For two distinct points p_1 and p_2 on $\mathbb{S}^2$, consider a spherical line

$$G_{p_1,p_2} = \{p \in \mathbb{S}^2 \mid d_{\mathbb{S}^2}(p_1, p) = d_{\mathbb{S}^2}(p_2, p)\}.$$

By (2.2),

$$\begin{aligned} G_{p_1,p_2} &= \{p \in \mathbb{S}^2 \mid d(p_1, p) = d(p_2, p)\} \\ &= \mathbb{S}^2 \cap \{p \in \mathbb{R}^3 \mid d(p_1, p) = d(p_2, p)\} \\ &= \mathbb{S}^2 \cap P_{p_1,p_2}, \end{aligned}$$

which is a intersection of the sphere and a plane P_{p_1,p_2}. The plane P_{p_1,p_2} passes through the origin because

$$d(p_1, \mathbf{0}) = 1 = d(p_2, \mathbf{0}),$$

i.e., $d(p_1, \mathbf{0}) = d(p_2, \mathbf{0})$. □

Points on the sphere are said to be *collinear* if they lie on a great circle.

Lemma 2.4. *An isometry of the sphere maps non-collinear points p_1, p_2, and p_3 to non-collinear points.*

Proof. Let $\phi : \mathbb{S}^2 \to \mathbb{S}^2$ be an isometry. Suppose that the points $\phi(p_1)$, $\phi(p_2)$, and $\phi(p_3)$ are collinear, then they lie on a great circle $G_{p,q}$. Thus, we have

$$\begin{aligned} d_{\mathbb{S}^2}(p, \phi(p_1)) &= d_{\mathbb{S}^2}(q, \phi(p_1)), \\ d_{\mathbb{S}^2}(p, \phi(p_2)) &= d_{\mathbb{S}^2}(q, \phi(p_2)) \end{aligned}$$

and

$$d_{\mathbb{S}^2}(p, \phi(p_3)) = d_{\mathbb{S}^2}(q, \phi(p_3)).$$

However, then,

$$d_{\mathbb{S}^2}(\phi^{-1}(p), p_1) = d_{\mathbb{S}^2}(\phi^{-1}(q), p_1),$$

$$d_{\mathbb{S}^2}(\phi^{-1}(p), p_2) = d_{\mathbb{S}^2}(\phi^{-1}(q), p_2)$$

and

$$d_{\mathbb{S}^2}(\phi^{-1}(p), p_3) = d_{\mathbb{S}^2}(\phi^{-1}(q), p_3),$$

which imply that the points p_1, p_2, and p_3 lie on the great circle $G_{\phi^{-1}(p),\phi^{-1}(q)}$. Because this is a contradiction, the points $\phi(p_1)$, $\phi(p_2)$, and $\phi(p_3)$ are non-collinear. $\square$

In Theorem 1.4, we saw that an isometry of $\mathbb{R}^2$ is determined by how it maps three non-collinear points. The following theorem is a version of Theorem 1.4 for the spherical geometry.

Theorem 2.5 (Three points theorem for the sphere). *Let ϕ and ψ be isometries of the sphere. If*

$$\phi(p_1) = \psi(p_1), \phi(p_2) = \psi(p_2) \text{ and } \phi(p_3) = \psi(p_3)$$

for some set of non-collinear points p_1, p_2, and p_3, then $\phi = \psi$.

Proof. According to Lemma 2.4, the three points $\phi(p_1)$, $\phi(p_2)$, and (p_3) are also non-collinear.

Suppose that $\phi \neq \psi$. Then, there exists a point p such that

$$\phi(p) \neq \psi(p),$$

and we can define a great circle $G = G_{\phi(p),\psi(p)}$. Note that

$$\begin{aligned} d_{\mathbb{S}^2}(\phi(p), \phi(p_1)) &= d_{\mathbb{S}^2}(p, p_1) && (\because\ \phi \text{ is an isometry}) \\ &= d_{\mathbb{S}^2}(\psi(p), \psi(p_1)) && (\because\ \psi \text{ is an isometry}) \\ &= d_{\mathbb{S}^2}(\psi(p), \phi(p_1)), \end{aligned}$$

i.e., $d_{\mathbb{S}^2}(\phi(p), \phi(p_1)) = d_{\mathbb{S}^2}(\psi(p), \phi(p_1))$. So $\phi(p_1) \in G$. Similarly,

$$\phi(p_2) \in G \text{ and } \phi(p_3) \in G.$$

However, the three points $\phi(p_1)$, $\phi(p_2)$, and (p_3) are then collinear, which is a contradiction. $\square$

Exercises

2.1. Let $p_1 = \frac{1}{\sqrt{2}}(1, 1, 0)$ and $p_2 = \frac{1}{\sqrt{2}}(1, 0, 1)$. Calculate the following:

(a) $d(p_1, p_2)$ (b) $d_{\mathbb{S}^2}(p_1, p_2)$.

2.2. (a) Show that there is no map $f : \mathbb{R}^2 \to \mathbb{S}^2$ such that

$$d(p, q) = d_{\mathbb{S}^2}\,(f(p), f(q))$$

for all points p and q in $\mathbb{R}^2$.

(b) Show that there is no map $g : \mathbb{S}^2 \to \mathbb{R}^2$ such that

$$d_{\mathbb{S}^2}(p, q) = d\,(g(p), g(q))$$

for all points p and q in $\mathbb{S}^2$.

2.3. A spherical circle C of radius ρ with its center $p \in \mathbb{S}^2$ is defined by

$$C = \{x \in \mathbb{S}^2 \mid d_{\mathbb{S}^2}(p, x) = \rho\}.$$

Determine its circumference $\Pi(\rho)$. Show that $\Pi(\rho) < 2\pi\rho$ and

$$\lim_{\rho \to 0^+} \frac{\Pi(\rho)}{\rho} = 2\pi.$$

2.2 Isometries of the Sphere $\mathbb{S}^2$

The reflection $\bar{r}_{P_{p_1,p_2}}$ in the plane P_{p_1,p_2} is an isometry of $\mathbb{R}^3$ such that the line segment from the given point p in $\mathbb{R}^3$ to the point $\bar{r}_{P_{p_1,p_2}}(p)$ intersects the plane P_{p_1,p_2} orthogonally at its midpoint. For example, if P is the yz-plane, then

$$\bar{r}_P(x, y, z) = (-x, y, z).$$

Similar to a reflection in a line, a reflection in a plane satisfies the following:

(a)

$$\bar{r}_{P_{p_1,p_2}}(p_1) = p_2, \bar{r}_{P_{p_1,p_2}}(p_2) = p_1.$$

for $m \in \mathbb{N}_0$, $s \in (m, m+1)$, $\theta = s - [s]$ and $1 < p < \infty$, often called Sobolev-Slobodeckij spaces,

(f) and the complex interpolation spaces

$$H^{s,p}(\Omega) = \left[W^{m,p}(\Omega), W^{m+1,p}(\Omega)\right]_\theta$$

for $1 \leq p \leq \infty$, $0 < \theta < 1$, $s = (1-\theta)m + \theta(m+1) = m + \theta$, defined on open sets $\Omega \subset \mathbb{R}^n$. We do not give precise definitions of these spaces here and refer the reader e.g. to the a classical monograph by Triebel [149] or the recent one by Amann [12].

1.2 The Vector Valued Setting

As before, we start this section by introducing basic facts on distributions and Fourier transforms, now however in the *vector-valued setting*.

Banach Space Valued Distributions

We note that the proofs of the assertions listed below on distributions are only straightforward modifications of the ones for the scalar case described in Sect. 1.1.

Let X be a Banach space. We denote by $\mathcal{S}(\mathbb{R}^n; X)$ the Schwartz space of smooth rapidly decreasing X-valued functions on $\mathbb{R}^n$. Then

$$\mathcal{D}(\mathbb{R}^n; X) \overset{d}{\hookrightarrow} \mathcal{S}(\mathbb{R}^n; X) \overset{d}{\hookrightarrow} \mathcal{E}(\mathbb{R}^n; X),$$

where $\mathcal{D}(\mathbb{R}^n; X)$ is the space of all X–valued C^∞-functions on $\mathbb{R}^n$ with compact supports, as usual equipped with the inductive limit topology, and $\mathcal{E}(\mathbb{R}^n; X) := C^\infty(\mathbb{R}^n; X)$ equipped with the bounded convergence topology.

The space $\mathcal{S}'(\mathbb{R}^n; X)$ of X–valued temperate distributions is defined by $\mathcal{S}'(X) := \mathcal{L}(\mathcal{S}(\mathbb{R}^n); X)$; the spaces $\mathcal{E}'(\mathbb{R}^n; X)$ and $\mathcal{D}'(\mathbb{R}^n; X)$ are defined analogously. Then

$$\mathcal{E}'(\mathbb{R}^n; X) \hookrightarrow \mathcal{S}'(\mathbb{R}^n; X) \hookrightarrow \mathcal{D}'(\mathbb{R}^n; X).$$

Finally, the space $\mathcal{O}_M(\mathbb{R}^n; X)$ of all X–valued slowly increasing smooth functions on $\mathbb{R}^n$ consists of all $u \in \mathcal{E}(\mathbb{R}^n; X)$ such that, given $\alpha \in \mathbb{N}_0^n$, there exists $m_\alpha \in \mathbb{N}$ and $C_\alpha > 0$ such that

$$\|\partial^\alpha u(x)\| \leq C_\alpha (1 + |x|^2)^{m_\alpha}, \quad x \in \mathbb{R}^n.$$

Observe that $\mathcal{S}(\mathbb{R}^n; X) \hookrightarrow \mathcal{O}_M(\mathbb{R}^n; X) \hookrightarrow \mathcal{S}'(\mathbb{R}^n; X)$. We also write $\mathcal{S}(\mathbb{R}^n) := \mathcal{S}(\mathbb{R}^n; \mathbb{K})$, $\mathcal{S}'(\mathbb{R}^n) := \mathcal{S}'(\mathbb{R}^n; \mathbb{K})$ and $\mathcal{O}_M(\mathbb{R}^n) := \mathcal{O}_M(\mathbb{R}^n; \mathbb{K})$, where $\mathbb{K} \in \{\mathbb{C}, \mathbb{R}\}$.

We next turn our attention to the Bochner integral. To this end, given an interval I in $\mathbb{R}$, bounded or unbounded, or a rectangle I in $\mathbb{R}^2$, we call a function $g : I \to X$ a *simple* function if it is of the form $g(t) = \sum_{j=1}^n x_j \chi_{S_j}(t)$ for some $n \in \mathbb{N}$, $x_j \in X$

and Lebesgue measurable sets $S_j \subset I$ with finite Lebesgue measure $\mu(S_j)$; g is called a *step function* if S_j can be chosen to be an interval. A function $f : I \to X$ is called *measurable* if there exists a sequence of simple functions g_n such that $f(t) = \lim_{n\to\infty} g_n(t)$ for almost all $t \in I$. For a simple function $g : I \to X$ of the form $g = \sum_{j=1}^{n} x_j \chi_{S_j}$ we define

$$\int_I g(t)dt := \sum_{j=1}^{n} x_j \mu(S_j).$$

A function $f : I \to X$ is then called *Bochner integrable* if there exist simple functions g_n such that $g_n \to f$ pointwise almost everywhere and $\lim_{n\to\infty} \int_I \|f(t) - g_n(t)\| dt = 0$. In this case, the *Bochner integral of f on I* is given by

$$\int_I f(t)dt := \lim_{n\to\infty} \int_I g_n(t)dt.$$

The class of Bochner integrable functions can be characterized as follows.

Proposition 1.2.1 (Bochner) *A function $f : I \to X$ is Bochner integrable if and only if f is measurable and $\|f\|$ is integrable. If f is Bochner integrable, then*

$$\Big\| \int_I f(t)dt \Big\| \le \int_I \|f(t)\| dt.$$

For $1 \le p < \infty$, we denote by $L^p(I; X)$ the space of all measurable functions $f : I \to X$ such that

$$\|f\|_p := \Big(\int_I \|f(t)\|^p dt \Big)^{1/p} < \infty.$$

Furthermore, we set $L^\infty(I; X)$ to be the space of all measurable functions $f : I \to X$ such that

$$\|f\|_\infty := \operatorname*{ess\,sup}_{t\in I} \|f(t)\| < \infty.$$

With the usual identifications, $L^p(I; X)$ becomes a Banach space for all $1 \le p \le \infty$. We note that the above theory of integration works in the same way, when the interval I is replaced by a measurable set in $\mathbb{R}^n$. It follows from Fubini's theorem that for $1 \le p < \infty$ there is an isometric isomorphism between $L^p(I \times \Omega; X)$ and $L^p(I; L^p(\Omega; X))$ for any measurable set $\Omega \subset \mathbb{R}^n$ given by $f \mapsto g$, where

$$(g(s))(t) := f(s, t).$$

We further note that for $1 \le p < \infty$ the norm of a function $f \in L^p(\mathbb{R}^n; X)$ can be calculated by

$$\begin{aligned} &\|f\|_{L^p(\mathbb{R}^n;X)} \\ &\quad = \sup \Big\{ \Big| \int_{\mathbb{R}^n} < g(x), f(x) > dx \Big| : g \in L^{p'}(\mathbb{R}^n; X'), \|g\|_{L^{p'}(\mathbb{R}^n;X')} \le 1 \Big\}. \end{aligned} \tag{1.2.1}$$

Given $u \in L^1(\mathbb{R}^n; X)$ we define the *Fourier transform* of u by

$$\mathcal{F}u(\xi) := \hat{u}(\xi) := \int_{\mathbb{R}^n} e^{-i<x,\xi>} u(x)dx, \quad \xi \in \mathbb{R}^n,$$

where as above $< x, \xi >= \sum_{j=1}^n x_j \xi_j$. The *Fourier inversion theorem* guarantees that the Fourier transform $\mathcal{F}$ is an isomorphism on $\mathcal{S}(\mathbb{R}^n; X)$ and that

$$\mathcal{F}^{-1}u = (2\pi)^{-n} \check{\hat{u}} = (2\pi)^{-n} \hat{\check{u}}, \quad u \in \mathcal{S}(\mathbb{R}^n; X) \tag{1.2.2}$$

where $\check{u}(x) := u(-x)$ for $x \in \mathbb{R}^n$ denotes the reflection of u. The Fourier transform $\hat{u} := \mathcal{F}u$ of $u \in \mathcal{S}'(\mathbb{R}^n; X)$ is defined by

$$\hat{u}(\varphi) := u(\hat{\varphi}), \quad \varphi \in \mathcal{S}(\mathbb{R}^n).$$

Defining $\check{u}(\varphi) := u(\check{\varphi})$ for $u \in \mathcal{D}'(\mathbb{R}^n; X)$ and $\varphi \in \mathcal{D}(\mathbb{R}^n)$ it follows that $\mathcal{F}$ is an isomorphism on $\mathcal{S}'(\mathbb{R}^n; X)$ and that (1.2.2) holds for $u \in \mathcal{S}'(\mathbb{R}^n; X)$.

Let $\varphi \in \mathcal{S}(\mathbb{R}^n)$ and $u \in \mathcal{S}'(\mathbb{R}^n; X)$. Then the convolution $u * \varphi$ of u and φ is defined by

$$(u * \varphi)(x) := u(\tau_x \check{\varphi}), \quad x \in \mathbb{R}^n,$$

where $\tau_a \varphi(x) := \varphi(x - a)$ for $x \in \mathbb{R}^n$ and $a \in \mathbb{R}^n$. Moreover, the convolution theorem states that

$$(u * \varphi)\hat{} = \hat{u}\hat{\varphi}.$$

Finally, let H be a Hilbert space. Then $L^2(\mathbb{R}^n; H)$ is a Hilbert space with respect to the inner product

$$(u|v)_2 := (u|v)_{L^2(\mathbb{R}^n;H)} := \int_{\mathbb{R}^n} u \cdot \overline{v}\, dx.$$

We note that Plancherel's theorem carries over to the situation of Hilbert space valued functions. More precisely, the following holds.

Proposition 1.2.2 (Plancherel's Theorem in Hilbert Spaces) *Let H be a Hilbert space and $u, v \in \mathcal{S}(\mathbb{R}^n; H)$. Then*

$$(\hat{u}|\hat{v})_2 = (2\pi)^n (u|v)_2$$

Moreover, $(2\pi)^{-n/2}\mathcal{F}$ is a unitary operator on $L^2(\mathbb{R}^n; H)$.

Singular Integrals: Classical Theory

Singular integral operators will be an important tool in the analysis of the Stokes equation in the following sections. We now state two results on the L^p-boundedness of singular integral operators in the vector valued setting.

Consider a kernel operator of the form

$$(Tf)(x) = \int_{\mathbb{R}^n} K(x, y) f(y) d\mu(y), \tag{1.2.3}$$

where the kernel K is singular near $x = y$, and (1.2.3) is meaningful only in some limiting sense. More precisely, we assume that for $f \in L^2(\mathbb{R}^n; X)$ with compact support, the integral in (1.2.3) converges absolutely for a. a. $x \in (\operatorname{supp} f)^C$ and that (1.2.3) holds for these x, where the kernel K is assumed to belong to $L^1_{loc}(\mathbb{R}^n \times \mathbb{R}^n, \mathcal{L}(X, Y))$.

Theorem 1.2.3 *Let X and Y be Banach spaces and let T be defined as in (1.2.3). Assume that there exists a constant $C > 0$ such that*

(i) $\|Tf\|_{L^2(\mathbb{R}^n;Y)} \le C\|f\|_{L^2(\mathbb{R}^n;X)}$ *for all* $f \in L^2(\mathbb{R}^n; X)$
(ii) There exists a constant $r > 1$ such that for all $y_1 \in \mathbb{R}^n$, $\delta > 0$

$$\int_{B(y_1, r\delta)^C} \left\| K(x, y_1) - K(x, y_2) \right\|_{\mathcal{L}(X,Y)} d\mu(x) \le C \text{ if } y_2 \in B(y_1, \delta)$$

Then, for all $1 < p < 2$, there exists a constant C_p (depending only on C and p) such that

$$\|Tf\|_{L^p(\mathbb{R}^n;Y)} \le C_p \|f\|_{L^p(\mathbb{R}^n;X)}, \text{ for } f \in L^p(\mathbb{R}^n; X).$$

We note that the proof of the scalar-valued version of Theorem 1.2.3 given e.g. in [140] extends without any difficulties to the situation considered above.

Remark 1.2.4 It is worthwhile to point out the following variant of Theorem 1.2.3. Assume that T defined as in (1.2.3) satisfies the condition

$$\|Tf\|_{L^r(\mathbb{R}^n;Y)} \le C\|f\|_{L^r(\mathbb{R}^n;X)}, \qquad f \in L^r(\mathbb{R}^n; X)$$

for some $r \in (1, \infty)$ and condition (ii) of Theorem 1.2.3. Then T admits a bounded extensions to L^p for $1 < p < r$. The proof follows the lines of the proof given in [140] and is left to the reader.

Consider now the special case of convolution operators. More specifically, let X and Y be Banach spaces and suppose that $K \in L^1_{loc}(\mathbb{R}^n \setminus \{0\}, \mathcal{L}(X, Y))$. Then the integral

$$Tf(x) := \int_{\mathbb{R}^n} K(x - y)f(y)dy \tag{1.2.4}$$

is well defined for $f \in L^\infty(\mathbb{R}^n; X)$ with compact support and $x \in (suppf)^C$. For operators of the form (1.2.4), the condition (ii) of Theorem 1.2.3 is equivalent to the *Hörmanders's condition*

$$\int_{|x|>2|y|} \big\|K(x - y) - K(x)\big\|dx \leq C < \infty, \quad y \in \mathbb{R}^n\setminus\{0\}. \tag{1.2.5}$$

The following result due to Benedek, Calderón and Panzone says that operators of the form (1.2.4) are bounded operators on $L^p(\mathbb{R}^n; X)$, for $1 < p < \infty$, provided this holds for some $r \in (1, \infty)$ and condition (1.2.5) is satisfied.

Theorem 1.2.5 (Benedek, Calderón, Panzone) *[16] Suppose that* $T \in \mathcal{L}(L^r(\mathbb{R}^n; X)\ L^r(\mathbb{R}^n; Y))$ *for some* $r \in (1, \infty)$. *Assume that* T *may be represented by (1.2.4) for* $f \in L^\infty(\mathbb{R}^n; X)$ *with compact support and* $x \in (\,supp\ f)^C$, *and that* (1.2.5) *is satisfied. Then* T *admits a bounded extension to* $L^p(\mathbb{R}^n; X)$ *for* $p \in (1, \infty)$. *Moreover, there exists a constant C such that*

$$\|Tf\|_{L^p(\mathbb{R}^n;Y)} \leq C\|f\|_{L^p(\mathbb{R}^n;X)}, \quad 1 < p < \infty.$$

Proof We note that for $p \in (1, r)$ the assertion follows from Remark 1.2.4 since for translation invariant operators of the form (1.2.4), the condition ii) of Theorem 1.2.3 is equivalent to (1.2.5). The remaining case where $p \in (r, \infty)$ follows by a duality argument. □

Hilbert Transform and UMD-Spaces

An interesting application of Theorem 1.2.5 concerns the Hilbert transform on $L^p(\mathbb{R}; X)$. We already saw in the previous Sect. 1.1 that the Hilbert transform acts boundedly on $L^p(\mathbb{R})$. As in the scalar case, we define for $u \in \mathcal{S}(\mathbb{R}^n; X)$ the *Hilbert transform* Hu of u by

$$Hu := \frac{1}{\pi} pv(1/t) * u, \quad u \in \mathcal{S}(\mathbb{R}^n; X).$$

For the time being, assume that for some $p \in (1, \infty)$ we have $\|Hu\|_{L^p(\mathbb{R};X)} \leq C\|u\|_{L_p(\mathbb{R};X)}$ for $u \in \mathcal{S}(\mathbb{R}; X)$. Then there exists a unique extension of H to a bounded operator on $L^p(\mathbb{R}; X)$. This extension, also denoted by H, is called the *Hilbert transform* on $L^p(\mathbb{R}; X)$. Since $\widehat{Hu} = -isign(\cdot)\hat{u}$, it follows from Plancherel's Theorem 1.2.2 that

$$(Hu|Hv)_2 = \frac{1}{2\pi}(\widehat{Hu}|\widehat{Hv})_2 = \frac{1}{2\pi}(\hat{u}|\hat{v})_2 = (u|v)_2$$

for $u, v \in \mathcal{S}(\mathbb{R}; X)$. By density, H is an isomorphism on $L^2(\mathbb{R}; X)$ satisfying $H^{-1}v = -Hv$ for $v \in L^2(\mathbb{R}; X)$. We summarize these observations in part (a) of the following proposition.

Proposition 1.2.6 *Let X be a Banach space.*

(a) The Hilbert transform is a unitary operator on $L^2(\mathbb{R}; X)$ provided X is a Hilbert space.
(b) Suppose that the Hilbert transform is bounded on $L^p(\mathbb{R}; X)$ for some $p \in (1, \infty)$. Then it is bounded on $L^q(\mathbb{R}; X)$ for all $q \in (1, \infty)$.

Proof Note that assertion (b) is an immediate consequence of Theorem 1.2.5 since

$$\int_{|x|>2|y|} \|K(x-y) - K(x)\| dx = \int_{|x|>2|y|} \Big|\frac{1}{x-y} - \frac{1}{x}\Big| dx \le C.$$

□

Let us remark that the Hilbert transform is not bounded on $L^p(\mathbb{R}; X)$, in general. Banach spaces for which the Hilbert transform is, however, bounded for some (and then all) $p \in (1, \infty)$ play an important role in the regularity theory of parabolic evolution equations. We finish this section with the definition of such spaces.

Definition 1.2.7 A Banach space X is called a *UMD-space* if the Hilbert transform is bounded on $L^p(\mathbb{R}; X)$ for some (and then all) $p \in (1, \infty)$.

The word UMD stands for the property of *unconditional martingale differences* and goes back to the work of Burkholder [24] and Bourgain [20]. For a comprehensive treatment of these spaces we refer to the monographs [87] and [8]. The following remark collects some basic facts and examples of UMD-spaces.

Remarks 1.2.8

(a) Let us remark here that every finite dimensional Banach space or any Hilbert space is a UMD-space.
(b) UMD spaces are reflexive. The converse is not true.
(c) If X is a UMD space and (Ω, μ) a σ-finite measure space, then $L^p(\Omega, \mu; X)$ has the UMD-property provided $1 < p < \infty$.
(d) All closed linear subspaces of UMD-spaces are UMD spaces.
(e) $L^1(\Omega, \mu)$ or spaces of continuous functions $C(K)$ do not have the UMD property.

Mechanical Curves

In this chapter we shall describe mechanical curves from the Lagrangian and Hamiltonian point of view. In this way, many geometric properties of these curves will be derived from the variational formalism.

A mechanical curve is a curve described by a particle on which acts an exterior force. For instance the circle, cycloid, hypocycloid, astroid, etc are models of particle trajectories under some exterior forces. A particle on which acts a central force of constant magnitude describes a circle. A point on a circle which rolls on a line, without slipping, describes a cycloid. A point on a circle tangent interior to another circle, which rotates without slipping in the interior of the large circle, describes a hypocycloid.

12.1 The areal velocity

Suppose an object moves in the plane from the point A to point B along a continuous arc $\widehat{AB}$. Let $\mathcal{A}$ be the area swept by the vectorial radius $\overrightarrow{OX}$ with $X \in \widehat{AB}$. We shall consider positive the orientation given by the clock-wise rotation of $\overrightarrow{OX}$. An elementary calculus formula in polar coordinates yields

$$\mathcal{A} = \frac{1}{2}\int_0^{\phi} r^2\, d\phi, \tag{12.1.1}$$

where $r = r(\phi)$ is the length of the vectorial radius and the argument angle $\phi = \angle AOX$.

Written in differential form, we have $d\mathcal{A} = \dfrac{1}{2} r^2\, d\phi$. Let t be the time parameter. Then

$$\frac{d\mathcal{A}}{dt} = \frac{1}{2} r^2 \frac{d\phi}{dt} = \frac{1}{2} r^2 \dot{\phi}. \tag{12.1.2}$$

The derivative $d\mathcal{A}/dt$ is called *areal velocity*.

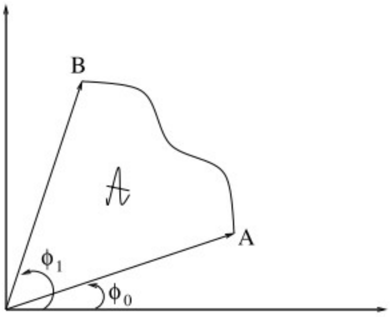

Figure 12.1: The area swept by the vectorial radius between two points.

12.1.0.1 Areal velocity as an angular momentum

Using polar coordinates $x = r\ \cos\phi,\ y = r\ \sin\phi$, the areal velocity becomes

$$\begin{aligned}\frac{d\mathcal{A}}{dt} &= \frac{1}{2}r^2\dot{\phi} = \frac{1}{2}\big(r\cos\phi\, r\cos\phi\,\dot{\phi} - r\sin\phi\,(-r\cos\phi)\,\dot{\phi}\big)\\ &= \frac{1}{2}(x\dot{y} - y\dot{x}).\end{aligned}$$

The expression $x\dot{y} - y\dot{x} = \langle (x, y), (\dot{x}, -\dot{y})\rangle$ is called *angular momentum.*

If $x\dot{y} - y\dot{x}$ is constant, the particle moves such that equal areas are described in equal amounts of time *i.e.*, the vectorial radius sweeps out equal areas in equal time. This happens for instance, in the case of a particle in uniform motion on a circle or in the case of a planet in the revolution motion around the sun (Kepler's second law).

12.2 The circular motion

Consider a particle in the (x, y)-plane which is described by the Lagrangian

$$L(x, y, \dot{x}, \dot{y}) = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + (x\dot{y} - y\dot{x}) \tag{12.2.3}$$

i.e., the particle moves on a trajectory which is an extremizer for the action

$$S = \int L(x, y, \dot{x}, \dot{y}). \tag{12.2.4}$$

The Lagrangian L is the sum of the kinetic energy and the angular momentum.

Theorem 12.1. *The Euler–Lagrange system associated with the Lagrangian* (12.2.3) *is*

$$\begin{cases}\ddot{x} - 2\dot{y} &= 0,\\ \ddot{y} + 2\dot{x} &= 0.\end{cases} \tag{12.2.5}$$

The solutions of the system (12.2.5) *with the boundary conditions*

$$x(0) = \mathbf{x}_0, \qquad x(\tau) = \mathbf{x}, \qquad y(0) = \mathbf{y}_0, \qquad y(\tau) = \mathbf{y}, \tag{12.2.6}$$

with $0 < \tau < \pi$, *are*

$$\begin{aligned} x(s) &= \pm C \sin s\ \sin(s + \alpha_0) + \mathbf{x}_0, \\ y(s) &= \pm C \sin s\ \cos(s + \alpha_0) + \mathbf{y}_0, \end{aligned}$$

with $C = \sqrt{\frac{E}{2}}$ *and the energy* E *given by*

$$E = \frac{(\mathbf{x} - \mathbf{x}_0)^2 + (\mathbf{y} - \mathbf{y}_0)^2}{2 \sin^2 \tau}. \tag{12.2.7}$$

Proof. Using

$$\begin{aligned} &\frac{\partial L}{\partial \dot{x}} = \dot{x} - y, \qquad \frac{d}{dt}\frac{\partial L}{\partial \dot{x}} = \ddot{x} - \dot{y}, \qquad \frac{\partial L}{\partial x} = \dot{y}, \\ &\frac{\partial L}{\partial \dot{y}} = \dot{y} + x, \qquad \frac{d}{dt}\frac{\partial L}{\partial \dot{y}} = \ddot{y} + \dot{x}, \qquad \frac{\partial L}{\partial \dot{y}} = -\dot{x}, \end{aligned}$$

it is easy to see that the Euler–Lagrange system becomes (12.2.5).

Multiplying the first equation of (12.2.5) by $\dot{x}$ and the second by $\dot{y}$ and adding yields $\dot{x}\ddot{x} + \dot{y}\ddot{y} = 0$, therefore

$$\frac{d}{dt}(\dot{x}^2 + \dot{y}^2) = 0 \Longrightarrow \dot{x}^2 + \dot{y}^2 = C^2 \tag{12.2.8}$$

where C is a constant along the trajectory. Let $E = \frac{1}{2}(\dot{x}^2 + \dot{y}^2)$ denote the first integral of energy. Using (12.2.8) there is a smooth function $\alpha = \alpha(s)$ such that

$$\begin{aligned} \dot{x}(s) &= \pm C \sin\alpha(s) \Longrightarrow \ddot{x}(s) = \pm C \cos\alpha(s)\, \dot{\alpha}(s), \\ \dot{y}(s) &= \pm C \cos\alpha(s) \Longrightarrow \ddot{y}(s) = \mp C \sin\alpha(s)\, \dot{\alpha}(s). \end{aligned}$$

Substituting back in the system (12.2.5) yields

$$\begin{aligned} \pm \cos^2\alpha(s)\, \dot{\alpha}(s) &= \pm 2 \cos^2\alpha(s), \\ \mp \sin^2\alpha(s)\, \dot{\alpha}(s) &= \mp 2 \sin^2\alpha(s). \end{aligned}$$

Subtracting we get

$$\dot{\alpha}(s) = 2 \Longrightarrow \alpha(s) = 2s + \alpha_0, \tag{12.2.9}$$

with α_0 constant. Hence

$$\begin{aligned}\dot{x}(s) &= \pm C\sin(2s+\alpha_0) \Longrightarrow x(s) = \pm C\int_0^s \sin(2u+\alpha_0)\,du + \mathbf{x}_0\\ &= \pm C\frac{1}{2}(-\cos w)\Big|_{\alpha_0}^{2s+\alpha_0} + \mathbf{x}_0 = \pm\frac{C}{2}\Big(\cos\alpha_0 - \cos(2s+\alpha_0)\Big) + \mathbf{x}_0\\ &= \pm C\sin s\sin(s+\alpha_0) + \mathbf{x}_0,\end{aligned}$$

where we used

$$\begin{aligned}\cos\alpha_0 - \cos(2s+\alpha_0) &= -2\sin\frac{\alpha_0+2s+\alpha_0}{2}\sin\frac{\alpha_0-2s-\alpha_0}{2}\\ &= 2\sin(s+\alpha_0)\sin s.\end{aligned}$$

Substituting $\alpha(s)$ in the formula for $\dot{y}(s)$ yields

$$\begin{aligned}\dot{y}(s) &= \pm C\cos\alpha(s) = \pm C\cos(2s+\alpha_0)\\ \Longrightarrow y(s) &= \pm C\int_0^s \cos(2u+\alpha_0)\,du + \mathbf{y}_0\\ &= \pm\frac{1}{2}C\sin w\Big|_{\alpha_0}^{2s+\alpha_0} + \mathbf{y}_0\\ &= \pm\frac{1}{2}C\Big(\sin(2s+\alpha_0) - \sin\alpha_0\Big) + \mathbf{y}_0\\ &= \pm C\sin s\cos(s+\alpha_0) + \mathbf{y}_0,\end{aligned}$$

where we used

$$\begin{aligned}\sin(2s+\alpha_0) - \sin\alpha_0 &= 2\sin\frac{2s+\alpha_0-\alpha_0}{2}\cos\frac{2s+\alpha_0+\alpha_0}{2}\\ &= 2\sin s\cos(s+\alpha_0).\end{aligned}$$

Hence we have arrived at

$$x(s) = \pm C\sin s\ \sin(s+\alpha_0) + \mathbf{x}_0, \tag{12.2.10}$$

$$y(s) = \pm C\sin s\ \cos(s+\alpha_0) + \mathbf{y}_0, \tag{12.2.11}$$

where α_0 is a constant. We shall show that energy $E = C^2/2$ does not depend on α_0. Making $s = \tau$ in (12.2.10), (12.2.11) yields

$$\mathbf{x} = \pm C\sin\tau\ \sin(\tau+\alpha_0) + \mathbf{x}_0, \tag{12.2.12}$$

$$\mathbf{y} = \pm C\sin\tau\ \cos(\tau+\alpha_0) + \mathbf{y}_0, \tag{12.2.13}$$

hence it follows that

$$\Big(\frac{\mathbf{x}-\mathbf{x}_0}{\sin\tau}\Big)^2 = C^2\sin^2(\tau+\alpha_0), \tag{12.2.14}$$

$$\Big(\frac{\mathbf{y}-\mathbf{y}_0}{\sin\tau}\Big)^2 = C^2\cos^2(\tau+\alpha_0). \tag{12.2.15}$$

Adding yields

$$2E = C^2 = \frac{(\mathbf{x}-\mathbf{x}_0)^2 + (\mathbf{y}-\mathbf{y}_0)^2}{\sin^2\tau},$$

which is (12.2.7). ∎

Remark 12.2 *Let* $d = \sqrt{(\mathbf{x}-\mathbf{x}_0)^2 + (\mathbf{y}-\mathbf{y}_0)^2}$ *denote the Euclidean distance between* $(\mathbf{x}_0, \mathbf{y}_0)$ *and* $(\mathbf{x}, \mathbf{y})$. *We note the fact that the energy* $E = \dfrac{d^2}{2\sin^2\tau}$ *is not Euclidean. Replacing* $\sin^2\tau$ *by* τ^2 *we obtain the Euclidean energy.*
Let δ *be the Riemannian distance in which the solutions of the Euler–Lagrange equations become geodesics. Then* $E = \dfrac{\delta^2}{2\tau^2}$. *Then* $\delta^2 = \left(\dfrac{\tau}{\sin\tau}\right)^2 d^2$, *and hence* d *and* δ *are homothetic.*

The action

The action $S = S(\mathbf{x}_0, \mathbf{y}_0, \mathbf{x}, \mathbf{y}, \tau)$ satisfies the Hamilton–Jacobi equation

$$\begin{aligned} \frac{\partial S}{\partial \tau} &= -E = -\frac{d^2}{2\sin^2\tau} = \frac{d^2}{2}\frac{\partial}{\partial\tau}(\cot\tau) \\ \Longrightarrow 0 &= \frac{\partial}{\partial\tau}\Big(S - \frac{d^2}{2}\cot\tau\Big) \Longrightarrow S = S_0 + \frac{d^2}{2}\cot\tau. \end{aligned} \tag{12.2.16}$$

Proposition 12.3 *The Hamiltonian associated with the Lagrangian* (12.2.3) *is*

$$H(x, y, p_1, p_2) = \frac{1}{2}\big(p_1 + y\big)^2 + \frac{1}{2}\big(p_2 - x\big)^2. \tag{12.2.17}$$

Proof. The Hamiltonian system for the Hamiltonian (12.2.17) yields

$$\begin{aligned} \dot{x} &= H_{p_1} = p_1 + y \Longrightarrow p_1 = \dot{x} - y, \\ \dot{y} &= H_{p_2} = p_2 - x \Longrightarrow p_2 = \dot{y} + x. \end{aligned}$$

Using the Legendre transform we have

$$\begin{aligned} L &= p_1\dot{x} + p_2\dot{y} - H \\ &= (\dot{x} - y)\dot{x} + (\dot{y} + x)\dot{y} - \frac{1}{2}\big(p_1 + y\big)^2 - \frac{1}{2}\big(p_2 - x\big)^2 \\ &= (\dot{x} - y)\dot{x} + (\dot{y} + x)\dot{y} - \frac{1}{2}\dot{x}^2 - \frac{1}{2}\dot{y}^2 \\ &= \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + x\dot{y} - y\dot{x}. \end{aligned}$$

∎

We note that the Hamiltonian (12.2.17) is the principal symbol of the operator

$$P = \frac{1}{2}\big(\partial_x + y\big)^2 + \frac{1}{2}\big(\partial_y - x\big)^2$$
$$= \frac{1}{2}(\partial_x^2 + \partial_y^2) + y\partial_x - x\partial_y + \frac{1}{2}(x^2 + y^2),$$

which describes the circular motion.

12.3 The astroid

The trajectory of a point P on the unit circle which rolls without slipping in the interior of a circle of radius 4 is a hypocycloid with four cuspidal points. This curve is called *astroid*. The equation of the astroid is

$$x^{2/3} + y^{2/3} = 1. \tag{12.3.18}$$

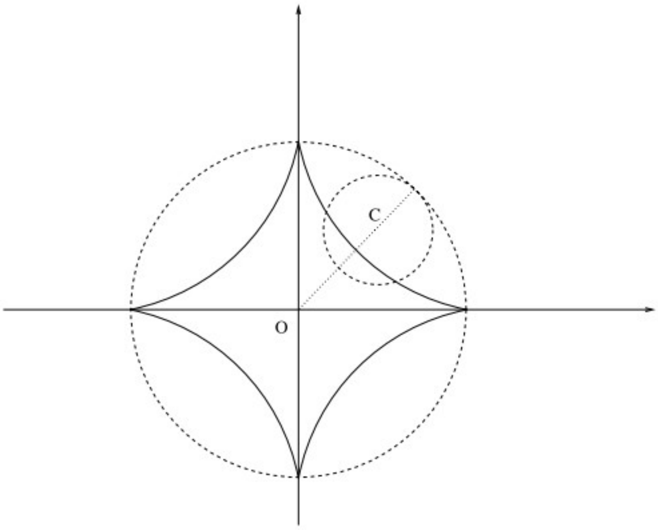

Figure 12.2: The astroid.

If P starts at the cuspidal point (4, 0) and s denotes the angle argument of the center C, we have

$$x(s) = \cos^3 s, \qquad y(s) = \sin^3 s, \tag{12.3.19}$$

which are equivalent with

$$x(s) = 3\cos s + \cos 3s, \qquad y(s) = 3\sin s - \sin 3s. \tag{12.3.20}$$

A simple computation shows that (12.3.20) is the solution of the system

$$\begin{cases} \ddot{x} - 2\dot{y} + 3x = 0, \\ \ddot{y} + 2\dot{x} + 3y = 0, \end{cases} \tag{12.3.21}$$

with initial conditions

$$x(0) = 4, \quad \dot{x}(0) = \dot{y}(0) = y(0) = 0. \tag{12.3.22}$$

Standard ODE techniques show that the solution (12.3.20) is unique.

Proposition 12.4 *The system* (12.3.21) *is the Euler–Lagrange system associated with the Lagrangian*

$$L(x, y, \dot{x}, \dot{y}) = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + x\dot{y} - \dot{x}y - \frac{3}{2}(x^2 + y^2). \tag{12.3.23}$$

Proof. We have

$$\frac{\partial L}{\partial \dot{x}} = \dot{x} - y, \quad \frac{d}{dt}\frac{\partial L}{\partial \dot{x}} = \ddot{x} - \dot{y}, \quad \frac{\partial L}{\partial x} = \dot{y} - 3x,$$

$$\frac{\partial L}{\partial \dot{y}} = \dot{y} + x, \quad \frac{d}{dt}\frac{\partial L}{\partial \dot{y}} = \ddot{y} + \dot{x}, \quad \frac{\partial L}{\partial y} = -\dot{x} - 3y.$$

Then

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{x}} = \frac{\partial L}{\partial x}, \quad \frac{d}{dt}\frac{\partial L}{\partial \dot{y}} = \frac{\partial L}{\partial y}$$

yields the system (12.3.21). ■

12.3.0.2 Noether's Theorem

The Lagrangian (12.3.23) is invariant under rotations centered at the origin. The vector field associated with this rotation at the point (x, y) is $(-y, x)$. Noether's theorem yields a first integral of motion given by

$$\begin{aligned} I &= \langle \left(\frac{\partial L}{\partial \dot{x}}, \frac{\partial L}{\partial \dot{y}}\right), (-y, x) \rangle = (\dot{x} - y)(-y) + (\dot{y} + x)x \\ &= -\dot{x}y + y^2 + \dot{y}x + x^2 = x^2 + y^2 + x\dot{y} - \dot{x}y \\ &= r^2 + 2\frac{d\mathcal{A}}{ds}, \end{aligned}$$

where $x = r\cos\phi$, $y = r\sin\phi$. We have arrived at the following result.

Proposition 12.5 *For any solution of the system* (12.3.21) *there is a constant C such that*

(i)
$$r^2 + 2\frac{d\mathcal{A}}{ds} = C,$$

(ii)
$$\phi(s) = C\int_0^s \frac{du}{r^2(u)} - s$$

along the solution.

Proof. (i) It clearly follows from the fact that the first integral is constant along the solutions.
(ii) We have

$$\begin{aligned} C &= r^2 + x\dot{y} - \dot{x}y \\ &= r^2 + r^2\dot{\phi} \\ &= r^2(1+\dot{\phi}) \\ \Longrightarrow \frac{d\phi}{ds} &= \frac{C}{r^2} - 1. \end{aligned}$$

Integrating yields the desired result. ■

We can get the same result if we write the Euler–Lagrange system in polar coordinates. See Exercise 2.

As the astroid is a solution of the system (12.3.21), the above proposition applies to it. In this case the constant C is obtained by taking the value at $s = 0$,

$$\begin{aligned} C &= x^2(0) + y^2(0) + x(0)\dot{y}(0) - \dot{x}(0)y(0) \\ &= 16. \end{aligned}$$

Proposition 12.6 *The Hamiltonian associated with the Lagrangian* (12.3.23) *is*

$$H(p_1, p_2, x, y) = \frac{1}{2}[(p_1 + y)^2 + (p_2 - x)^2] + \frac{3}{2}(x^2 + y^2). \tag{12.3.24}$$

Proof. The momenta are $p_1 = \dfrac{\partial L}{\partial \dot{x}} = \dot{x} - y, \quad p_2 = \dfrac{\partial L}{\partial \dot{y}} = \dot{y} + x$, and then

$$\dot{x} = p_1 + y, \quad \dot{y} = p_2 - x. \tag{12.3.25}$$

Using (12.3.25), the Legendre transform yields

$$\begin{aligned} H(p_1, p_2, x, y) &= p_1\dot{x} + p_2\dot{y} - \frac{1}{2}(\dot{x}^2 + \dot{y}^2) - x\dot{y} + \dot{x}y + \frac{3}{2}(x^2 + y^2) \\ &= p_1(p_1 + y) + p_2(p_2 - x) - \frac{1}{2}\Big((p_1 + y)^2 + (p_2 - x)^2\Big) \\ &\quad -x(p_2 - x) + (p_1 + y)y + \frac{3}{2}(x^2 + y^2) \\ &= \frac{1}{2}(p_1^2 + p_2^2) + p_1 y - p_2 x + 2(x^2 + y^2) \\ &= \frac{1}{2}\Big[(p_1 + y)^2 + (p_2 - x)^2\Big] + \frac{3}{2}(x^2 + y^2). \end{aligned}$$

■

12.3.0.3 The first integral of energy

As

$$\frac{\partial H}{\partial t} = 0 \quad \text{and} \quad \frac{\partial H}{\partial t} = \frac{dH}{dt},$$

it follows that H is preserved along the trajectory. The value of H along the trajectory is called *the total energy*. In x, y, $\dot{x}$, $\dot{y}$ coordinates the energy takes the form

$$E = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + \frac{3}{2}(x^2 + y^2). \tag{12.3.26}$$

Note that E does not depend on the angular momentum as the Lagrangian does. It depends only on the magnitude of the velocity and the distance to the origin.

12.3.0.4 Physical interpretation

The speed of a particle described by a solution of the Euler–Lagrange system is

$$v = \sqrt{\dot{x}^2 + \dot{y}^2}.$$

If $r = \sqrt{x^2 + y^2}$ denotes the distance from the origin to the point (x, y), formula (12.3.26) yields

$$v^2 = 2E - 3r^2.$$

In the case of the astroid with the initial conditions (12.3.26) we have $E = 24$. Thus $v = \sqrt{3(16 - r^2)}$ with $r \in [0, 4]$. The speed on the astroid is zero iff $r = 4$, which occurs only at the cuspidal points.

12.4 The cycloid

Consider a particle described by a Lagrangian, which is the sum of the kinetic, angular momentum and potential energy in the x-direction

$$L(x, y, \dot{x}, \dot{y}) = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + \frac{1}{2}(x\dot{y} - \dot{x}y) + x. \tag{12.4.27}$$

The Euler–Lagrange system of equations associated with the Lagrangian (12.4.27) is

$$\begin{cases} \ddot{x} - \dot{y} = 1, \\ \ddot{y} + \dot{x} = 0. \end{cases} \tag{12.4.28}$$

If we consider the initial conditions

$$x(0) = 0, \quad \dot{x}(0) = 0, \quad y(0) = 0, \quad \dot{y}(0) = 0$$

2 Calculus on surfaces

In this section we discuss basic concepts of differential geometry. We start in Section 2.1 by describing the parametric representation of γ via charts. This classical point of view is critical to introduce the first fundamental form $\mathbf{g}$, the area element q, and the unit normal $\boldsymbol{\nu}$ of γ. We present in Section 2.2 the tangential operators (gradient ∇_γ, divergence div_γ, and Laplace–Beltrami Δ_γ) as well as the Weingarten map; we also discuss H^2-regularity for Δ_γ on surfaces γ of class C^2. We introduce the signed distance function d in Section 2.3 and derive several important properties of it; this intrinsic approach avoids parametrizations and allows for implicit representations of γ. We devote Section 2.4 to the second fundamental form of γ and its principal curvatures using both parametric and intrinsic approaches.

of functions $\widetilde{u} \in H^2(\gamma)$ provided γ is of class C^2. This turns out to be essential for our later error analysis of the trace and narrow band methods for C^2 surfaces. In Section 4 we give a self-contained exposition of parametric FEMs for surfaces of class $C^{1,\alpha}$ and C^2, including a priori and a posteriori error analyses. In Section 5 we describe the trace method and conclude in Section 6 with the narrow band method. Both discussions assume C^2 regularity of γ.

2 Calculus on surfaces

In this section we discuss basic concepts of differential geometry. We start in Section 2.1 by describing the parametric representation of γ via charts. This classical point of view is critical to introduce the first fundamental form $\mathbf{g}$, the area element q, and the unit normal $\boldsymbol{\nu}$ of γ. We present in Section 2.2 the tangential operators (gradient ∇_γ, divergence div_γ, and Laplace–Beltrami Δ_γ) as well as the Weingarten map; we also discuss H^2-regularity for Δ_γ on surfaces γ of class C^2. We introduce the signed distance function d in Section 2.3 and derive several important properties of it; this intrinsic approach avoids parametrizations and allows for implicit representations of γ. We devote Section 2.4 to the second fundamental form of γ and its principal curvatures using both parametric and intrinsic approaches.

2.1 Parametric surfaces

We assume that γ is a closed, compact, orientable manifold of class $C^{1,\alpha}$, $0 < \alpha \leq 1$, and co-dimension 1 in $\mathbb{R}^{n+1}$. It can be represented parametrically by an atlas $\{(\mathcal{V}_i, \mathcal{U}_i, \boldsymbol{\chi}_i)\}_{i\in I}$, where the individual charts $\boldsymbol{\chi}_i : \mathcal{V}_i \to \mathcal{U}_i \cap \gamma \subset \mathbb{R}^{n+1}$ are isomorphisms of class $C^{1,\alpha}$ compatible with the orientation of γ; the open connected sets $\mathcal{V}_i \subset \mathbb{R}^n$ are the parametric domains. Unless stated otherwise, it will be often sufficient to consider a single chart and resort to a partition of the unity. We thus drop the index i for convenience. For $\mathbf{x} \in \mathcal{U} \cap \gamma$, we set $\mathbf{y} := \boldsymbol{\chi}^{-1}(\mathbf{x}) \in \mathcal{V}$.

Let $\partial_j \boldsymbol{\chi}(\mathbf{y})$ be the column vector of jth partial derivatives of $\boldsymbol{\chi}(\mathbf{y})$ for $1 \leq j \leq n$ at $\mathbf{y} \in \mathcal{V}$. By definition, the rank of $D\boldsymbol{\chi}(\mathbf{y}) = (\partial_j \boldsymbol{\chi}(\mathbf{y}))_{j=1}^n \in \mathbb{R}^{(n+1)\times n}$ is n (full rank). This implies that $\{\partial_j \boldsymbol{\chi}(\mathbf{y})\}_{j=1}^n$ are linearly independent and span the tangent hyperplane to γ at $\mathbf{x}$.

The *first fundamental form* is the symmetric and positive definite matrix $\mathbf{g} \in \mathbb{R}^{n\times n}$ defined by

$$\mathbf{g}(\mathbf{y}) := D\boldsymbol{\chi}(\mathbf{y})^t D\boldsymbol{\chi}(\mathbf{y}) \quad \forall \mathbf{y} \in \mathcal{V}. \tag{1}$$

If $\mathbf{g} = (g_{ij})_{i,j=1}^n$, then the components g_{ij} read

$$g_{ij} = \partial_i \boldsymbol{\chi}^t \partial_j \boldsymbol{\chi} = \partial_i \boldsymbol{\chi} \cdot \partial_j \boldsymbol{\chi},$$

which depends on the choice of parametrization. A normal vector $\mathbf{N}(\mathbf{y})$ to γ at $\mathbf{x}$ can be written as $\mathbf{N}(\mathbf{y}) = \sum_{j=1}^{n+1} A_j(\mathbf{y})\mathbf{e}_j$, where $A_j := \det(\mathbf{e}_j, D\boldsymbol{\chi})$ and $\{\mathbf{e}_j\}_{j=1}^{n+1}$ is the canonical basis of $\mathbb{R}^{n+1}$. In fact, since

$$\mathbf{N}\cdot\partial_i\boldsymbol{\chi} = \sum_{j=1}^{n+1}\mathbf{e}_j\cdot\partial_i\boldsymbol{\chi}\det(\mathbf{e}_j, D\boldsymbol{\chi}) = \det\left(\sum_{j=1}^{n+1}(\mathbf{e}_j\cdot\partial_i\boldsymbol{\chi})\mathbf{e}_j, D\boldsymbol{\chi}\right) = \det(\partial_i\boldsymbol{\chi}, D\boldsymbol{\chi}) = 0,$$

and $A_j \neq 0$ for at least one j because $D\boldsymbol{\chi}$ has rank n, we deduce that

$$\boldsymbol{\nu}(\mathbf{y}) := \frac{\mathbf{N}(\mathbf{y})}{|\mathbf{N}(\mathbf{y})|} \quad \forall \mathbf{y}\in\mathcal{V} \tag{2}$$

is a well-defined unit normal vector to γ. Therefore, the matrix

$$\mathbf{T}(\mathbf{y}) := [D\boldsymbol{\chi}(\mathbf{y}), \boldsymbol{\nu}(\mathbf{y})] \in \mathbb{R}^{(n+1)\times(n+1)} \quad \forall \mathbf{y}\in\mathcal{V}$$

has rank $n + 1$ and so is invertible. We write its inverse as

$$\mathbf{T}^{-1} = \begin{bmatrix}\mathbf{B}\\ \mathbf{v}^t\end{bmatrix}, \quad \mathbf{B}\in\mathbb{R}^{n\times(n+1)}, \mathbf{v}\in\mathbb{R}^n,$$

and note that

$$\mathbf{I}_{(n+1)\times(n+1)} = \mathbf{T}^{-1}\mathbf{T} = \begin{bmatrix}\mathbf{B}\,D\boldsymbol{\chi} & \mathbf{B}\mathbf{v}\\ \mathbf{v}^t\ D\boldsymbol{\chi} & \mathbf{v}^t\boldsymbol{\nu},\end{bmatrix}$$

whence

$$\mathbf{B}\,D\boldsymbol{\chi} = \mathbf{I}_{n\times n}, \quad \mathbf{v}^t D\boldsymbol{\chi} = 0, \quad \mathbf{v}^t\,\boldsymbol{\nu} = 1.$$

The last two equalities imply $\mathbf{v} = \boldsymbol{\nu}$. Reversing the order of multiplication yields

$$\mathbf{I}_{(n+1)\times(n+1)} = \mathbf{T}\,\mathbf{T}^{-1} = D\boldsymbol{\chi}\,\mathbf{B} + \boldsymbol{\nu}\boldsymbol{\nu}^t,$$

whence the *projection matrix* $\Pi\in\mathbb{R}^{(n+1)\times(n+1)}$ on the tangent hyperplane to γ has the form

$$\Pi := \mathbf{I} - \boldsymbol{\nu}\otimes\boldsymbol{\nu} = D\boldsymbol{\chi}\,\mathbf{B}. \tag{3}$$

To obtain an explicit expression for $\mathbf{B}$ note that

$$D\boldsymbol{\chi} = (\mathbf{I} - \boldsymbol{\nu}\otimes\boldsymbol{\nu})^t D\boldsymbol{\chi} = \mathbf{B}^t D\boldsymbol{\chi}^t D\boldsymbol{\chi} = \mathbf{B}^t\mathbf{g} \quad\Rightarrow\quad \mathbf{B} = \mathbf{g}^{-1}D\boldsymbol{\chi}^t.$$

This leads to the following useful expression of Π defined in (3):

$$\Pi = D\boldsymbol{\chi}\,\mathbf{g}^{-1}D\boldsymbol{\chi}^t. \tag{4}$$

The *area element* $q(\mathbf{y})$ is the ratio of the infinitesimal volume at $\mathbf{y}\in\mathcal{V}$ and area of γ at $\mathbf{x} = \boldsymbol{\chi}(\mathbf{y})$, namely the volume of the parallelotope in the tangent plane to γ spanned by the vectors $\{\boldsymbol{\chi}_j\}_{j=1}^n$:

$$q(\mathbf{y}) := \det([\boldsymbol{\nu}(\mathbf{y}), D\boldsymbol{\chi}(\mathbf{y})]) \quad \forall \mathbf{y}\in\mathcal{V}. \tag{5}$$

To obtain a more familiar form of q we argue as follows:

$$q=\frac{1}{|N|}\det([\mathbf{N}, D\boldsymbol{\chi}])=\frac{1}{|N|}\det\left([\mathbf{N}, D\boldsymbol{\chi}]^t[\mathbf{N}, D\boldsymbol{\chi}]\right)^{\frac{1}{2}}=\sqrt{\det\mathbf{g}}, \tag{6}$$

because $\det([\mathbf{N}, D\boldsymbol{\chi}]^t[\mathbf{N}, D\boldsymbol{\chi}])=|\mathbf{N}|^2\det(D\boldsymbol{\chi}^tD\boldsymbol{\chi})=|\mathbf{N}|^2\det\mathbf{g}$. Moreover, exploiting that $|\mathbf{N}|^2=\sum_{j=1}^{n+1}A_j\det([\mathbf{e}_j, D\boldsymbol{\chi}])=\det([\mathbf{N}, D\boldsymbol{\chi}])$, we deduce

$$q=|\mathbf{N}|. \tag{7}$$

An integrable function $v:\mathcal{V}\to\mathbb{R}$ induces an integrable function $\widetilde{v}:\gamma\to\mathbb{R}$ by composition $v=\widetilde{v}\circ\boldsymbol{\chi}$, or equivalently $\widetilde{v}(\mathbf{x})=v(\mathbf{y})$ for all $\mathbf{y}\in\mathcal{V}$. The area element allows for integration over γ via the formula

$$\int_\gamma\widetilde{v}=\int_{\mathcal{V}}vq \quad \forall v\in L_1(\mathcal{V}). \tag{8}$$

This definition does not depend on the parametrization: if $\boldsymbol{\chi}_1, \boldsymbol{\chi}_2$ are parametrizations of γ, then $\boldsymbol{\chi}_1=\boldsymbol{\chi}_2\circ(\boldsymbol{\chi}_2^{-1}\circ\boldsymbol{\chi}_1)$ and $D\boldsymbol{\chi}_1=D\boldsymbol{\chi}_2D(\boldsymbol{\chi}_2^{-1}\circ\boldsymbol{\chi}_1)$ whence

$$q_1=\left|\det\left(D(\boldsymbol{\chi}_2^{-1}\circ\boldsymbol{\chi}_1)\right)\right|q_2 \quad\Rightarrow\quad \int_{\mathcal{V}_1}vq_1=\int_{\mathcal{V}_2}vq_2.$$

2.2 Differential operators

If a function $v:\mathcal{V}\to\mathbb{R}$ is of class C^1, we can define the *tangential (or surface) gradient* of the corresponding function $\widetilde{v}:\gamma\to\mathbb{R}$ as a vector tangent to γ that satisfies the chain rule

$$\nabla v(\mathbf{y})=D\boldsymbol{\chi}(\mathbf{y})^t\nabla_\gamma\widetilde{v}(\mathbf{x}) \quad \forall\mathbf{y}\in\mathcal{V}. \tag{9}$$

Since $\nabla_\gamma\widetilde{v}$ is spanned by $\{\partial_j\boldsymbol{\chi}\}_{j=1}^n$, we get $\nabla_\gamma\widetilde{v}=D\boldsymbol{\chi}w$ for some $w\in\mathbb{R}^n$ whence $w=\mathbf{g}^{-1}\nabla v$ and

$$\nabla_\gamma\widetilde{v}(\mathbf{x})=D\boldsymbol{\chi}(\mathbf{y})\mathbf{g}(\mathbf{y})^{-1}\nabla v(\mathbf{y}) \quad \forall\mathbf{y}\in\mathcal{V}. \tag{10}$$

If $\widetilde{\mathbf{v}}=(\widetilde{v}_i)_{i=1}^{n+1}:\gamma\to\mathbb{R}^{n+1}$ is a vector field of class C^1, we define its tangential differential $D_\gamma\widetilde{\mathbf{v}}\in\mathbb{R}^{(n+1)\times(n+1)}$ as a matrix whose ith row is $(\nabla_\gamma\widetilde{v}_i)^t$. If γ is of class C^2, then the unit normal vector $\boldsymbol{\nu}$ is of class C^1 and its differential

$$\mathbf{W}(\mathbf{x})=D_\gamma\boldsymbol{\nu}(\mathbf{x}) \quad \forall\mathbf{x}\in\gamma \tag{11}$$

is called the *Weingarten* (or shape) map of γ. In addition, the *tangential divergence* of $\widetilde{\mathbf{v}}$ is the trace of $D_\gamma\widetilde{\mathbf{v}}$

$$\operatorname{div}_\gamma\widetilde{\mathbf{v}}(\mathbf{x})=\operatorname{trace}\left(D_\gamma\widetilde{\mathbf{v}}(\mathbf{x})\right)=\sum_{i,j=1}^n g^{ij}(\mathbf{y})\,\partial_i\boldsymbol{\chi}(\mathbf{y})\cdot\partial_j\mathbf{v}(\mathbf{y}) \quad \forall\mathbf{y}\in\mathcal{V}, \tag{12}$$

Vector Differential and Integral Calculus

7.1 INTRODUCTION

Vector calculus (or analysis) is a branch of mathematics concerned with differentiation and integration of vector fields. Vector calculus plays an important role in differential geometry and in the study of partial differential equations. It is used extensively in physics and engineering, especially in the description of electromagnetic fields, fluid flow, and gravitational fields. In this chapter, we shall study the vector differential and integral calculus. We often call this study as *vector field theory* or *vector analysis*. We first introduce the some concepts.

(i) Scalar Function

A scalar function $f(x, y, z)$ is a function defined at each point in a certain domain D in space. Its value is real and depends only on the point $P(x, y, z)$ in space, but not on any particular coordinate system being used, for example, the distance function in 3D space which defines the distance between the points $P(x, y, z)$ and $Q(x_0, y_0, z_0)$, then

$$D = f(P) = \sqrt{(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2} \text{ defines a scalar field.}$$

(ii) Vector Function

A function $\vec{F} = \vec{F}(P) = F_1\,\hat{i} + F_2\,\hat{j} + F_3\,\hat{k}$ defined at each point $P \in D$ is called a vector function. We say that a vector field is defined in D. In Cartesian coordinates, we can write

$$\vec{F} = F_1(z, y, z)\,\hat{i} + F_2(z, y, z)\,\hat{j} + F_3(z, y, z)\,\hat{k}$$

If the scalar and vector fields depend on time also then we denote them as $f(P, t)$ and $\vec{F}\,(P, t)$, respectively. Both the fields are independent of the choice of the coordinate systems.

(iii) Level Surfaces

If $f(x, y, z)$ be a single-valued continuous scalar function defined at every point $P(x, y, z)$ in the domain D. Then $f(x, y, z) = c$, a constant defines the equation of a surface and is called *a level surface of the function*. For the different values of C, we obtain the different surfaces, no two of which intersect.

7.2 PARAMETRIC REPRESENTATION OF VECTOR FUNCTIONS

The two-dimensional curve C can be parametrized by $x = x(t)$, $y = y(t)$, $a \le t \le b$. Then, the position vector of a point P on the curve C can be written as follows:

$$\vec{r}(t) = x(t)\hat{i} + y(t)\hat{j}$$

Similarly, a three-dimensional curve can be parametrized as

$$\vec{r}(t) = x(t)\hat{i} + y(t)\hat{j} + z(t)\hat{k}; \quad a \le t \le b$$

Parametric Forms of the Standard Curves

(i) Straight Line $\vec{r}(t) = \vec{a} + \vec{b}t$

The parametric form is

$$\vec{r}(t) = t\,\hat{i} + (1-t)\,\hat{j} \qquad 0 \le t \le 1$$

(ii) Circle $x^2 + y^2 = a^2$, the parametric form of the circle is

$$\vec{r}(t) = a\cos t\,\hat{i} + a\sin t\,\hat{j}; \qquad 0 \le t \le 2\pi$$

(iii) Parabola Consider the parabola $y^2 = 4ax$.

Then we assume $y = t$ as a parameter and the parametric form of the parabola as

$$\vec{r}(t) = \left(\frac{t^2}{4a}\right)\hat{i} + t\,\hat{j}; \qquad -\infty < t < \infty$$

(iv) Ellipse The parametric form of the ellipse $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$ can be written as

$$\vec{r}(t) = a\cos t\,\hat{i} + b\sin t\,\hat{j}; \qquad 0 \le t \le 2\pi$$

7.3 LIMIT, CONTINUITY, AND DIFFERENTIABILITY OF A VECTOR FUNCTION

A vector function $\vec{F}(t)$ is said to a limit 'l', when t tends to t_0, if for any given positive number $\in$, however small, there corresponds a positive number δ such that

$$|\vec{F}(t) - l| < \varepsilon, \text{ whenever } |t - t_0| < \delta$$

If $\vec{F}(t)$ tends to a limit 'l' as t tends to t_0,

$$\therefore \qquad \lim_{t \to t_0} \vec{F}(t) = l$$

A vector point function $\vec{F}(t)$ is said to be continuous for a value t_0 of t if $\vec{F}(t_0)$ is defined and for any given positive number ε, however small, there exists a positive number δ such that

$$|\vec{F}(t) - \vec{F}(t_0)| < \varepsilon, \text{ whenever } |t - t_0| < \delta.$$

A vector function $\vec{F}(t)$ is said to be differentiable at $t = t_0$, if the limit $\lim_{t_0 \to 0} \frac{\overline{F}(t+t_0) - \overline{F}(t)}{t_0}$ exists.

3

Complex Variables and Calculus

3.1 COMPLEX NUMBER

An ordered pair of real numbers x and y to be written as $z = (x, y)$ is called a complex number. Also, we may write $z = (x, y) = x + iy$, where imaginary unit i(iota) is defined as $i = (0, 1)$. Here x is called real part of z and y is called imaginary part of z. The real part of z is denoted by Re(z) and the imaginary part of z by Im(z).

Set of Complex Numbers

The set of all complex numbers is denoted by C, i.e.,

$$C = \{x + iy \mid x, y \in R\}.$$

Since a real number 'x' can be written as $x + oi$,

$\therefore$ Every real number is a complex number. Hence $R \subset C$, where R is the set of all real numbers.

3.2 EQUALITY OF COMPLEX NUMBERS

Two complex numbers $z_1 = x_1 + iy_1$ and $z_2 = x_2 + iy_2$ are equal if $x_1 = x_2$ and $y_1 = y_2$, i.e. $\text{Re}(z_1) = \text{Re}(z_2)$ and $\text{Im}(z_1) = \text{Im}(z_2)$.

3.3 FUNDAMENTAL OPERATIONS WITH COMPLEX NUMBERS

Let $z_1 = x_1 + iy_1$ and $z_2 = x_2 + iy_2$ be two complex numbers, then

(i) Addition of Complex Numbers

Addition of two complex numbers z_1 and z_2 is denoted by $z_1 + z_2$ and is defined as

$$z_1 + z_2 = (x_1 + x_2) + i(y_1 + y_2)$$

i.e., $\text{Re}(z_1 + z_2) = \text{Re}(z_1) + \text{Re}(z_2)$

and $\text{Im}(z_1 + z_2) = \text{Im}(z_1) + \text{Im}(z_2)$.

Properties of Addition of Complex Numbers

(a) Addition is commutative for any two complex numbers z_1 and z_2, we have

$$z_1 + z_2 = z_2 + z_1.$$

(b) *Addition is associative* For any three complex numbers z_1, z_2, z_3, we have

$$(z_1 + z_2) + z_3 = z_1 + (z_2 + z_3).$$

(c) *Existence of additive identity* The complex number $0 = 0 + 0i$ is an identity element for addition, i.e. $z + 0 = z = 0 + z$ for al $z \in C$.

(d) *Existence of additive inverse* For every non-zero complex number $z = x + iy$ and there exists an additive inverse $z = -(x + iy)$, then

$$\begin{aligned} z + (-z) &= (x + iy) - (x + iy) \\ &= 0 + 0i \\ &= 0 \end{aligned}$$

(ii) Subtraction of Complex Numbers

The subtraction of z_2 from z_1 is denoted by $z_1 - z_2$ and is defined as the addition of z_1 and z_2.
Thus, $z_1 +(-z_2) = z_1 - z_2 = (x_1 + iy_1) - (x_2 + iy_2)$

$$= (x_1 - x_2) + i(y_1 - y_2).$$

(iii) Multiplication of Complex Numbers

The multiplication of z_1 with z_2 is denoted by z_1z_2 and is defined as the complex number

$$(x_1x_2 - y_1y_2) + i(x_1y_2 + x_2y_1).$$

Thus,

$$\begin{aligned} z_1z_2 &= (x_1 + i\, y_1) \cdot (x_2 + \mathrm{i}y_2) \\ &= (x_1x_2 - y_1y_2) + i(x_1y_2 + x_2y_1). \end{aligned}$$

$\Rightarrow$

$$z_1z_2 = [\mathrm{Re}(z_1)\,\mathrm{Re}(z_2) - \mathrm{Im}(z_1)\,\mathrm{Im}(z_2)] + i\,[\mathrm{Re}(z_1)\,\mathrm{Im}(z_2) + \mathrm{Re}(z_2)\,\mathrm{Im}(z_1)]$$

Properties of Multiplication

(a) *Multiplication is commutative* For any two complex numbers z_1 and z_2, we have

$$z_1z_2 = z_2z_1.$$

(b) *Multiplication is associative* For any three complex numbers z_1, z_2, z_3, we have

$$(z_1\, z_2)\, z_3 = z_1(z_2\, z_3).$$

(c) *Existence of identity element for multiplication* The complex number $1 = 1 + oi$ is the identity element for multiplication, i.e. for every complex number z, we have
$z \cdot 1 = z = 1 \cdot z$.

(d) *Existence of multiplicative inverse* For every non-zero complex number $z = x + iy$, there exists a complex number $z_1 = x_1 + iy_1$. Such that

$$z\, z_1 = 1 = z_1\, z.$$

(e) *Multiplication of complex numbers is distributive over addition of complex numbers* For any three complex numbers z_1, z_2, z_3, we have
(i) $z_1(z_2 + z_3) = z_1z_2 + z_1z_3$ (Left distributivity)
(ii) $(z_2 + z_3)z_1 = z_2z_1 + z_3z_1$ (Right distributivity)

3.4 DIVISION OF COMPLEX NUMBERS

The division of a complex number z_1 by a non-zero complex number z_2 is defined as the multiplication of z_1 by the multiplicative inverse of z_2 and is denoted by $\dfrac{z_1}{z_2} = z_1 \cdot (z_2)^{-1} = z_1 \cdot \left(\dfrac{1}{z_2}\right)$.

14

Calculus of Variations

14.1 INTRODUCTION

Calculus of variations plays an important role in modern developments in analysis, geometry and physics. Originating as a study of certain maximum and minimum problems not treatable by the methods of elementary calculus, variational calculus in its present form provides powerful methods for the treatment of differential equations, theory of invariants, existence theorems in geometric function theory, variational principles in mechanics. It is also important to the applications to boundary value problems in partial differential equations and in the numerical calculation of many types of problems which can be stated in variational form. No literature representing these diverging viewpoints is to be found among standard texts on calculus of variations, and in this course an attempt will be made to do justice to this variety of problems. The subject matter with which calculus of variations is concerned is a class of extremum (i.e., maximum or minimum) problems which can be considered as an extension of the familiar class of extremum problems dealt with by elementary differential calculus. In the elementary problems, one seeks extremal values of a function of one or more (but in any case a finite number) real variables in the more general problems considered by calculus of variations, the functions to be extremized, sometimes called functionals, have functions as independent variables. In this chapter, we will study various method of variational with fixed boundaries

14.2 FUNCTION

Let X and Y be any two non-empty sets and there be a correspondence or association between the elements of X and Y such that for every elements of X and Y, there exists a unique element $y \in Y$ written as $y = f(x)$ then we say that y is a mapping or function from X to Y and written as $f: X \rightarrow Y$ such that $y = f(x)\ \forall\ x \in X, y \in X$.

14.3 FUNCTIONAL

Let there be functional belonging to class of functions. Then a variable quantity denoted by $I[y(x)]$ is a functional if to each function belonging to the class of functions there is definite value of I.

Thus functional is a function between the set of functions and set variable quantity. Obviously, domain of the functional is a set of functions for which the functional have been defined as following:

(i) $\int_{x_1}^{x_2} \sqrt{\left[1+\left(\frac{dy}{dx}\right)^2\right]}\,dx$ determines the length of arc between the points (x_1, y_1) and (x_2, y_2) on the curve $y = f(x)$. Length of the arc is determined by the choice of functions. Thus, we see corresponding to functions through (x_1, y_1) and (x_2, y_2) determine the length of arc between these points. Therefore it is a clear example of functional. Thus we note $I\left[y(x)\right]=\int_{x_1}^{x_2}\sqrt{\left[1+\left(\frac{dy}{dx}\right)^2\right]}dx.$ We can also write it as $I\left[y(x)\right]=\int_{x_1}^{x_2} f\left[x, y(x), y'(x)\right]dx.$

(ii) Area S of a surface bounded by a given curve C is determined by the surface $z = z(x, y)$ and given by $\iint_D \sqrt{\left(1+\left(\frac{\partial z}{\partial x}\right)^2+\left(\frac{\partial z}{\partial y}\right)^2\right)}dxdy$ where D is the projection of area bounded by curve on xy-plane.

14.4 DIFFERENCE BETWEEN FUNCTION AND FUNCTIONAL

S.No	Function	Functional
1.	The variable y is called a function of a variable x, in writing as $y = y(x)$.	The variable I is called a functional depending on a function $y = y(x)$, in writing as $I = I[y(x)]$.
2.	If to each value of x from a certain domain there corresponds a certain value of y, to a given number x, there corresponds a number y.	If to each function $y(x)$, from a certain class of function there corresponds a certain value of I, to a given function $y(x)$, there corresponds a number I.
3.	The increment Δx of the argument x of a function $y(x)$ is the difference of two values of this argument $\Delta x = x - x_1$. If x is the independent variable, then the differential of x coincides with its increment $dx = \Delta x$.	The increment or the variation δy of the argument $y(x)$ of a functional $I[y(x)]$ is the difference of two functions $\delta y = y(x) - y_1(x)$. It is assumed that the argument is $y(x)$ runs through a certain class of functions.
4.	A function $y(x)$ is said to be a continuous function, if small variations of x always lead to small variations of the functions $y(x)$. 	A functional $I[y(x)]$ is said to be a continuous function, if small variations of $y(x)$ always lead to small variations of the functional $I[y(x)]$. 
5.	The function $l(x)$ is called linear if $l(cx) = cl(x)$.	The functional $L(x)$ is called linear, if $L(cx) = cL(x)$.
6.	If the increment $\Delta y = y = y(x + \Delta x) - y(x)$ is of the form $\Delta y = A(x)\Delta x + \beta(x, \Delta x).\Delta x$.	If the increment $\Delta I = I\left[y(x)+\delta y)\right]-I\left[y(x)\right]$ of a functional is of the form $\Delta I = L\left[y(x),\delta x\right]+\beta(y(x),\delta y).\max\left\|\delta y\right\|$.
7.	The differential of a function $y(x)$ is given by $\left(\frac{\partial}{\partial\alpha} y(x+\alpha.\Delta x)\right)_{\alpha=0}$.	The variation of a functional $I[y(x)]$ is given by $\left(\frac{\partial}{\partial\alpha} I\left[y(x+\alpha.\delta y)\right]\right)_{\alpha=0}$.

14.5 CLOSENESS OF CURVES

In the calculus of real variable we have defined the continuity of function at $x = a$. As the variable x is becoming closer to a, then $f(x)$ becomes closer to $f(a)$.

Here in case of functional, domain is the class of functions and here idea of closeness of $y(x)$ and $y_1(x)$ is to say that the absolute value of their difference, i.e. $|y(x) - y_1(x)|$ is small for all x for which $y(x)$ and $y_1(x)$ are defined.

If it happens then we say $y(x)$ is close to $y_1(x)$ in the sense of zero order proximity. $I\left[y(x)\right]=\int_{x_1}^{x_2} f\left[x, y(x), y'(x)\right]dx$. Curve $y(x)$ and $y_1(x)$ are said to be close in the sense of n^{th} order proximity if $|y(x) - y_1(x)|$, $\left|y'(x)-y_1{}'(x)\right|\cdots\left|y^n(x)-y_1^n(x)\right|$ are small for the values of for x which these functions are defined.

14.6 CONTINUITY OF FUNCTIONAL

Domain of functional is the set of functions, therefore continuity of functional at some function is defined as following: Functional $I[y(x)]$ is said to be continuous at $y = y_0(x)$ in the sense of $n^{\underline{\text{th}}}$ order proximity if given for any positive number ε, $\exists\ \delta > 0$ such that $\left|I\left[y(x)\right]-I\left[y_0(x)\right]\right| < \varepsilon$

for $\left|y(x)-y_0(x)\right| < \delta, \left|y'(x)-y_0{}'(x)\right| < \delta \cdots \left|y^n(x)-y_0^n(x)\right| < \delta$

Linear Property Let the functional $I[y(x)]$ be defined in the linear space M of the functions $y(x)$. Functional $I[y(x)]$ is said to be linear if it satisfies the following conditions

(a) $I\left[c\ y(x)\right] = c\ I\left[y(x)\right]$ where c is any arbitrary constant.

(b) $I\left[\ y_1(x)+y_2(x)\right]=I\left[y_1(x)\right]+I\left[y_2(x)\right]$ where $y_1(x)$ and $y_2(x) \in M$

Example 1 Functional $I\left[y(x)\right]=\int_a^b\left(y'+2y\right)dx$ defined in the space which consists of the continuous function possessing continuous derivatives of first order.

> The indeterminism appears however only in the physical space, while in the space of all states (Hilbert space) everything is perfectly deterministic. The wave function evolves in a deterministic way according to the time-dependent Schrödinger equation (1.10).

The puzzling way in which indeterminism operates will be shown below.

1.3 The Heisenberg uncertainty principle

Consider two mechanical quantities A and B, for which the corresponding Hermitian operators (constructed according to Postulate II), $\hat{A}$ and $\hat{B}$, give the commutator $\left[\hat{A}, \hat{B}\right] = \hat{A}\hat{B} - \hat{B}\hat{A} = i\hat{C}$, where $\hat{C}$ is a Hermitian operator.[52] This is what happens for example for $A = x$ and $B = p_x$. Indeed, for any differentiable function ϕ one has $[\hat{x}, \hat{p_x}]\phi = -xi\hbar\phi' + i\hbar(x\phi)' = i\hbar\phi$, and therefore the operator $\hat{C}$ in this case means simply multiplication by $\hbar$.

> From axioms of quantum mechanics one can prove that a product of errors (in the sense of standard deviation) of measurements of two mechanical quantities is greater than or equal to $\frac{1}{2}\left\langle[\hat{A}, \hat{B}]\right\rangle$, where $\left\langle[\hat{A}, \hat{B}]\right\rangle$ is the mean value of the commutator $[\hat{A}, \hat{B}]$.

This is known as the Heisenberg uncertainty principle.

Werner Heisenberg did not provide any formal proof; instead he carried out a *Gedankenexperiment* (an ideal thought experiment) with an electron interacting with an electromagnetic wave ("Heisenberg's microscope").

The formal proof goes as follows.

---

[52] This is guaranteed. Indeed, $\hat{C} = -i\left[\hat{A}, \hat{B}\right]$ and then the Hermitian character of $\hat{C}$ is shown by the following chain of transformations: $\left\langle f|\hat{C}g\right\rangle = -i\left\langle f|\left[\hat{A}, \hat{B}\right]g\right\rangle = -i\left\langle f|(\hat{A}\hat{B} - \hat{B}\hat{A})g\right\rangle = -i\left\langle(\hat{B}\hat{A} - \hat{A}\hat{B})f|g\right\rangle = \left\langle -i(\hat{A}\hat{B} - \hat{B}\hat{A})f|g\right\rangle = \left\langle\hat{C}f|g\right\rangle$.

Werner Karl Heisenberg (1901–1976) was born in Würzburg (Germany), attended high school in Munich, and then (with his friend Wolfgang Pauli) studied physics at Munich University under Sommerfeld's supervision. In 1923 he defended his doctoral thesis on turbulence in liquids. Reportedly, during the doctoral examination he had problems writing down the chemical reaction in lead batteries. He joined the laboratory of Max Born at Göttingen (following his friend Wolfgang) and in 1924 the Institute of Theoretical Physics in Copenhagen, working under the supervision of Niels Bohr. A lecture delivered by Niels Bohr decided the future direction of his work. Heisenberg later wrote: "*I was taught optimism by Sommerfeld, mathematics in Göttingen, physics by Bohr*." In 1925 (only a year after being convinced by Bohr) Heisenberg developed a formalism, which became the first successful quantum theory. Then, in 1926 Heisenberg, Born, and Jordan elaborated the formalism, which resulted in a coherent theory ("matrix mechanics"). In 1927 Heisenberg obtained a chair at Leipzig University, which he held until 1941 (when he became director of the Kaiser Wilhelm Physics Institute in Berlin). Heisenberg received the Nobel Prize in 1932 "*for the creation of quantum mechanics, the application of which has, inter alia, led to the discovery of the allotropic forms of hydrogen*." In 1937 Werner Heisenberg was at the height of his powers. He was nominated professor and got married. However, just after returning from his honeymoon, the rector of the university called him, saying that there was a problem. In the SS weekly, an article by Professor Johannes Stark (a Nobel Prize winner and faithful Nazi) was about to appear claiming that Professor Heisenberg is not such a good patriot as he pretends, because he socialized in the past with Jewish physicists. Soon Professor Heisenberg was invited to the SS headquarters at Prinz Albert Strasse in Berlin. The interrogation took place in the basement. On the raw concrete wall the scoffing slogan "*Breathe deeply and quietly*" was written. One of the questioners was a PhD student from Leipzig, who had once been examined by Heisenberg. The terrified Heisenberg told his mother about the problem. She recalled that in her youth she had made the acquaintance of Heinrich Himmler's mother. Frau Heisenberg paid a visit to Frau Himmler and asked her to pass a letter from her son to Himmler. At the beginning Himmler's mother tried to separate her maternal feelings for her beloved son from politics. She was finally convinced after Frau Heisenberg said "*we mothers should care about our boys*." After a certain time, Heisenberg received a letter from Himmler saying that his letter "coming through unusual channels" has been examined especially carefully. He promised to stop the attack. In the *post scriptum* there was a precisely tailored phrase: "*I think it best for your future, if for the benefit of your students, you would carefully separate scientific achievements from the personal and political beliefs of those who carried them out. Your faithfully, Heinrich Himmler*" (after D. Bodanis, "$E = mc^2$," Fakty, Warsaw, 2001, p. 130) ©The Nobel Foundation.

Recall the definition of the variance, or the square of the standard deviation $(\Delta A)^2$, of measurements of the quantity A:

$$(\Delta A)^2 = \langle \hat{A}^2 \rangle - \langle \hat{A} \rangle^2, \tag{1.22}$$

where $\langle X \rangle$ means the mean value of many measurements of the quantity X. The *standard deviation* ΔA *represents the width of the distribution of* A, i.e., *the error made.* Eq. (1.22) is equivalent to[53]

$$(\Delta A)^2 = \langle (\hat{A} - \langle \hat{A} \rangle)^2 \rangle. \tag{1.23}$$

Consider the product of the standard deviations for the operators $\hat{A}$ and $\hat{B}$, taking into account that $\langle \hat{u} \rangle$ denotes (Postulate IV) the integral $\langle \Psi | \hat{u} | \Psi \rangle$ according to (1.20). One obtains (denoting $\hat{\mathcal{A}} = \hat{A} - \langle \hat{A} \rangle$ and $\hat{\mathcal{B}} = \hat{B} - \langle \hat{B} \rangle$; of course, $[\hat{\mathcal{A}}, \hat{\mathcal{B}}] = [\hat{A}, \hat{B}]$)

$$(\Delta A)^2 \cdot (\Delta B)^2 = \langle \Psi | \hat{\mathcal{A}}^2 \Psi \rangle \langle \Psi | \hat{\mathcal{B}}^2 \Psi \rangle = \langle \hat{\mathcal{A}} \Psi | \hat{\mathcal{A}} \Psi \rangle \langle \hat{\mathcal{B}} \Psi | \hat{\mathcal{B}} \Psi \rangle,$$

where the Hermitian character of the operators $\hat{\mathcal{A}}$ and $\hat{\mathcal{B}}$ is used. Now, let us use the Schwarz inequality (Appendix B) $\langle f_1 | f_1 \rangle \langle f_2 | f_2 \rangle \geq |\langle f_1 | f_2 \rangle|^2$:

$$(\Delta A)^2 \cdot (\Delta B)^2 = \langle \hat{\mathcal{A}} \Psi | \hat{\mathcal{A}} \Psi \rangle \langle \hat{\mathcal{B}} \Psi | \hat{\mathcal{B}} \Psi \rangle \geq |\langle \hat{\mathcal{A}} \Psi | \hat{\mathcal{B}} \Psi \rangle|^2.$$

Next,

$$\begin{aligned} \langle \hat{\mathcal{A}} \Psi | \hat{\mathcal{B}} \Psi \rangle &= \langle \Psi | \hat{\mathcal{A}} \hat{\mathcal{B}} \Psi \rangle = \langle \Psi | \{[\hat{\mathcal{A}}, \hat{\mathcal{B}}] + \hat{\mathcal{B}} \hat{\mathcal{A}}\} \Psi \rangle = i \langle \Psi | \hat{C} \Psi \rangle + \langle \Psi | \hat{\mathcal{B}} \hat{\mathcal{A}} \Psi \rangle \\ &= i \langle \Psi | \hat{C} \Psi \rangle + \langle \hat{\mathcal{B}} \Psi | \hat{\mathcal{A}} \Psi \rangle = i \langle \Psi | \hat{C} \Psi \rangle + \langle \hat{\mathcal{A}} \Psi | \hat{\mathcal{B}} \Psi \rangle^*. \end{aligned}$$

Hence,

$$i \langle \Psi | \hat{C} \Psi \rangle = 2i \ \mathrm{Im}\{\langle \hat{\mathcal{A}} \Psi | \hat{\mathcal{B}} \Psi \rangle\}.$$

This means that $\mathrm{Im}\{\langle \hat{\mathcal{A}} \Psi | \hat{\mathcal{B}} \Psi \rangle\} = \frac{\langle \Psi | \hat{C} \Psi \rangle}{2}$, which gives $|\langle \hat{\mathcal{A}} \Psi | \hat{\mathcal{B}} \Psi \rangle| \geq \frac{\left|\langle \Psi | \hat{C} \Psi \rangle\right|}{2}$. Hence,

$$(\Delta A)^2 \cdot (\Delta B)^2 \geq |\langle \hat{\mathcal{A}} \Psi | \hat{\mathcal{B}} \Psi \rangle|^2 \geq \frac{|\langle \Psi | \hat{C} \Psi \rangle|^2}{4} \tag{1.24}$$

or, taking into account that $|\langle \Psi | \hat{C} \Psi \rangle| = |\langle \Psi | [\hat{A}, \hat{B}] \Psi \rangle|$, we have[54]

$$\Delta A \cdot \Delta B \geq \frac{1}{2} |\langle \Psi | [\hat{A}, \hat{B}] \Psi \rangle|. \tag{1.25}$$

---

[53] Because $\langle (\hat{A} - \langle \hat{A} \rangle)^2 \rangle = \langle \hat{A}^2 - 2\hat{A}\langle \hat{A} \rangle + \langle \hat{A} \rangle^2 \rangle = \langle \hat{A}^2 \rangle - 2\langle \hat{A} \rangle^2 + \langle \hat{A} \rangle^2 = \langle \hat{A}^2 \rangle - \langle \hat{A} \rangle^2$.

[54] This particular result was used later by Mandelshtam and Tamm to derive the energy-time uncertainty – an analogy to the Heisenberg uncertainty principle; see p. 100.

There are two important special cases.

(a) $\hat{C} = 0$, i.e., the operators $\hat{A}$ and $\hat{B}$ commute. We have $\Delta A \cdot \Delta B \geq 0$, i.e., *the errors can be arbitrarily small*. Both quantities therefore *can be* measured simultaneously without error.

(b) $\hat{C} = \hbar$, as in the case of $\hat{x}$ and $\hat{p_x}$. Then, $(\Delta A) \cdot (\Delta B) \geq \frac{\hbar}{2}$.

In particular, for $\hat{A} = \hat{x}$ and $\hat{B} = \hat{p}_x$, if quantum mechanics is valid, *one cannot determine the exact position and the exact momentum of a particle*. The sense of this statement is the following: even if it *may happen* that we get as a result of a measurement the exact position and the exact momentum of the particle, by repeating many times the measurement (in order to be sure about the error made) we are unable to get zero standard deviation (error) for position and energy measurements. When the precision with which x is measured increases, the particle's momentum has so wide a distribution that the error of determining p_x is huge.[55] Fig. 1.13 shows why the Heisenberg principle does not represent any mystery, but is a natural consequence of the wave nature of particles. Also, the principle does not rely on any putative perturbation of position or momentum of the particle during measurement.

The power of the Heisenberg uncertainty principle is seen when it is used for estimation, just from scratch, of the size of some systems.

Example 1 (Size of the hydrogen atom). How on earth this can be estimated from virtually no information? Let us see.

We assume that the electron moves, while the nucleus does not.[56] Whatever the electron does in the hydrogen atom, it has to conform to the uncertainty principle $\Delta x \cdot \Delta p_x \geq \frac{\hbar}{2}$, i.e., in the most compact state we may expect the *equality* $\Delta x \cdot \Delta p_x = \frac{\hbar}{2}$. We may estimate Δx as the radius r of the atom, while $\Delta p_x = \sqrt{\langle p_x^2 \rangle - \langle p_x \rangle^2} = \sqrt{\langle p_x^2 \rangle - 0} = \sqrt{\langle p_x^2 \rangle}$. Therefore, we have an estimation $r \cdot \sqrt{\langle p_x^2 \rangle} = \frac{\hbar}{2}$, or $\sqrt{\langle p_x^2 \rangle} = \frac{\hbar}{2r}$. The total energy may be estimated as the sum of the kinetic and potential energies: $E = \frac{\langle p^2 \rangle}{2m} - \frac{e^2}{r} = \frac{\langle p_x^2 + p_y^2 + p_z^2 \rangle}{2m} - \frac{e^2}{r} = \frac{3\hbar^2}{8mr^2} - \frac{e^2}{r}$. Now, let us find the minimum of $E(r)$ as its probable value: $\frac{\mathrm{d}E}{\mathrm{d}r} = 0 = -2\frac{3\hbar^2}{8mr^3} + \frac{e^2}{r^2}$, or $e^2 = \frac{3}{4}\frac{\hbar^2}{mr}$.

---

[55] There is an apocryphal story about a *Polizei* patrol stopping Professor Heisenberg for speeding. The very serious man asks: "*Do you know how fast you were going when I stopped you?*" Professor Heisenberg answered: "*I have absolutely no idea, Herr Oberleutnant, but I can tell you precisely where you stopped me.*"

[56] Note that by the momentum conservation law the nucleus moves 1840 times slower than the electron. This practically means the electron moves in the electric field of the immobilized nucleus.

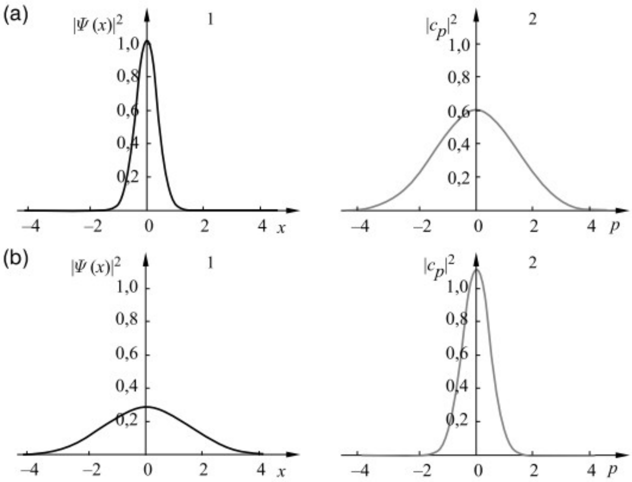

Fig. 1.13. Illustration of the Heisenberg uncertainty principle in case of a single particle moving on the x axis. (a1) $|\Psi(x)|^2$ (i.e., the probability density distribution of finding the particle) as function of coordinate x. The width of this distribution is related to the expected error of determining x. The curve is narrow, which means the error in determining the particle's position is expected to be small. The wave function $\Psi(x)$ can be expanded in the infinite series $\Psi(x) = \sum_p c_p \exp(ipx)$, where p denotes the momentum. Note that each individual function $\exp(ipx)$ is an eigenfunction of momentum, and therefore, if $\Psi(x) = \exp(ipx)$, a measurement of momentum would give exactly p. If, however, $\Psi(x) = \sum_p c_p \exp(ipx)$, then such a measurement yields a given p with the probability $|c_p|^2$. (a2) $|c_p|^2$ as function of p. As one can see a broad range of p (large uncertainty of momentum) ensures a sharp $|\Psi(x)|^2$ distribution (small uncertainty of position in (a1)). Simply the waves $\exp(ipx)$ to obtain a sharp peak of $\Psi(x)$ should exhibit a perfect constructive interference in a small region and a perfect destructive interference elsewhere. This requires a lot of different p's, i.e., a broad momentum distribution. This means that a small error in determining the particle's position is necessarily associated with a large error in determining the particle's momentum (Heisenberg uncertainty principle). (b1, b2) The same is shown, but this time a narrow p distribution gives a broad x distribution. The Heisenberg uncertainty principle has nothing mysterious in it and does not represent a unique feature of quantum mechanics. If one wanted to construct from the ocean waves (of various directions and wave lengths) a tall water pole in the middle of the still ocean, one would be forced to use many wave lengths to get the constructive interference in one spot and destructive interference in all the others.

Hence, we have an estimation, $r = \frac{3}{4}\frac{\hbar^2}{me^2} = 0.75 \cdot a_0$, where $a_0 = 0.529$ Å (as will be shown in Chapter 4, Eq. (4.41), p. 232) is known as the "Bohr first orbit radius of the hydrogen atom." Thus, just from the Heisenberg uncertainty principle we got a value, which has the correct order of magnitude!

We have an important result.

The Heisenberg uncertainty principle prevents atoms from collapsing (the electron falling down to the nucleus, $x = 0$, $\Delta x = 0$, its energy would be equal to $-\infty$), which would mean a catastrophe in the Universe (emission of an infinite amount of energy). The principle also gives a correct order of magnitude for the density of matter.

Example 2 (Size of nucleus). How large is an atomic nucleus? Well, again we may estimate its size from the Heisenberg uncertainty principle knowing only one thing: that the binding energy per nucleon is of the order of 8 MeV. We are now in the realm of nuclear forces acting among nucleons. It seems therefore our task is extremely difficult. We just ignore all these extremely complex forces, considering instead *a single nucleon moving in a mean potential, bound with the energy* $E = 8$ MeV, *and therefore its kinetic energy has to be of the same order of magnitude*. We focus on this kinetic energy[57] of the nucleon assuming simply that $E = \frac{\langle p^2\rangle}{2m_N} = \frac{\langle(\Delta p)^2\rangle}{2m_N}$. From this we calculate $\sqrt{\langle(\Delta p)^2\rangle} = \Delta p = \sqrt{2m_N E}$ and, using the Heisenberg uncertainty principle, we have the uncertainty of the nucleon's position as $a = \frac{\hbar}{2\Delta p} = \frac{\hbar}{2\sqrt{2m_N E}}$. Calculating this in atomic units ($\hbar = 1$, $e = 1$, $m = 1$, where m is the electron mass) we get $a = \frac{\hbar}{2\sqrt{2m_N E}} = \frac{1}{2\sqrt{2\cdot 1840\cdot 8\cdot 10^6\cdot 3.67516\cdot 10^{-2}}} = 0.0000152$ a.u. $\approx 10^{-13}$ cm, 100,000 times smaller than the hydrogen atom. Experiments confirm our number: this is indeed the order of magnitude of the sizes of atomic nuclei!

1.4 The Copenhagen interpretation of the world[58]

The picture of the world that emerged from quantum mechanics was "diffuse" with respect to classical mechanics. In classical mechanics one could measure a particle's position and momentum with a desired accuracy,[59] whereas the Heisenberg uncertainty principle states that this is simply *impossible*.

Bohr presented a philosophical interpretation of the world, which at its foundation had in a sense a *nonreality of the world*.

---

[57] We are interested in the order of its magnitude only.

[58] Schrödinger did not like the Copenhagen interpretation. Once, Bohr and Heisenberg invited him for a Baltic Sea cruise and tried to indoctrinate him so strongly that Schrödinger became ill and stopped participating in their discussions.

[59] This is an exaggeration. Classical mechanics also has its own problems with uncertainty. For example, obtaining the same results for a game of dice would require a perfect reproduction of the initial conditions, which is never feasible.

According to Bohr, before a measurement on a particle is made *nothing* can be said about the value of a given mechanical quantity, unless the wave function represents an eigenfunction of the operator of this mechanical quantity. Moreover, except this case, the particle *does not have* any fixed value of mechanical quantity at all.

A measurement gives a value of the mechanical property (A). Then, according to Bohr, after the measurement is completed, the state of the system changes (the so-called *wave function collapse* or *decoherence*) to the state described by *an eigenfunction of the corresponding operator* $\hat{A}$, and as the *measured value one obtains the eigenvalue corresponding to the wave function*. According to Bohr, there is no way to foresee which eigenvalue one will get as the result of the measurement. However, one can calculate the *probability* of getting a particular eigenvalue. This probability may be computed as the square of the overlap integral (cf. p. 29) of the initial wave function and the eigenfunction of $\hat{A}$.

1.5 How to disprove the Heisenberg principle? The Einstein–Podolsky–Rosen's recipe

The Heisenberg uncertainty principle came as a shock. Many scientists felt a strong imperative to prove that the principle is false. One of them was Albert Einstein, who used to play with ideas by performing some (as he used to say) ideal thought experiments (in German *Gedankenexperiment*) in order to demonstrate internal contradictions in theories. Einstein believed in the reality of our world. With his colleagues Podolsky and Rosen ("EPR team") he designed a special *Gedankenexperiment*.[60] It represented an attempt to disprove the Heisenberg uncertainty principle and to show that one *can* measure the position and momentum of a particle *without any error*. To achieve this, the gentlemen invoked the help of a second particle.

The key statement of the whole reasoning, given in the EPR paper, was the following: "*If, without in any way disturbing a system, we can predict with certainty (i.e., with probability equal to unity) the value of a physical quantity, then there exists an element of physical reality corresponding to this physical quantity*." In other words, the quantity to be measured *has* a particular, albeit maybe unknown, value. EPR considered a coordinate system fixed in space and two particles: particle 1 with coordinate x_1 and momentum p_{x1} and particle 2 with coordinate x_2 and momentum p_{x2}, the total system being in a well-defined total momentum, $P = p_{x1} + p_{x2}$, and a well-defined relative position, $x = x_1 - x_2$. The meaning of the words "well-defined" is that, according to quantum mechanics, there is a possibility of the *exact measurement* of the two quantities (x and P), because the two operators $\hat{x}$ and $\hat{P}$ do commute.[61] At this point, Einstein and his colleagues and the great interpreters of quantum theory agreed.

---

[60] A. Einstein, B. Podolsky, N. Rosen, *Phys. Rev.*, 47(1935)777.

We now come to the crux of the real controversy.

The particles interact, then separate and fly far away (at any time we are able to measure exactly both x and P). When they are extremely far from each other (e.g., one close to us, the other one millions of light years away), we begin to suspect that each of the particles may be treated as free. Then, we decide to measure p_{x1}. However, after we do it, we know *with absolute certainty the momentum of the second particle* $p_{x2} = P - p_{x1}$, and this knowledge has been acquired *without any perturbation of particle* 2. According to the above cited statement, one has to admit that p_{x2} represents an element of physical reality. So far so good. However, we *might have decided* with respect to particle 1 to measure its *coordinate* x_1. If this happened, then we would know *with absolute certainty the position of the second particle*, $x_2 = x - x_1$, without perturbing particle 2 at all. Therefore, x_2, as p_{x2}, is an element of physical reality. The Heisenberg uncertainty principle says that it is *impossible* for x_2 and p_{x2} to be exactly measurable quantities. Conclusion: the Heisenberg uncertainty principle is wrong, and quantum mechanics is at least incomplete.

A way to defend the Heisenberg principle was to treat the two particles as an indivisible total system and reject the supposition that the particles are independent, even if they are millions of light years apart. This is how Niels Bohr desperately defended himself against Einstein (and his two colleagues). He said that the state of the total system in fact never fell apart into particles 1 and 2, and still is in what is known as an *entangled quantum state*[62] of the system of particles 1 and 2, and

> any measurement influences the state of the system as a whole, *independently of the distance of particles* A and B.

This reduces to the statement that measurement manipulations on particle 1 influence the results of measurements on particle 2. This correlation between measurements on particles 1 and 2 has to take place *immediately, regardless of the space that separates them.*[63] This is a shocking and nonintuitive feature of quantum mechanics. This is why it is often said that quantum mechanics cannot be understood. One can apply it successfully and obtain an excellent agreement with experiment, but there is something strange in its foundations. This represents a challenge: an excellent theory, but based on some unclear foundations.

---

[61] Indeed, $\hat{x}\hat{P} - \hat{P}\hat{x} = (\hat{x}_1 - \hat{x}_2)(\hat{p}_{x1} + \hat{p}_{x2}) - (\hat{p}_{x1} + \hat{p}_{x2})(\hat{x}_1 - \hat{x}_2) = [\hat{x}_1, \hat{p}_{x1}] - [\hat{x}_2, \hat{p}_{x2}] + [\hat{x}_1, \hat{p}_{x2}] - [\hat{x}_2, \hat{p}_{x1}] = -i\hbar + i\hbar + 0 - 0 = 0.$

[62] To honor Einstein, Podolsky, and Rosen the entanglement of states is sometimes called the EPR effect.

[63] Nevertheless, the correlation is not quite clear. One may pose some questions. The statement about the instantaneous correlation between particles 1 and 2 in the EPR effect cannot be correct, because the measurements are separated in the space–time manifold and the simultaneity is problematic (see Chapter 3). What is the laboratory fixed coordinate system? How is information about particle 2 transferred to where we carry out the measurement on particle 1? This takes time. After that time particle 1 is elsewhere. Is there anything to say about the separation time? In which coordinate system is the separation time measured?

In the following, some precise experiments will be described, in which it is shown that quantum mechanics is right, however absurd it looks. Before that let us consider a cat.

1.6 The life and death of Schrödinger's cat

The abovementioned paper by Einstein, Podolsky, and Rosen represented a severe critique of quantum mechanics in the form it has been presented by its fathers. After the appearance of the article, Erwin Schrödinger published a series of works[64] showing some other problematic issues in quantum mechanics. In particular, he described a *Gedankenexperiment*, later known as the Schrödinger's cat paradox. According to Schrödinger it shows some absurd consequences of quantum mechanics.

Here is the paradox. There is a cat closed in an isolated steel box (filled with air). Together with the cat there is a Geiger counter in the box (protected from the cat). We put in the counter a bit of a radioactive substance, carefully prepared in such a way that every hour two events happen with the same probability: either a radioactive nucleus decays or no radioactive nucleus decays. If a nucleus really decays, it causes ionization and electric discharge in the counter tube, which in turn results in a hammer hitting a glass capsule with hydrocyanic acid (HCN) gas, which kills the cat. If one puts the cat in for an hour, then *before* opening the box, one cannot say the cat is dead or alive. According to the Copenhagen interpretation, this is reflected by a proper wave function Ψ (for the box with everything in it), which is a superposition of two states with equal probability amplitudes: one state corresponds to the cat being alive, the other to the dead cat. The function Ψ describes therefore a cat in an intermediate state, neither alive nor dead, just in the middle between life and death, which, according to Schrödinger, would represent a totally absurd description. Einstein joined Schrödinger enthusiastically in this mockery from the Copenhagen interpretation, adding in his style "an even better" idea about how to kill the cat (gun powder instead of cyanide). All in all, in this way an atomic-scale phenomenon (decay of a nucleus) can result in some drastic events in the macroscopic world. If, after an hour, an observer opens the box ("measurement" of the state of the content of the box), then according to the Copenhagen interpretation, this will result in the collapse of the corresponding wave function and the observer will find the cat *either* alive *or* dead. This is the crux of the paradox.

Since the early days of quantum mechanics many scholars were trying to rationalize the paradox, always relying on some particular interpretation of quantum mechanics. In one of the interpretations, quantum mechanics does not describe a single system, but rather an infinite set of systems. We have therefore plenty of cats and the same number of boxes, each of them with the same macabre gear inside. Then, the paradox disappears, because, after the boxes are open, in 50% of cases the cats will be alive and in 50% they will be dead. In another interpretation it is criticized that Schrödinger treats the box as a quantum system, while the observer is treated classically. In this interpretation not only Schrödinger plays the role of the observer, but also the cat, and even the box itself (since it may contain a camera). What happened may be described differently by each of the observers, depending on what information they have about the whole system. For example, in the cat (alive or dead) there is information what has happened even *before* the box is open. The human observer does not have this information. Therefore, the collapse of the wave function happened earlier for the cat than for the observer! Only after the box is open it will turn out for the cat and for the observer that the collapse happened to the same state.

---

[64] E. Schrödinger, *Naturwissenschaften*, 23(1935)807, 823, 844.

Hugh Evereth stepped out with another, truly courageous, interpretation. According to Evereth we do not have our single Universe, as most of us might think naively, but a plethora of universes coexist, and in each of them some other things happen! When the box is open, the state of the box is entangled with the state of the observer, but then a collapse of the wave function happens, and in one of the universes the cat is alive, but in the other one it is dead (bifurcation). These two universes evolve independently ("parallel universes"), and they do not know about each other. Similar bifurcations happen massively in other events; hence, according to Evereth, the number of parallel Universes is astronomic.

The quantity of possible interpretations, large differences among them, and desperate character of some of them indicate that the problem of understanding quantum mechanics is still unsolved...

1.7 Bilocation

Assume that the world (stars, Earth, Moon, me, table, proton, electron, etc.) exists objectively. One may suspect this from everyday observations. For example, the Moon is seen by many people, who describe it in a similar way.[65] Instead of the Moon, let us begin with something simpler: how is it with electrons, protons, or other elementary particles? This is an important question because the world as we know it – including the Moon – is mainly composed of protons.[66] Here one encounters a mysterious problem. I will try to describe it by reporting results of several experiments.

---

[65] This *may* indicate that the Moon exists independently of our observations and overcome importunate suspicions that the Moon ceases to exist when we do not look at it. Besides, there are people who claim to have seen the Moon from very close and even touched it (admittedly through a glove) and this slightly strengthens our belief in the Moon's existence. First of all, one has to be cautious. For example, some chemical substances, hypnosis, or an ingenious set of mirrors may cause some people to be convinced about the reality of some phenomena, while others do not see them. Yet, would it help if even everybody saw? We should not verify serious things by voting. The example of the Moon also intrigued others; cf. D. Mermin, "*Is the Moon there, when nobody looks?*", *Phys. Today*, 38(1985)38.

Following Richard Feynman,[67] imagine two slits in a wall. Every second (the time interval has to be large enough to be sure that we deal with properties of a *single* particle) we send an electron towards the slits. There is a screen behind the two slits, and when an electron hits the screen, there is a flash (fluorescence) at the point of collision. Nothing special happens. Some electrons will not reach the screen at all, but traces of others form a pattern, which seems quite chaotic. The experiment looks monotonous and boring. Just a flash here, and another there. One cannot predict where a particular electron will hit the screen. But suddenly we begin to suspect that there is some regularity in the traces (Fig. 1.14).

A strange pattern appears on the screen: regions with high concentrations of traces are separated by regions of low concentration. This resembles the interference of waves, e.g., a stone thrown into water causes interference behind two slits: an alternation of high and low amplitudes of water level. Well, but what has an electron in common with a wave on the water surface? The interference on water was possible, because there were two sources of waves (the Huygens principle) – two slits.

Common sense tells us that nothing like this could happen with the electron, because, firstly, the electron could not pass through *both* slits, and, secondly, unlike the waves, the electron has hit a tiny spot on the screen (transferring there its energy). Let us repeat the experiment with a *single* slit. The electrons go through the slit and make flashes on the screen here and there, but there is only a single major concentration region (just facing the slit) fading away from the center (with some minor minima).

This result should make you feel faint. Why? You would like the Moon, a proton, or an electron to be solid objects, wouldn't you? All investigations made so far indicate that the electron is a point-like elementary particle. If, in the experiments we have considered, the electrons were to be divided into two classes, i.e., those that passed through slit 1 and those that passed through slit 2, then the electron patterns would be different. The pattern with the two slits *had to be* the

---

[66] In the darkest communist times a colleague of mine came to my office. Conspiratorially, very excited, and occasionally looking over his shoulder, he whispered: "*The proton decays!!!*" He just read in a government newspaper that the lifetime of a proton turned out to be finite. When asked about the lifetime, he gave an astronomical number, something like 10^{30} years or so. I said: "*Why do you look so excited then and why all this conspiracy?*" He answered: "*The Soviet Union is built of protons, and therefore is bound to decay as well!*"

[67] After Richard Feynman, "The Character of Physical Law," MIT Press, 1967.

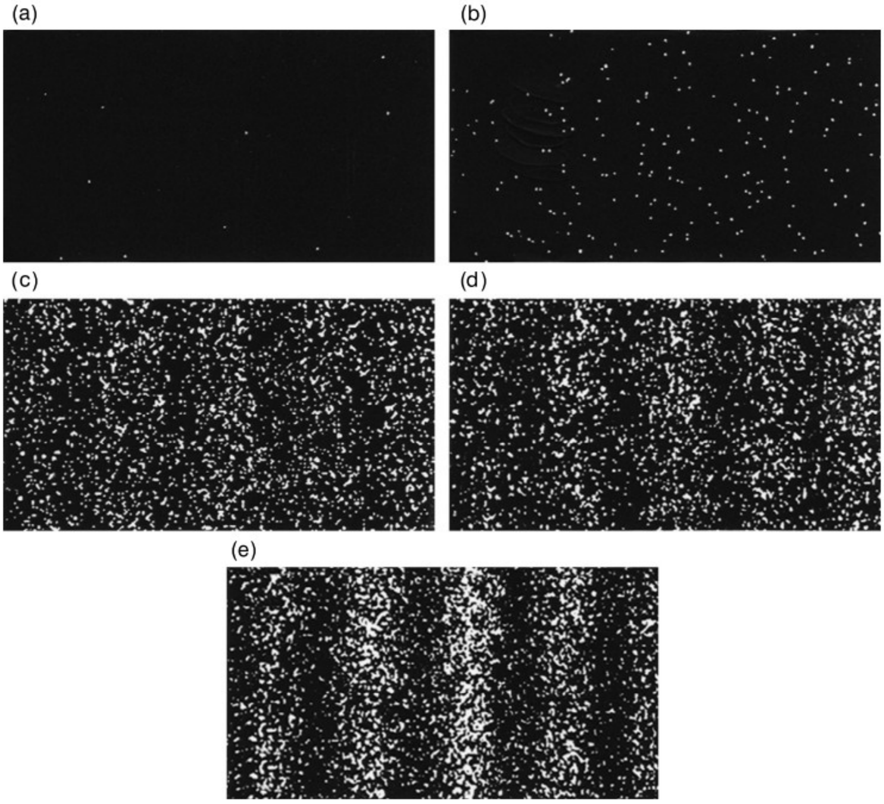

Fig. 1.14. Two-slit electron interference pattern registered by Akira Tonomura. (a) 10 electrons. (b) 100 electrons. (c) 3000 electrons – one begins to suspect something. (d) 20 000 electrons – no doubt, we will have a surprise. (e) 70 000 electrons – here it is! Conclusion: there is only one possibility – each electron went through the two slits (according to J. Gribbin, "*Q is for Quantum: An Encyclopedia of Particle Physics*," Weidenfeld and Nicolson, 1998).

sum of the patterns corresponding to only one open slit (facing slit 1 and slit 2). *We do not have that picture*.

> The *only* explanation for this interference of the electron with itself is that with the two slits open it went through *both*.

Clearly, the two parts of the electron united somehow and caused the flash at a single point on the screen. The quantum world is really puzzling. Despite the fact that the wave function is delocalized, the measurement gives its single point position (decoherence). How could an electron pass simultaneously through two slits? We do not understand this, but this is what happens.

Maybe it is possible to pinpoint the electron passing through two slits? Indeed, one may think of the Compton effect: a photon collides with an electron and changes its direction, and this can be detected (“a flash on the electron”). When one prepares two such ambushes at the two open slits, it turns out that the flash is *always on a single slit, not on both*. This cannot be true! If it were true, then the pattern would be of a *noninterference* character (and had to be the sum of the two one-slit patterns), but we have the interference. No. There is no interference. *Now*, the pattern does not show the interference. The interference was when the electrons were not observed. When we observe them, there is no interference... Somehow we perturb the electron’s momentum (the Heisenberg principle) and the interference disappears.

We have to accept that the electron passes through two slits. Maybe it only pertains to the electron, maybe the Moon is something completely different? A weak hope. The same thing happens to protons. Sodium atoms were also found to interfere.[68] A sodium atom, of diameter of a few Å, looks like an ocean liner when compared to a child’s toy boat of a tiny electron (almost 42 000 times lighter). And this ocean liner passed through two slits separated by thousands of Å. At the end of 1999 similar interference was observed for fullerene,[69] a giant C_{60} molecule, about one million times heavier than the electron. It is worth noting that after such adventure the fullerene molecule remained intact: somehow all its atoms, with the details of their chemical bonds, preserved their nature. There is something intriguing in this.

1.8 The magic of erasing the past

John Archibald Wheeler was not completely satisfied by the description of the hypothetical two-slit experiment, if it were performed at an astronomically large scale. Indeed, there was something puzzling in it. Suppose we have the two slits far away from us. A photon goes through the slit region, then flies towards us for a long time, and finally arrives to our screen. At large numbers of such photons, we obtain *an interference picture on the screen that witnesses each photon went through two slits*. However, when a photon passed the slit region, leaving the slits behind and heading towards us, we had plenty of time (say, of the order of a billion of years) to think. In particular, we might have an idea to replace the screen by two telescopes, each directed on one slit. In a similar situation we never observe half of the photon in one telescope and half in the other one: there is always a photon seen in *one* telescope only. *The*

---

[68] To observe such phenomena the slit distance has to be of the order of the de Broglie wave length, $\lambda = h/p$, where h is the Planck constant and p is the momentum. Cohen-Tannoudji lowered the temperature to such an extent that the momentum was close to 0, and λ could be of the order of thousands of Å.

[69] M. Arndt, O. Nairz, J. Voss-Andreae, C. Keller, G. van der Zouw, A. Zeilinger, *Nature*, 401(1999)680.

telescopes allow us to identify unambiguously which slit the particular photon passed through. Therefore, we may divide all such photons into two classes (depending on the slit they were through), and their distribution cannot be interference-like; it has to be bullet-like (it is a sum of distributions of both classes). And now we have a paradox.

> *Quantum eraser*
>
> Our decision (taken *after* the photons passed the slits) to replace the screen by the telescopes visibly changed the way the photons have been passing the slits. The problem is that the photon's decision must have been anticipating our action by some billion years or so.

This strange behavior (for a much shorter time scale) has been confirmed experimentally[70] in 2007. Well, this is a kind of drama. How may such a thing happen, however absurd it looks? Nobody knows. Let us put that clearly: it seems there is something fundamentally wrong in our current understanding of the world. Therefore, it is perhaps more safe to limit ourselves to strict physical *measurements* rather than telling pure science-fiction-like stories about traveling particles and their decisions anticipating situations that will happen in some billion years. Note also that we have "changed the past" only in a very special sense, since we are speaking here about two separate experiments: one with the telescopes and afterwards the other one with the screen. This is not like undoing an airplane catastrophe that has already taken place, but rather like changing something before the catastrophe takes place in order not to have it come.

1.9 A test for common sense: the Bell inequality

John Stuart Bell (1928–1990), Irish mathematician at Centre Européen de la Recherche Nucleaire (CERN) in Geneva. In the 1960s Bell attacked an old controversy of locality versus nonlocality, hidden variables, etc., apparently exhausted after exchange of ideas between Einstein and Bohr.

John Bell proved a theorem in 1964 that pertains to the results of measurements carried out on particles and some of the inequalities they have to fulfill. The theorem pertains to the basic logic of the measurements and is valid independently of the kind of particles and of the nature of their interaction. The theorem soon became abstract Heisenberg algebra. Schrödinger proved the equivalence of both theories, gave the solution for the hydrogen atom, and introduced the variational principle. ★ The time-dependent perturbation theory described in this chapter was developed by Paul Dirac in 1926. Twenty years later, Enrico Fermi, lecturing at the University of Chicago, coined the term "The Golden Rule" for these results. Since then, they are known as the Fermi Golden Rule.

2.1 Symmetry of the nonrelativistic Hamiltonian and the conservation laws

From classical mechanics it follows that for an isolated system (and assuming the forces to be central and obeying the action-reaction principle), its *energy*, *momentum*, and *angular momentum* are conserved.

Emmy Noether (1882–1935), German mathematician, informally professor, formally only the assistant of David Hilbert at the University of Göttingen (in the first quarter of the 20th century, women were not allowed to be professors in Germany). Her outstanding achievements in mathematics meant nothing to the Nazis, because Noether was Jewish (people should be reminded of such problems) and in 1933 Noether was forced to emigrate to the USA (Institute for Advanced Study in Princeton).

Imagine a well-isolated space ship observed in a space-fixed coordinate system. Its *energy is preserved*, its center of mass moves along a straight line with constant velocity (*the total, or center-of-mass, momentum vector is preserved*), and it preserves its *total angular momentum*.[2] The same is true for a molecule or atom, but the conservation laws have to be formulated in the language of quantum mechanics.

---

[2] That is, its *length and direction*. Think of a skater performing a spin: extending the arms sideways slows down the rotation, while stretching them along the axis of rotation results in faster rotation. *But all the time the total angular momentum vector is the same*. Well, what happens to the angular momentum, when the dancer finally stops rotating due to the friction? The angular momentum attains zero? No way. This is simply impossible. When the dancer increases its angular velocity, the Earth's axis changes a bit its direction to preserve the previous angular momentum of the total system (the Earth plus the dancer). When the dancer stops, the Earth's axis comes back towards its previous position, but not completely, because a part of the angular momentum is hidden in the rotation of molecules caused by the friction. Whatever happens, the total angular momentum has to be preserved! If the space ship captain wanted to stop the rotation of the ship which is making the crew sick, he could either throw something (e.g., gas from a steering jet) away from the ship, or spin a well-oriented body fast inside the ship. But even the captain is unable to change the *total* angular momentum.

Where do the conservation laws come from? Emmy Noether proved that they follow from the symmetry operations, with respect to which the equation of motion is invariant.[3]

> Thus, it turned out that invariance of the equation of motion with respect to an arbitrary:
> – *translation in time* (time homogeneity) results in the *energy conservation principle*;
> – *translation in space* (space homogeneity) gives the *total momentum conservation principle*;
> – *rotation in space* (space isotropy) implies the *total angular momentum conservation principle*.

These may be regarded as the foundations of science.[4] The homogeneity of time allows one to expect that repeating experiments give the same results. The homogeneity of space makes it possible to compare the results of the same experiments carried out in two different laboratories. Finally, the isotropy of space allows one to reject any suspicion that a different orientation of our laboratory bench changes the result.

Conservation laws represent most precious information about our system. It is not important what happens to the *isolated* system, what it is composed of, how complex the processes taking place in it are, whether they are slow or violent, whether there are people in the system or not, or whether they think about how to cheat the conservation laws; *nothing can violate the conservation of the energy, momentum, or angular momentum.*

Now, let us try to incorporate this into quantum mechanics.

---

[3] In case of a one-parameter family of operations $\hat{S}_\alpha \hat{S}_\beta = \hat{S}_{\alpha+\beta}$, e.g., translation ($\alpha$, β stand for the translation vectors), rotation (α, β are rotational angles), etc. Some other operations may not form such families and then the Noether theorem is no longer valid. This was an important discovery. Symmetry of a theory is much more fundamental than symmetry of an object. *The symmetry of a theory means that phenomena are described by the same equations no matter what laboratory coordinate system is chosen.*

[4] Well, to some extent. For example, the Universe does not show exact isotropy, because the matter there does not show spherical symmetry. Moreover, even if only one object were in the Universe, this very object would itself destroy the anisotropy of the Universe. We should rather think of this as a kind of idealization (approximation of the reality).

All symmetry operations (e.g., translation, rotation, reflection in a plane) are isometric, i.e., $\hat{U}^{\dagger} = \hat{U}^{-1}$ and $\hat{U}$ does not change distances between points of the transformed object (Figs. 2.2 and 2.3).

> The operator $\hat{U}$ acting in three-dimensional Cartesian space corresponds to the operator $\hat{\mathcal{U}}$ acting in the Hilbert space; cf. Eq. (C.2), p. 608. Thus the function $f(\mathbf{r})$ transforms to $f' = \hat{\mathcal{U}} f = f(\hat{U}^{-1}\mathbf{r})$, while the operator $\hat{A}$ transforms to $\hat{A}' = \hat{\mathcal{U}} \hat{A} \hat{\mathcal{U}}^{-1}$ (Fig. 2.3). The formula for $\hat{A}'$ *differs* in general from $\hat{A}$, but *when it does not*, i.e., $\hat{A}' = \hat{A}$, then $\hat{\mathcal{U}}$ commutes with $\hat{A}$.

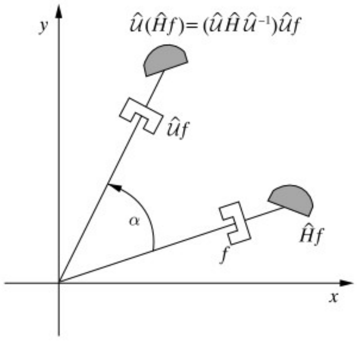
Fig. 2.2. (a) An *object* is rotated by angle α. (b) The *coordinate system* is rotated by angle $-\alpha$. The new position of the object in the old coordinate system (a) is the same as the initial position of the object in the new coordinate system (b).

Indeed, then $\hat{A} = \hat{\mathcal{U}} \hat{A} \hat{\mathcal{U}}^{-1}$, i.e., one has the commutation relation $\hat{A}\hat{\mathcal{U}} = \hat{\mathcal{U}}\hat{A}$, which means that $\hat{\mathcal{U}}$ and $\hat{A}$ share their eigenfunctions (Appendix B, p. 595).

Let us take the Hamiltonian $\hat{H}$ as the operator $\hat{A}$. Before writing it down let us introduce *atomic units*. Their justification comes from something similar to laziness. The quantities one calculates in quantum mechanics are stuffed up by some constants: $\hbar = \frac{h}{2\pi}$, where h is the Planck constant, the electron charge $-e$, the electron (rest) mass m_0, etc. These constants appear in clumsy formulae with various powers, in the nominator and denominator (see Table of units, p. 763). One always knows, however, that the quantity one com-



y

f
x

Fig. 2.3. A schematic view from the Hilbert space of functions $f(x, y)$. The f and $\hat{H}f$ represent, in general, different functions. Rotation (by α) of function $\hat{H}f$ gives function $\hat{\mathcal{U}}(\hat{H}f)$ and, in consequence, is bound to denote the *rotation of* f (i.e., $\hat{U}f$) and the transformation $\hat{U}\hat{H}\hat{U}^{-1}$ *of the operator* $\hat{H}$. Indeed, only then $\hat{\mathcal{U}}\hat{H}\hat{\mathcal{U}}^{-1}$ when acting on the *rotated* function, i.e., $\hat{\mathcal{U}}f$ gives $\hat{\mathcal{U}}\hat{H}\hat{\mathcal{U}}^{-1}(\hat{\mathcal{U}}f) = \hat{\mathcal{U}}(\hat{H}f)$, i.e., the rotated result of the Hamiltonian action. Because of $\hat{\mathcal{U}}(\hat{H}f) = (\hat{\mathcal{U}}\hat{H})(\hat{\mathcal{U}}f)$, when verifying the invariance of $\hat{H}$ with respect to transformation $\hat{\mathcal{U}}$, it is sufficient to check whether $\hat{\mathcal{U}}\hat{H}$ has the same formula as $\hat{H}$, but expressed in the new coordinates. Only this $\hat{\mathcal{U}}\hat{H}$ will fit to f expressed in the new coordinates, i.e., to $\hat{\mathcal{U}}f$. This is how we will proceed shortly.

putes is energy, length, time, etc., and how energy, length, etc., are expressed in $\hbar$, e, m_0, etc.

ATOMIC UNITS

If one inserts $\hbar = 1$, $e = 1$, $m_0 = 1$, this gives a dramatic simplification of the formulae. One has to remember though that these units have been introduced and, whenever needed, one can evaluate the result in other units (see Table of conversion coefficients, p. 764).

The Hamiltonian for a system of M nuclei (with charges Z_I and mass m_I, $I = 1, ..., M$) and N electrons, in the nonrelativistic approximation and assuming point-like particles without any internal structure,[5] takes in atomic units (a.u.) the following form (see p. 22):

---

[5] No internal structure of the electron has yet been discovered. The electron is treated as a point-like particle. Contrary to this, nuclei have a rich internal structure and nonzero dimensions.
A clear multilevel-like structure appears (which has to a large extent forced a similar structure on the corresponding scientific methodologies):

- Level I. A nucleon (neutron, proton) consists of three (the valence) quarks, clearly seen on the scattering image obtained for the proton. Nobody has yet observed a free quark.

$$\hat{H} = \hat{T}_n + \hat{T}_e + \hat{V}, \tag{2.1}$$

where the kinetic energy operators for the nuclei and electrons (in a.u.) read as

$$\hat{T}_n = -\frac{1}{2}\sum_{I=1}^{M}\frac{1}{m_I}\Delta_I, \tag{2.2}$$

$$\hat{T}_e = -\frac{1}{2}\sum_{i=1}^{N}\Delta_i, \tag{2.3}$$

where the Laplacians are

$$\Delta_I = \frac{\partial^2}{\partial X_I^2} + \frac{\partial^2}{\partial Y_I^2} + \frac{\partial^2}{\partial Z_I^2},$$
$$\Delta_i = \frac{\partial^2}{\partial x_i^2} + \frac{\partial^2}{\partial y_i^2} + \frac{\partial^2}{\partial z_i^2},$$

and x, y, z stand for the Cartesian coordinates of the nuclei and electrons indicated by vectors $\mathbf{R}_I = (X_I, Y_I, Z_I)$ and $\mathbf{r}_i = (x_i, y_i, z_i)$, respectively.

- Level II. The strong forces acting among nucleons have a range of about 1–2 fm (1 fm $= 10^{-15}$ m). Above 0.4–0.5 fm they are attractive, at shorter distances they correspond to repulsion. One does not need to consider their quark structure when computing the forces among nucleons, but they may be treated as particles *without internal structure*. The attractive forces between nucleons practically do not depend on the nucleon's charge and are so strong that they may overcome the Coulomb repulsion of protons. Thus nuclei composed of many nucleons (various chemical elements) may be formed, which in mean-field theory exhibit a shell structure (analogous to the electronic structure, cf. Chapter 8) related to the packing of the nucleons. The motion of the nucleons is strongly correlated. A nucleus may have various energy states (ground and excited), may be distorted, may undergo splitting, etc. About 2000 nuclei are known, of which only 270 are stable. The smallest nucleus is the proton, the largest known so far is ^{209}Bi (209 nucleons). The largest observed number of protons in a nucleus is 118. Even the largest nuclei have diameters about 100 000 times smaller than the electronic shells of the atom. Even for an atom with atomic number 118, the first Bohr radius is equal to $\frac{1}{118}$ a.u., or $5 \cdot 10^{-13}$ m, still about 100 times larger than the nucleus.
- Level III. Chemists *can* neglect the internal structure of nuclei. A nucleus *can* be treated as a structureless point-like particle and using the theory described in this book, one is able to predict extremely precisely virtually all the chemical properties of atoms and molecules. Some interesting exceptions will be given at the end of Chapter 6.

The operator $\hat{V}$ corresponds to the electrostatic interaction of all the particles (nucleus–nucleus, nucleus–electron, electron–electron)[6]:

$$\hat{V} = \sum_{I=1}^{M}\sum_{J>I}^{M} \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|} - \sum_{I=1}^{M}\sum_{i=1}^{N} \frac{Z_I}{|\mathbf{r}_i - \mathbf{R}_I|} + \sum_{i=1}^{N}\sum_{j>i}^{N} \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}, \tag{2.4}$$

or, in a simplified form,

$$\hat{V} = \sum_{I=1}^{M}\sum_{J>I}^{M} \frac{Z_I Z_J}{R_{IJ}} - \sum_{I=1}^{M}\sum_{i=1}^{N} \frac{Z_I}{r_{iI}} + \sum_{i=1}^{N}\sum_{j>i}^{N} \frac{1}{r_{ij}}. \tag{2.5}$$

If the Hamiltonian turned out to be invariant with respect to a symmetry operation $\hat{U}$ (translation, rotation, etc.), this would imply the commutation of $\hat{U}$ and $\hat{H}$. We will check this in more detail below.

Note that the distances R_{IJ}, r_{iI}, and r_{ij} in the Coulombic potential energy (2.5) witness about assumption of instantaneous interactions in nonrelativistic theory (infinite travel speed of the interaction through space).

2.1.1 *Invariance with respect to translation*

Translation by vector $\mathbf{T}$ of function $f(\mathbf{r})$ in space means the function $\hat{\mathcal{U}} f(\mathbf{r}) = f\left(\hat{U}^{-1}\mathbf{r}\right) = f(\mathbf{r} - \mathbf{T})$, i.e., an opposite (by vector $-\mathbf{T}$) translation of the coordinate system (Fig. 2.4).

The transformation $\mathbf{r}' = \mathbf{r} + \mathbf{T}$ does not change the Hamiltonian. This is evident for the potential energy $\hat{V}$, because the translations $\mathbf{T}$ are canceled out, leaving the interparticle distances unchanged. For the kinetic energy one obtains $\frac{\partial}{\partial x'} = \sum_{\sigma=x,y,z} \frac{\partial \sigma}{\partial x'}\frac{\partial}{\partial \sigma} = \frac{\partial x}{\partial x'}\frac{\partial}{\partial x} = \frac{\partial}{\partial x}$, and all the kinetic energy operators (Eqs. (2.2) and (2.3)) are composed of the operators having this form.

> The Hamiltonian is therefore invariant with respect to any translation of the coordinate system.

There are two main consequences of translational symmetry:

---

[6] We do not include in this Hamiltonian tiny magnetic interactions of electrons and nuclei coming from their spin and orbital angular momenta, because they are of relativistic nature (see Chapter 3). In Chapter V2-4 we will be interested just in such small magnetic effects and the Hamiltonian will have to be generalized to include these interactions.

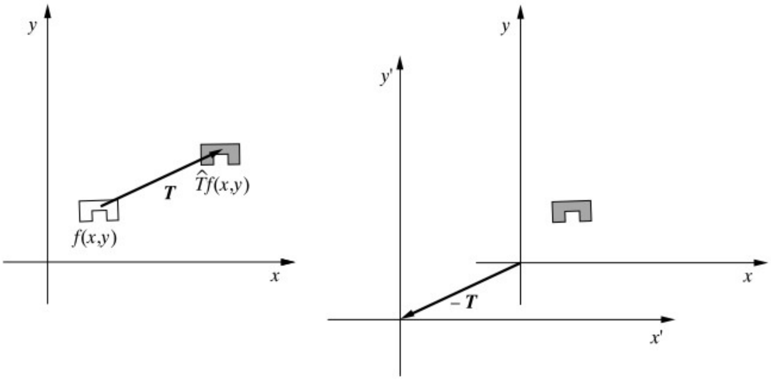

Fig. 2.4. A *function* f shifted by vector $\mathbf{T}$ (symmetry operation $\hat{T}$), i.e., $\hat{T}f(x,y)$ in the coordinate system (x,y) is the same as function $f\left(x',y'\right)$ in the *coordinate system* (x',y') shifted by $-\mathbf{T}$.

- No matter whether the coordinate system used is fixed in Trafalgar Square or in the center of mass of the system, one has to solve the same mathematical problem.
- The solution to the Schrödinger equation corresponding to the space-fixed coordinate system located in Trafalgar Square is Ψ_{pN}, whereas Ψ_{0N} is calculated in the body-fixed coordinate system (see Appendix J) located in the center of mass at $\mathbf{R}_{CM}$ that moves in the space-fixed coordinate system with the (total) momentum $\mathbf{p}_{CM}$. These two solutions are related by[7] $\Psi_{pN} = \Psi_{0N}\ \exp(i\mathbf{p}_{CM}\cdot\mathbf{R}_{CM})$. The number $N = 0, 1, 2, \ldots$ counts the energy states after the center-of-mass motion is separated.

> This means that the energy spectrum represents a continuum, because the center of mass may have any (nonnegative) kinetic energy $p_{CM}^2/(2m)$. If, however, one assumes that $p_{CM} = const$, then the energy spectrum is *discrete* for low-energy eigenvalues for atoms and molecules (see Eq. (1.13)).

This spectrum corresponds to the bound states, i.e., those states which do not correspond to any kind of dissociation (including ionization). Higher energy states lead to dissociation of the molecule, and the fragments may have any kinetic energy. Therefore, above the discrete spectrum one has a continuum of states. The states Ψ_{0N} will be called *spectroscopic states*. The bound states Ψ_{0N} are square integrable, as opposed to Ψ_{pN}, which are not because of function $exp(i\mathbf{p}\mathbf{R}_{CM})$, which describes the free motion of the center of mass.

---

[7] This follows from the separation of the center-of-mass motion (Appendix J) and noting that $\exp(i\mathbf{p}_{CM}\cdot\mathbf{R}_{CM})$ represents a solution for the motion of a free particle (Chapter 4).

2.1.2 Invariance with respect to rotation

The Hamiltonian is also invariant with respect to any rotation in space $\hat{U}$ of the coordinate system about a fixed axis. The rotation is carried out by applying an orthogonal matrix transformation[8] $\mathbf{U}$ of vector $\mathbf{r} = (x, y, z)^T$ that describes any particle of coordinates x, y, z. Therefore, all the particles undergo the same rotation and the new coordinates are $\mathbf{r}' = \hat{U}\mathbf{r} = \mathbf{U}\mathbf{r}$. Again, there is no problem with the potential energy, because a rotation does not change the interparticle distances. What about the Laplacians in the kinetic energy operators? Let us see. We have

$$\Delta = \sum_{k=1}^{3} \frac{\partial^2}{\partial x_k^2} = \sum_{k=1}^{3} \frac{\partial}{\partial x_k}\frac{\partial}{\partial x_k} = \sum_{k=1}^{3} \left(\sum_{i=1}^{3} \frac{\partial}{\partial x_i'}\frac{\partial x_i'}{\partial x_k} \right) \left(\sum_{i=1}^{3} \frac{\partial}{\partial x_i'}\frac{\partial x_i'}{\partial x_k} \right) =$$

$$\sum_{i=1}^{3}\sum_{j=1}^{3}\sum_{k=1}^{3} \left(\frac{\partial}{\partial x_i'}\frac{\partial x_i'}{\partial x_k} \right) \left(\frac{\partial}{\partial x_j'}\frac{\partial x_j'}{\partial x_k} \right) =$$

$$\sum_{i=1}^{3}\sum_{j=1}^{3}\sum_{k=1}^{3} \left(\frac{\partial}{\partial x_i'} U_{ik} \right) \left(\frac{\partial}{\partial x_j'} U_{jk} \right) = \sum_{i=1}^{3}\sum_{j=1}^{3}\sum_{k=1}^{3} \left(\frac{\partial}{\partial x_i'} U_{ik} \right) \left(\frac{\partial}{\partial x_j'} U_{kj}^{\dagger} \right) =$$

$$\sum_{i=1}^{3}\sum_{j=1}^{3} \left(\frac{\partial}{\partial x_i'} \right) \left(\frac{\partial}{\partial x_j'} \right) \sum_{k=1}^{3} U_{ik} U_{kj}^{\dagger} =$$

$$\sum_{i=1}^{3}\sum_{j=1}^{3} \left(\frac{\partial}{\partial x_i'} \right) \left(\frac{\partial}{\partial x_j'} \right) \delta_{ij} = \sum_{k=1}^{3} \frac{\partial^2}{\partial \left(x_k' \right)^2} = \Delta'.$$

Thus, one has invariance of the Hamiltonian with respect to any rotation about the origin of the coordinate system. This means (see p. 665) that the Hamiltonian and the operator of the square of the total angular momentum $\hat{J}^2$ (as well as of one of its components, denoted by $\hat{J}_z$) commute. One is able, therefore, to measure simultaneously the energy, the square of the total angular momentum as well as one of the components of the total angular momentum, and (as will be shown in Section 4.9) one has ($\mathbf{r}$ and $\mathbf{R}$ denote the electronic and the nuclear coordinates, respectively)

$$\hat{J}^2 \Psi_N(\mathbf{r}, \mathbf{R}) = J(J+1)\hbar^2 \Psi_N(\mathbf{r}, \mathbf{R}), \tag{2.6}$$

$$\hat{J}_z \Psi_N(\mathbf{r}, \mathbf{R}) = M_J \hbar \Psi_N(\mathbf{r}, \mathbf{R}), \tag{2.7}$$

where $J = 0, 1, 2...$ and $M_J = -J, -J+1, ... + J$.

---

[8] $\mathbf{U}^T = \mathbf{U}^{-1}$.

Any rotation matrix may be shown as a product of "elementary" rotations, each about the x, y, or z axis. For example, rotation about the y axis by angle θ corresponds to the matrix $\begin{pmatrix} \cos\theta & 0 & -\sin\theta \\ 0 & 1 & 0 \\ \sin\theta & 0 & \cos\theta \end{pmatrix}$. The pattern of such matrices is simple: one has to put in some places sines, cosines, zeros, and ones with the proper signs.[9] This matrix is orthogonal,[10] i.e., $\mathbf{U}^T = \mathbf{U}^{-1}$, which you may easily check. The product of two orthogonal matrices represents an orthogonal matrix; therefore, any rotation corresponds to an orthogonal matrix.

2.1.3 Invariance with respect to permutation of identical particles (fermions and bosons)

The Hamiltonian also has permutational symmetry. This means that if someone exchanged labels numbering the identical particles, independently of how it was done, he/she would always obtain the identical mathematical expression for the Hamiltonian. This implies that any wave function has to be either symmetric (for bosons) or antisymmetric (for fermions) with respect to the exchange of labels between two identical particles (cf. p. 39).

2.1.4 Invariance of the total charge

In addition to the energy, momentum, and angular momentum, strict conservation laws exist exclusively for total electric charge and the baryon and lepton numbers (a given particle contributes $+1$, the corresponding antiparticle -1).[11] The charge conservation (whatever happens) follows from the gauge symmetry: total electric charge conservation follows from the fact that a description of the system has to be invariant with respect to the mixing of the particle and antiparticle states, which is analogous to rotation.

---

[9] Clockwise and counterclockwise rotations and two possible signs at sines cause a problem with memorizing the right combination. In order to choose the correct one, one may use the following trick. First, we decide that what moves is an *object* (e.g., a function, not the coordinate system). Then, you have to have this book in your pocket. In Fig. 2.2a one sees that the rotation of the point with coordinates $(1, 0)$ by angle $\theta = 90°$ should give the point (0, 1), and this is ensured only by the rotation matrix: $\begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}$.

[10] And therefore also unitary (cf. Appendix A, p. 589).

[11] For example, in the Hamiltonian (2.1) it is assumed that whatever might happen to our system, the numbers of the nucleons and electrons will remain constant.

2.1.5 Fundamental and less fundamental invariances

The conservation laws described are of a fundamental character, because they are related to the homogeneity of space and time, the isotropy of space, and the nondistinguishability of identical particles.

Besides these strict conservation laws (energy, momentum, angular momentum, permutation of identical particles, charge, and baryon and lepton numbers), there are also some approximate laws. Two of these, parity and charge conjugation, will be discussed below. They are rooted in these strict laws, but are valid only in some conditions. For example, in most experiments, not only the baryon number, but also the number of nuclei of each kind is conserved. Despite the importance of this law in chemical reaction equations, this does not represent any strict conservation law, as shown by radioactive transmutations of elements.

Some other approximate conservation laws will soon be discussed.

2.1.6 Invariance with respect to inversion – parity

There are orthogonal transformations which are not equivalent to any rotation, e.g., the matrix of inversion $\begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix}$, which corresponds to changing $\mathbf{r}$ to $-\mathbf{r}$ for all the particles, does not represent any rotation. If one performs such a symmetry operation, the Hamiltonian remains invariant and $|\Psi_{0N}(-\mathbf{r},-\mathbf{R})|^2 = |\Psi_{0N}(\mathbf{r},\mathbf{R})|^2$. This is evident, both for $\hat{V}$ (the interparticle distances do not change) and for the Laplacian (single differentiation changes sign, double does not). Two consecutive inversions mean identity operation: $\Psi_{0N}(\mathbf{r},\mathbf{R}) = \exp(i\alpha)\Psi_{0N}(-\mathbf{r},-\mathbf{R}) = [\exp(i\alpha)]^2\Psi_{0N}(\mathbf{r},\mathbf{R})$. Hence, $[\exp(i\alpha)]^2 = 1$, $\exp(i\alpha) = \pm 1$ and one has

$$\Psi_{0N}(-\mathbf{r},-\mathbf{R}) = \Pi\Psi_{0N}(\mathbf{r},\mathbf{R}), \quad \text{where } \Pi \in \{1,-1\}.$$

Therefore,

> the wave function of a stationary state represents an eigenfunction of the inversion operator, and the eigenvalue can be either $\Pi = 1$ or $\Pi = -1$. This property is known as parity (P).

Now the reader will be taken by surprise. From what we have said, it follows that *no molecule has a nonzero dipole moment*. Indeed, the dipole moment is calculated as the mean value of the dipole moment operator (as usual in quantum mechanics, see Postulate IV in Chapter 1), i.e.,

$\boldsymbol{\mu} = \langle \Psi_{0N} | \hat{\boldsymbol{\mu}} \Psi_{0N} \rangle = \langle \Psi_{0N} | \left(\sum_i q_i \mathbf{r}_i \right) \Psi_{0N} \rangle$, where q's represent particles' charges. This integral will be calculated very easily: the integrand is antisymmetric with respect to inversion[12] and therefore $\boldsymbol{\mu} = \mathbf{0}$.

Is therefore the very meaning of the dipole moment, a quantity often used in chemistry and physics, a fairy tale? If HCl has no dipole moment, then it is more understandable that also H_2 does not. All this seems absurd.

Let us stress that our conclusion pertains to the *total* wave function, which has to reflect the space isotropy leading to the zero dipole moment, because all orientations in space are equally probable. If one applied the transformation $\mathbf{r} \rightarrow -\mathbf{r}$ only to *some* particles in the molecule (e.g., electrons) and not to others (e.g., the nuclei), the wave function will show no parity (it would be neither symmetric nor antisymmetric). We will introduce the Hamiltonian in Chapter 6, which corresponds to immobilizing the nuclei (the adiabatic or Born–Oppenheimer approximation) in certain positions in space, and in such a case the wave function depends on the electronic coordinates only. This wave function may be neither symmetric nor antisymmetric with respect to the *partial* inversion transformation $\mathbf{r} \rightarrow -\mathbf{r}$ (for the electrons only). To give an example, let us imagine an HF molecule in a coordinate system, its origin being in the middle between the H and F nuclei. Consider a particular configuration of the 10 electrons of the molecule; all close to the fluorine nucleus in some well-defined points. One may compute the value of the wave function for this configuration of electrons. Its square gives us the probability density of finding this particular configuration of electrons. Now, imagine the (*partial*) inversion $\mathbf{r} \rightarrow -\mathbf{r}$ applied to all the electrons. Now they will all be close to the proton. If one computes the probability density for the new situation, one would obtain a completely different value (much, much smaller, because the electrons prefer the fluorine, not the hydrogen), so we have no symmetry or antisymmetry. No wonder therefore that if one computed $\boldsymbol{\mu} = \langle \Psi_{0N} | \hat{\boldsymbol{\mu}} \Psi_{0N} \rangle$ with such a function (integration is over the electronic coordinates only), the result would differ from zero. This is why chemists believe the HF molecule has a nonzero dipole moment.[13] On the other hand, if the molecule taken as the example were B_2 (also ten electrons), then the two values have to be equal, because they describe the same physical situation. This corresponds, therefore, to a wave function with definite parity (symmetric or antisymmetric), and therefore, in this case $\boldsymbol{\mu} = \mathbf{0}$. This is why chemists believe molecules such as H_2, B_2, and O_2 have no dipole moment.

---

[12] Ψ_{0N} may be symmetric or antisymmetric, but $|\Psi_{0N}|^2$ is bound to be symmetric. Therefore, since $\sum_i q_i \mathbf{r}_i$ is antisymmetric, indeed, the integrand is antisymmetric (while the integration limits are symmetric).

[13] What therefore they do measure? The answer will be given in Chapter V2-4.

Product of inversion and rotation

The Hamiltonian is also invariant with respect to some other symmetry operations, like changing the sign of the x coordinates of all particles, or similar operations which are products of inversion and rotation. If one changed the sign of all the x coordinates, it would correspond to a mirror reflection. Since rotational symmetry stems from space isotropy (which we will treat as "trivial"), the mirror reflection may be identified with parity P.

Enantiomers

A consequence of inversion symmetry is that the wave functions have to be eigenfunctions of the inversion operator with eigenvalues $\Pi = 1$, i.e., the wave function is symmetric, or $\Pi = -1$, i.e., the wave function is antisymmetric. Any asymmetric wave function corresponding to a stationary state is therefore excluded ("illegal"). However, two optical isomers (enantiomers), corresponding to an object and its mirror image, do exist (Fig. 2.5).[14]

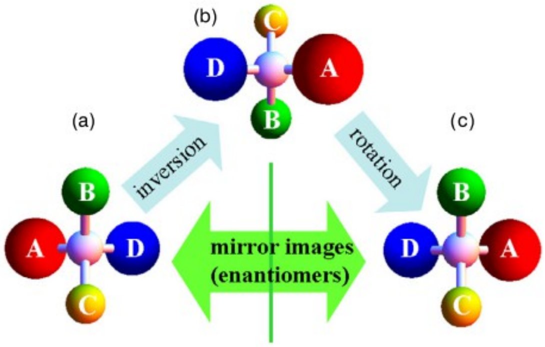

Fig. 2.5. Example of chirality. (a) A molecule's central atom with four different side groups (A, B, C, and D) in a nonplanar configuration. (b) The same molecule after applying the inversion operation (with respect to the central atom). (c) An attempt at superposing the initial and the transformed molecules by rotation, to get matching, fails. (a) and (c) as well as (a) and (b) represent an example of a pair of enantiomers. Each of these isomers, after reflection in a mirror (like, e.g., the central atom-BC plane), becomes identical to its partner.

---

[14] The property that distinguishes them is known as chirality (your hands are an example of chiral objects). The chiral molecules (enantiomers) exhibit optical activity, i.e., polarized light passing through a solution of one of the enantiomers undergoes a rotation of the polarization plane *always in the same direction* (which may be easily seen by reversing the direction of the light beam). The enantiomeric molecules have the same properties, provided one is checking this by using nonchiral objects. If the probe were chiral, one of the enantiomers would interact with it differently (for purely sterical reasons). Enantiomers (e.g., molecular associates) may be formed from chiral or nonchiral subunits.

We ask in a pharmacy for D-glucose. Strangely enough, the pharmacist is fully cooperative and does not make trouble. We pay a small sum and he gives us something which should not exist[15] – a substance with a single enantiomer. We should obtain a substance composed of molecules in their stationary states, which therefore have to have definite parity, either as a sum of the wave functions for the two enantiomers D and L ($\Pi = 1$, cf. Appendix D on p. 655, Case I), i.e., $\psi_+ = \psi_D + \psi_L$, or as the difference ($\Pi = -1$), i.e., $\psi_- = \psi_D - \psi_L$. The energies corresponding to ψ_+ and ψ_- differ, but the difference is extremely small (quasidegeneracy). The brave shopkeeper has given us something with the wave function $\psi = N(\psi_+ + \psi_-) = \psi_D$ (as result of decoherence), which therefore describes a nonstationary state.[16] As we will see in a moment (p. 107), the approximate lifetime of the state is proportional to the inverse of the integral $\left\langle \psi_D | \hat{H} \psi_L \right\rangle$. If one computed this integral, one would obtain an extremely small number.[17] It would turn out that the pharmacy could safely keep the stock of glucose for millions of years. Maybe the reason for decoherence is interaction with the rest of the Universe, maybe even interaction with a vacuum. The very existence of enantiomers, or even prevailing of one of them on Earth, does not mean breaking parity symmetry. This would happen if one of the enantiomers corresponded to a lower energy than the other.[18]

---

[15] More exactly, should be unstable.

[16] Only ψ_+ and ψ_- are stationary states.

[17] This is seen even after attempting to overlap two molecular models physically (Fig. 2.5), they do not match. The overlap of the wave functions will be small for the same reasons (the wave functions decay exponentially with distance).

[18] This is what happens in reality, although the energy difference is extremely small. Experiments with β-decay have shown that Nature breaks parity in weak interactions. The parity conservation law therefore has an approximate character.

With no preference for any of the enantiomers, one of them may *spontaneously* increase its concentration until 100%, i.e., with a complete elimination of the other one (0%)! Is something like that possible at all? It seems it contradicts common sense, since one of the enantiomers won, while the other lost, whereas their chances were exactly equal!

This phenomenon occurs in reality if autocatalysis is involved. The key information is the following: in such a system a *large random and self-augmenting fluctuation* is possible. Indeed, let us imagine just for simplicity 50 molecules of D and 50 molecules of L together with a certain number of molecules N (let us call them "neutral"), with the following possible reactions (giving equal chances to D and L):

$$\begin{gathered} \mathrm{D} + \mathrm{L} \rightarrow 2\mathrm{N} \\ \mathrm{D} + \mathrm{N} \rightarrow 2\mathrm{D} \\ \mathrm{L} + \mathrm{N} \rightarrow 2\mathrm{L}. \end{gathered}$$

The last two reactions (of autocatalytic character) represent in fact inducing an enantiomer ("forcing chirality") through interaction of N with a molecule of a given enantiomer. No preference of D or L is assumed in this induction. Nevertheless one of the enantiomers will defeat the other one! To explain this, let us assume that the elementary reactions 1, 2 or 3 of the individual molecules form a random chain in time, like, for example, 1, 2, 2, 3, 1, 3, ... If the chain starts by the first reaction, we have a situation similar to the starting one (49 : 49 instead of 50 : 50, in number of D:L molecules). If, however, the chain starts by chance from the second reaction,

Chen Ning Yang (b. 1922) and Tsung Dao Lee (b. 1926), American physicists, professors at the Advanced Study Institute in Princeton, predicted in 1956 parity breaking in the weak interactions, which a few months later was confirmed experimentally by Madam Wu. In 1957 Yang and Lee received the Nobel Prize "*for their penetrating investigation of parity laws, which led to important discoveries regarding elementary particles*."

2.1.7 Invariance with respect to charge conjugation

If one changed the signs of the charges of all particles, the Hamiltonian would not change.

---

there will be a 51 : 50 preference of D, while when the third reaction takes place one will have 50 : 51 preference of L. In the last two cases we have a deviation from the equal chances of two enantiomers (fluctuation). Suppose we have the second case, i.e., 51 : 50 preference of D. Note that *now, when continuing the reaction chain at random, the chance for reaction 2 to happen is greater than the chance of reaction 3*. It is seen therefore that any fluctuation from an "equal-chances situation" has a tendency to self-augment, although there is always a chance that the fluctuation disappears. The racemic mixture (with the important N molecules though) represents therefore an instable system. Sooner or later there will be a transition (first mild but then more and more violent) from racemate to the absolute prevailing of one of the enantiomers. Their chances were and are equal, but just by chance one of them won.

Sometimes random processes may lead to large fluctuations. For example, Louis Pasteur was able to crystallize the crystals of one enantiomer and the crystals of the other enantiomer from a racemic solution. This is possible not only without Louis Pasteur, but also without any human, just spontaneously. Suppose that two such pieces of crystals were created where the primordial life was to be started, and that afterwards a volcano explosion took place, in which the volcanic lava covered (or even destroyed) one of the crystals, eliminating it from anything that happened later on (e.g., the chiral induction during biological evolution). This simple argument, proposed by Leszek Stolarczyk, is worth to be considered in discussions on how it comes that in living nature there is a strong preference for one chirality.

This therefore corresponds to exchanging particles and antiparticles.[19] Such a symmetry operation is called the charge conjugation and is denoted as C symmetry. This symmetry will be not marked in the wave function symbol (because, as a rule, we have to do with matter, not antimatter), but we will remember it. Sometimes it may turn out unexpectedly to be useful (see Chapter V2-5, p. V2-367). After Wu's experiment, physicists tried to save the hypothesis that what is conserved is the CP symmetry, i.e., the product of charge conjugation and inversion. However, analysis of experiments with decay of K mesons has shown that even this symmetry is approximate (although the deviation is extremely small).

2.1.8 Invariance with respect to the symmetry of the nuclear framework

In many applications the positions of the nuclei are fixed (clamped nuclei approximation, Chapter 6), often in a high-symmetry configuration (cf. Appendix C, p. 605). For example, the benzene molecule in its ground state (after minimizing the energy with respect to the positions of the nuclei) has the symmetry of a regular hexagon. In such cases the electronic Hamiltonian additionally exhibits invariance with respect to some symmetry operations and therefore the wave functions are the eigenstates of these molecular symmetry operations. Therefore, any wave function may have an additional label: the symbol of the irreducible representation[20] it belongs to.

2.1.9 Conservation of total spin

In an isolated system the *total* angular momentum **J** is conserved. However, $\mathbf{J} = \mathbf{L} + \mathbf{S}$, where **L** and **S** stand for the orbital and spin angular momenta (sum over all particles), respectively. The spin angular momentum **S**, being a sum over all particles, is not conserved.

However, the (nonrelativistic) Hamiltonian does not contain any spin variables. This means that it commutes with the operator of the square of the total spin as well as with the operator of one of the spin components (by convention the z component). Therefore, in the nonrelativistic approximation one can simultaneously measure the energy E, the square of the spin S^2, and one of its components: S_z.

---

[19] Somebody thought he had carried out computations for benzene, but he also computed antibenzene. The wave functions for benzene and antibenzene are the same.

[20] Of the symmetry group composed of the symmetry operations mentioned above, see Appendix C.

2.1.10 Indices of spectroscopic states

In summary, assumptions about the homogeneity of space and time, isotropy of space, and parity conservation lead to the following quantum numbers (indices) for the spectroscopic states:

- N quantizes energy,
- J quantizes the length of total angular momentum,
- M quantizes the z component of total angular momentum,
- Π determines parity:

$$\boxed{\Psi_{N,J,M,\Pi}\left(\mathbf{r},\mathbf{R}\right).}$$

Besides these indices following from the fundamental laws (in the case of parity it is a little too exaggerated), there may be also some indices related to less fundamental conservation laws:

- the irreducible representation index of the symmetry group of the clamped nuclei Hamiltonian (Appendix C),
- the values of S^2 (traditionally one gives the *multiplicity* $2S+1$) and S_z.

2.2 Schrödinger equation for stationary states

It may be instructive to see how Erwin Schrödinger invented his famous equation (1.13) for *stationary states* ψ of energy E ($\hat{H}$ denotes the Hamiltonian of the system),

$$\hat{H}\psi = E\psi. \tag{2.8}$$

Schrödinger surprised the contemporary quantum elite (associated mainly with Copenhagen and Göttingen) by a clear formulation of quantum mechanics as wave mechanics. January 27, 1926, when Schrödinger submitted a paper entitled "*Quantisierung als Eigenwertproblem*"[21] to *Annalen der Physik,* may be regarded as the birthday of wave mechanics.

Most probably, Schrödinger's reasoning was as follows. De Broglie discovered that what people called a particle also had a wave nature (Chapter 1). That is really puzzling. If a wave is involved, then according to Debye's suggestion at the November seminar in Zurich, it might be possible to write the standing wave equation with $\psi\left(x\right)$ as its amplitude at position x, i.e.,

$$v^2\frac{d^2\psi}{dx^2}+\omega^2\psi=0, \tag{2.9}$$

---

[21] Quantization as an eigenproblem. Well, once upon a time quantum mechanics was discussed in German. Some traces of that period remain in the nomenclature. One is the "*eigen*value problem or *eigen*problem," which is a German-English hybrid.

Isaac Newton (1643–1727), English physicist, astronomer, and mathematician, professor at Cambridge University, from 1672 member of the Royal Society of London, from 1699 Director of the Royal Mint – said to be merciless to the forgers. In 1705 Newton became a Lord. In the *opus magnum* mentioned above he developed the notions of space, time, mass, and force, gave three principles of dynamics and the law of gravity, and showed that the latter pertains to problems that differ enormously in their scale (e.g., the famous apple and the planets). Newton is also a founder of differential and integral calculus (independently from G.W. Leibnitz). In addition Newton made some fundamental discoveries in optics; among other things he was the first to think that light is composed of particles.

The first portrait of Newton (at the age of 46) by Godfrey Kneller is shown. The readers are encouraged to read the excellent book "Isaac Newton" by G.E. Christianson, Oxford University Press, New York, 1996.

7.1 Rovibrational spectra – an example of accurate calculations: atom–diatomic molecule

One of the consequences of adiabatic approximation is the potential energy hypersurface $V(\mathbf{R})$ for the motion of nuclei. To obtain the wave function for the motion of nuclei (and then to construct the total product-like wave function for the motion of electrons and nuclei) we have to solve the Schrödinger equation with $V(\mathbf{R})$ as the potential energy. This is what this hypersurface is for. We will find rovibrational energy levels and the corresponding wave functions, which will serve us to obtain rovibrational spectra (frequencies and intensities) to compare with experimental results.

7.1.1 Coordinate system and Hamiltonian

Let us consider a diatomic molecule AB plus a weakly interacting atom C (e.g., HH$\cdots$Ar or CO$\cdots$He), the total system in its electronic ground state. Let us center the origin of the body-fixed coordinate system[2] (with the axes oriented as in the space-fixed coordinate system, see Appendix J, p. 691) in the center of mass of AB. The problem involves therefore $3 \times 3 - 3 = 6$ dimensions.

---

[2] Any coordinate system is equally good from the point of view of mathematics, but its particular choice may make the solution easy or difficult. In the case of a weak C$\cdots$AB interaction (our case) the proposed choice of the origin is one of the natural ones.

However strange it may sound, six is too much for contemporary (otherwise impressive) computer techniques. Let us subtract one dimension by assuming that no vibrations of AB occur (rigid rotator). The five-dimensional problem becomes manageable. The assumption about the stiffness of AB now also pays off because we exclude right away two possible chemical reactions C + AB→ CA + B and C + AB → CB + A, and admit therefore only some limited set of nuclear configurations – only those that correspond to a weakly bound complex C + AB. This approximation is expected to work better when the AB molecule is stiffer, i.e., has a larger force constant (and therefore vibration frequency).[3]

Carl Gustav Jacob Jacobi (1804–1851), German mathematical genius, son of a banker, graduated from school at the age of 12, then associated with the universities of Berlin and Königsberg. Jacobi made important contributions to number theory, elliptic functions, partial differential equations, and analytical mechanics.

We will introduce the *Jacobi coordinates* (Fig. 7.2): three components of vector **R** pointing to C from the origin of the coordinate system (the length R and angles Θ and Φ, both angles denoted by $\hat{\mathbf{R}}$) and the angles θ, ϕ showing the orientation $\hat{\mathbf{r}}$ of vector $\mathbf{r} = \overrightarrow{AB}$, altogether five coordinates – as there should be.

Now let us write down the Hamiltonian for the motion of the nuclei in the Jacobi coordinate system (with the stiff AB molecule with the AB equilibrium distance equal to r_{eq}).[4] We have

$$\hat{H} = -\frac{\hbar^2}{2\mu R^2}\frac{d}{dR}R^2\frac{d}{dR} + \frac{\hat{l}^2}{2\mu R^2} + \frac{\hat{j}^2}{2\mu_{AB} r_{eq}^2} + V,$$

where $\hat{l}^2$ denotes the operator of the square of the angular momentum of the atom C, $\hat{j}^2$ stands for the square of the angular momentum of the molecule AB, where

$$\hat{l}^2 = -\hbar^2\left[\frac{1}{\sin\Theta}\frac{\partial}{\partial\Theta}\sin\Theta\frac{\partial}{\partial\Theta} + \frac{1}{\sin^2\Theta}\frac{\partial^2}{\partial\Phi^2}\right],$$
$$\hat{j}^2 = -\hbar^2\left[\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\sin\theta\frac{\partial}{\partial\theta} + \frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\phi^2}\right],$$

---

[3] A certain measure of this might be the ratio of the dissociation energy of AB to the dissociation energy of C··· AB. The higher the ratio, the better our model will be.

[4] As proposed in S. Bratož, M.L. Martin, *J. Chem. Phys.*, 42(1965)1051.

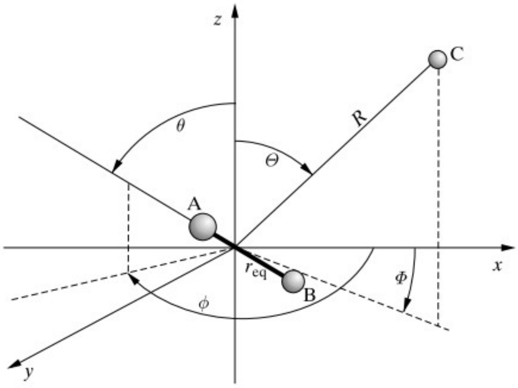

Fig. 7.2. The Jacobi coordinates for the C$\cdots$AB system. The origin is in the center of mass of AB (the distance AB is constant and equal to r_{eq}). The positions of atoms A and B are fixed by giving the angles θ,ϕ. The position of atom C is determined by three coordinates: R, Θ, and Φ. Altogether we have five coordinates: $R, \Theta, \Phi, \theta, \phi$ or (R, $\hat{\mathbf{R}}$ and $\hat{\mathbf{r}}$).

μ is the reduced mass of C and the mass of (A+B), μ_{AB} denotes the reduced mass of A and B, and V stands for the potential energy of the nuclear motion.

The expression for $\hat{H}$ is quite understandable. First of all, we have in $\hat{H}$ five coordinates, as there should be: R, two angular coordinates hidden in the symbol $\hat{\mathbf{R}}$, and two angular coordinates symbolized by $\hat{\mathbf{r}}$ – the four angular coordinates enter the operators of the squares of the two angular momenta. The first three terms in $\hat{H}$ describe the kinetic energy, V is the potential energy (the electronic ground-state energy depends on the nuclear coordinates). The kinetic energy operator describes the radial motion of C with respect to the origin (first term), the rotation of C about the origin (second term), and the rotation of AB about the origin (third term).

7.1.2 Anisotropy of the potential V

How to figure out the shape of V? Let us first make a section of V. If we freeze the motion of AB,[5] atom C would have (concerning the interaction energy) a sort of an energetic well around AB wrapping the AB molecule, caused by the C$\cdots$AB van der Waals interaction. The bottom of the well would be quite distant from the molecule (van der Waals equilibrium distance), while the shape determined by the bottom points would resemble the shape of AB, i.e., would be a little bit elongated. The depth of the well would vary depending on orientation with respect to the origin.

---

[5] That is, fixed the angles θ and ϕ.

If V were isotropic, i.e., if atom C would have C$\cdots$AB interaction energy independent[6] of $\hat{\mathbf{r}}$, then of course we might say that there is no coupling between the rotation of C and the rotation of AB. We would then have a conservation law separately for the first and the second angular momentum and the corresponding commutation rules (cf. Chapter 2 and Appendix F), i.e.,

$$\left[\hat{H}, \hat{l}^2\right] = \left[\hat{H}, \hat{j}^2\right] = 0,$$

$$\left[\hat{H}, \hat{l}_z\right] = \left[\hat{H}, \hat{j}_z\right] = 0.$$

Therefore, the wave function of the total system would be the eigenfunction of $\hat{l}^2$ and $\hat{l}_z$ as well as of $\hat{j}^2$ and $\hat{j}_z$. The corresponding quantum numbers $l = 0, 1, 2, \ldots$ and $j = 0, 1, 2, \ldots$, which determine the squares of the angular momenta for $\hat{l}^2$ and $\hat{j}^2$, as well as the corresponding quantum numbers $m_l = -l, -l+1, \ldots, l$ and $m_j = -j, -j+1, \ldots, j$, which determine the projections of the corresponding angular momenta on the z axis, would be legal[7] quantum numbers (full analogy with the rigid rotator, Chapter 4). The rovibrational levels could be labeled using pairs of quantum numbers: (l, j). In the absence of an external field (no privileged orientation in space) any such level would be $(2l+1)(2j+1)$-tuply degenerate, since this is the number of different projections of both angular momenta on the z axis.

7.1.3 Adding the angular momenta in quantum physics

However, V *is not isotropic* (although the anisotropy is small). What then? Then, of all angular momenta, only the *total* angular momentum $\mathbf{J} = \mathbf{l} + \mathbf{j}$ is conserved (the conservation law results from the very foundations of physics, cf. Chapter 2).[8] Therefore, the vectors $\mathbf{l}$ and $\mathbf{j}$, when added to $\mathbf{J}$, would make all allowed angles: from minimum angle (the quantum number $J = l + j$), through larger angles[9] and the corresponding quantum numbers $J = l + j - 1, l + j - 2$, etc., up to the maximum angle, corresponding to $J = |l - j|$). Therefore, the number of all possible values of J (each corresponding to a different energy) is equal to the number of projections of the *shorter*[10] of the vectors $\mathbf{l}$ and $\mathbf{j}$ on the longer one, i.e.,

---

[6] That is, the bottom of the well would be a sphere centered in the center of mass of AB and the well depth would be independent of the orientation.

[7] We use to say "*good*."

[8] Of course, the momentum has also been conserved in the isotropic case, but in this case the energy was identical independently of the quantum number J (resulting from different angles between $\mathbf{l}$ and $\mathbf{j}$).

[9] The projections of the angular momenta are quantized.

$$J = (l + j), (l + j - 1), \ldots, |l - j|. \tag{7.1}$$

For a given J there are $2J + 1$ projections of $\mathbf{J}$ on the z axis (because $|M_J| \le J$); without any external field all these projections correspond to identical energy.

Please check that the number of all possible eigenstates is equal to $(2l+1)(2j+1)$, i.e., exactly what we had in the isotropic case. For example, for $l = 1$ and $j = 1$ the degeneracy in the isotropic case is equal to $(2l+1)(2j+1) = 9$, while for anisotropic V we would deal with five states for $J = 2$ (all of the same energy), three states corresponding to $J = 1$ (the same energy, but different from $J = 2$), and a single state with $J = 0$ (still another value of energy), altogether nine states. This means that switching anisotropy on partially removed the degeneracy of the isotropic level (l, j) and gave the levels characterized by quantum number J.

7.1.4 Application of the Ritz method

We will use the Ritz variational method (see Chapter 5, p. 271) to solve the Schrödinger equation. What should we propose as the expansion functions? It is usually recommended that we proceed systematically and choose first a complete set of functions depending on R, then a complete set depending on $\hat{\mathbf{R}}$, and finally a complete set that depends on the $\hat{\mathbf{r}}$ variables. Next, one may create the complete set depending on all five variables (these functions will be used in the Ritz variational procedure) by taking all possible products of the three functions depending on R, $\hat{\mathbf{R}}$, and $\hat{\mathbf{r}}$. There is no problem with the complete sets that have to depend on $\hat{\mathbf{R}}$ and $\hat{\mathbf{r}}$, as these may serve the spherical harmonics (the wave functions for the rigid rotator) $\{Y_l^m(\Theta, \Phi)\}$ and $\{Y_{l'}^{m'}(\theta, \phi)\}$, while for the variable R we may propose the set of harmonic oscillator wave functions $\{\chi_v(R)\}$.[11] Therefore, we may use the following as the variational function[12]:

$$\Psi(R, \Theta, \Phi, \theta, \phi) = \sum c_{vlml'm'} \chi_v(R) Y_l^m(\Theta, \Phi) Y_{l'}^{m'}(\theta, \phi),$$

---

[10] In the case of two vectors of the same length, the role of the shorter vector may be taken by either of them.

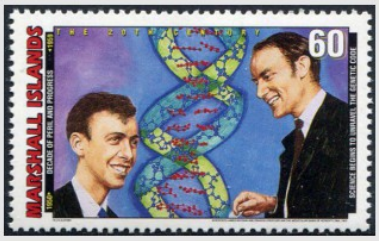
[11] See Chapter 4. Of course, our system does not represent any harmonic oscillator, but what counts is that the harmonic oscillator wave functions form a complete set (as the eigenfunctions of a Hermitian operator).

[12] The products $Y_l^m(\Theta, \Phi) Y_{l'}^{m'}(\theta, \phi)$ may be used to produce linear combinations that are automatically the eigenfunctions of $\hat{J}^2$ and $\hat{J}_z$, and have the proper parity (see Chapter 2). This may be achieved by using the Clebsch–Gordan coefficients (D.M. Brink, G.R. Satchler, *Angular Momentum*, Clarendon, Oxford, 1975). The good news is that this way we can obtain a smaller matrix for diagonalization in the Ritz procedure, the bad news is that the matrix elements will contain more terms to be computed. The method described above will give the same result as using the Clebsch–Gordan coefficients, because the eigenfunctions of the Hamiltonian obtained within the Ritz method will automatically be the eigenfunctions of $\hat{J}^2$ and $\hat{J}_z$ and have the proper parity.

where c are the variational coefficients and the summation goes over v, l, m, l', m' indices. The summation limits have to be finite in practical applications; therefore the summations go to some maximum values of v, l, and l' (m and m' vary from $-l$ to l and from $-l'$ to $+l'$). We hope (as always in quantum chemistry) that numerical results of a demanded accuracy will not depend on these limits. Then, as usual, the Hamiltonian matrix is computed and diagonalized (see p. 703), and the eigenvalues E_J as well as the eigenfunctions ψ_{J,M_J} of the ground and excited states are found. Each of the eigenfunctions will correspond to some J, M_J and to a certain parity. The problem is solved.

7.2 Force fields (FFs)

The middle of the 20th century marked the end of a long period of determining the building blocks of chemistry: chemical elements, chemical bonds, and bond angles. The lists of these are not definitely closed, but future changes will be rather cosmetic than fundamental. This made it possible to go one step further and begin to rationalize the structure of molecular systems as well as to foresee the structural features of the compounds to be synthesized. The crucial concept is based on the Born–Oppenheimer approximation and on the theory of chemical bonds and resulted in the spatial structure of molecules. The great power of such an approach was first proved by the construction of the DNA double-helix model by Watson and Crick. The first DNA model was build from iron spheres, wires, and tubes.



MARSHALL ISLANDS

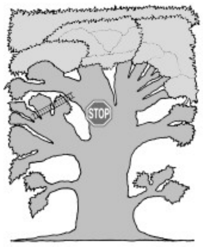
THE 20TH CENTURY
DECADE OF PERIL AND PROGRESS
SCIENCE BEGINS TO UNRAVEL THE GENETIC CODE

James Dewey Watson (left), born in 1928, American biologist, professor at Harvard University. Francis Harry Compton Crick (right) (1916–2004), British physicist, professor at Salk Institute in San Diego. Both scholars won the 1962 Nobel Prize for "*their discoveries concerning the molecular structure of nucleic acids and its significance for information transfer in living material*." At the end of the historic paper J.D. Watson, F.H.C. Crick, *Nature*, 737(1953) (of about 800 words) the famous enigmatic but crucial sentence appears: "*It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material*." The story behind the discovery is described in a colorful and nonconventional way by Watson in his book "*Double helix: A Personal Account of the Discovery of the Structure of DNA*."



CHAPTER 8

Orbital Model of Electronic Motion in Atoms and Molecules

Everything should be made as simple as possible, but not simpler.
Albert Einstein

Where are we?

We are in the upper part of the main trunk of the TREE.

An example

What is the electronic structure of atoms? How do atoms interact in a molecule? Two *neutral* moieties (say, hydrogen atoms) attract each other with a large force *of a similar order of magnitude* as the Coulombic forces between two ions. This is quite surprising. What pulls these neutral objects to one another? These questions are at the foundations of chemistry.

The isolobal analogy (△) **p. 578**

The Born–Oppenheimer (or adiabatic) approximation is the central point of this book (note its position in the TREE). Thanks to the approximation, we can consider *separately* two *coupled* problems concerning molecules:

- the motion of the electrons at fixed positions of the nuclei (to obtain the electronic energy),
- the motion of nuclei in the potential representing the electronic energy of the molecule (see Chapter 7).

From now on we will concentrate on the *motion of the electrons at fixed positions of the nuclei* (the Born–Oppenheimer approximation, p. 320).

To solve the corresponding Eq. (6.18), we have at our disposal the variational and the perturbation methods. The latter one should have a reasonable starting point (i.e., an unperturbed system). This is not the case in the problem we want to consider at the moment. Thus, only the variational method remains. If so, a class of the trial functions should be proposed. In this chapter the trial wave function will have a very specific form, bearing significant importance for the theory. We mean here the so-called Slater determinant, which is composed of molecular orbitals (MOs). At a certain level of approximation, each MO is a "home" for two electrons. We will now learn how to get the optimum MOs (Hartree–Fock method). In spite of some quite complex formulae, which will appear below, the main idea behind them is extremely simple. It can be expressed in the following way.

Let us consider road traffic; the cars (electrons) move at fixed positions of buildings (nuclei). The safe motion of the cars looks very complex indeed (as it does for the electrons). Is there any way at all to design such a complex many-body and safe motion? Well, one may radically simplify the problem and use the so-called mean-field approximation (paying necessarily the price of lower quality). In the mean-field approximation method we focus on the motion of *one car only*, considering its motion in such a way that the car avoids *those streets that are known as most jammed*. In this chapter we will treat the electrons in a similar manner (leaving the difficulties of considering the correlation of the motions of the electrons to Chapter V2-2). Now, the electrons will not feel the true electric field of the other electrons (as they should in a precise approach), but rather their static *mean* electric field, i.e., averaged over their motions. The idea looks hopeless, but it turns out to be a very effective and fruitful approach.

Translating this into quantum mechanical language, the underlying assumptions of the mean-field method for N identical particles (here: electrons) are the following:

- there is a certain "effective" *one-particle* operator $\hat{F}(i)$ of an identical mathematical form for all particles $i = 1, 2, ...N$, which has the eigenfunctions ϕ_k, i.e., $\hat{F}\phi_k = \varepsilon_k \phi_k$, such that
- $\left\langle \Psi | \hat{H} \Psi \right\rangle \approx \left\langle \tilde{\Psi} | \hat{H}^{ef} \tilde{\Psi} \right\rangle$, where $\tilde{\Psi}$ (normalized) is a wave function that approximates the exact wave function Ψ for the total system, $\hat{H}$ is the electronic Hamiltonian (in the clamped nuclei approximation, Chapter 6), and $\hat{H}^{ef} = \sum_{i=1}^{N} \hat{F}(i)$. In such a case the eigenvalue equation $\hat{H}^{ef} \Pi_{i=1}^{N} \phi_i(i) = E_0 \Pi_{i=1}^{N} \phi_i(i)$ holds, and the approximate total energy is equal to $E_0 = \sum_{i=1}^{N} \varepsilon_k$, *as if the particles were independent*.

Any mean-field method needs to solve two problems:

- How should $\tilde{\Psi}$ be constructed using N eigenfunctions ϕ_k?
- What is the form of the one-particle effective operator $\hat{F}$?

These questions will be answered in the present chapter.

Such effectively independent, yet interacting particles, are called quasiparticles or – as we sometimes use to say – bare particles dressed up by the interaction with others.

It is worth remembering that the mean-field method bears several different names in chemistry:

- one-determinant approximation,
- one-electron approximation,
- one-particle approximation,
- molecular orbital method,
- independent-particle approximation,
- mean-field approximation,
- Hartree–Fock method,
- self-consistent field method (as regards practical solutions).

It will be shown how the mean-field method implies that milestone of chemistry: the periodic table of chemical elements.

Next, we will endeavor to understand *why* two atoms create a chemical bond, and also what affects the ionization energy and the electron affinity of a molecule.

Then, still within the MO scheme, we will show how we can reach a localized description of a molecule, with chemical bonds between *some* atoms, with the inner electronic shells, and the lone electronic pairs. The last terms are elements of a rich and very useful language commonly used by chemists.

Why this is important?

Contemporary quantum chemistry uses better methods than the mean field, described in this chapter. We will get know them in Chapters V2-2 and V2-3. Yet all these methods *start from the mean-field approximation* and in most cases they only perform cosmetic changes in energy and in electron distribution.

For example, the methods described here yield about 99% of the total energy of a system.[1] There is one more reason for why this chapter is important. Methods beyond the one-electron approximation are – computationally – very time consuming (hence they may be applied only to small systems), while the molecular orbital approach is the "daily bread" of quantum chemistry. It is a sort of standard method, and the standards have to be learned.

What is needed?

- Postulates of quantum chemistry (Chapter 1, necessary),
- operator algebra, Hermitian operators (Appendix B, p. 595, necessary),
- complete set of functions (Chapter 1, necessary),
- Hilbert space (Appendix B, p. 595, recommended),
- determinants (Appendix A, p. 589, absolutely necessary),
- Slater–Condon rules (Appendix N, p. 707, only the results are needed),
- Lagrange multipliers (Appendix O, p. 719, necessary),
- Mulliken population analysis (Appendix V2-D, p. V2-595, occasionally used).

Classical works

This chapter deals with the basic theory explaining the electronic structure of atoms and molecules. This is why we begin with Dimitryi Ivanovitch Mendeleev, who discovered in 1865, when writing his textbook "*Osnovy Khimii*" ("*Principles of Chemistry*"), St. Petersburg, Tovarishchestvo Obshchestvennaya Polza, 1869-1871, his famous periodic table of elements – one of the greatest human achievements. ★ Gilbert Newton Lewis in the paper "*The Atom and the Molecule*," published in the *Journal of the American Chemical Society*, 38(1916)762, and Walter Kossel in the article "*Über die Molekülbildung als Frage des Atombaus*," published in *Annalen der Physik*, 49(1916)229, introduced such important algorithmic theoretical tools as the octet rule and stressed the importance of the noble gas electronic configurations. ★ As soon as quantum mechanics was formulated in 1926, Douglas R. Hartree published several papers in the *Proceedings of the Cambridge Philosophical Society*, 24(1927)89, 24(1927)111, 26(1928)89, entitled "*The Wave Mechanics of an Atom with a Non-Coulomb Central Field*," containing the computations for large atoms such as Rb and Cl. These were *self-consistent ab initio*[2] computations, and the wave function was assumed to be the *product* of spin orbitals. ★ The LCAO approximation (for the solid state) was introduced by Felix Bloch in his PhD thesis "*Über die Quantenmechanik der Elektronen in Kristallgittern*," University of Leipzig, 1928, and three years later Erich Hückel used this method to describe the first molecule (benzene) in a publication "*Quantentheoretische Beitrage zum Benzolproblem. I. Die Elektronenkonfiguration des Benzols*," which appeared in *Zeitschrift für Physik*, 70(1931)203. ★ Vladimir

---

[1] In physics and chemistry we are seldom interested in the total energy. The energy differences of various states are of importance. Sometimes such precision is not enough, but the result speaks for itself.

[2] That is, derived from the first principles of (nonrelativistic) quantum mechanics! Note that these young people worked incredibly fast (no email, no PCs).

Fock introduced the antisymmetrization of the spin orbital product in his publication "*Näherungsmethode zur Lösung des quantenmechanischen Mehrkörperproblems*," in *Zeitschrift für Physik*, 61(1930)126 and *ibid*. 62(1930)795. ★ John Slater proposed the idea of the multiconfigurational wave function ("*Cohesion in Monovalent Metals*," *Physical Review*, 35(1930)509). ★ The Hartree–Fock method in the LCAO approximation was formulated by Clemens C.J. Roothaan in his work "*New Developments in Molecular Orbital Theory*," published in the *Reviews of Modern Physics*, 23(1951)69, and, independently, by George G. Hall in the paper "*The Molecular Orbital Theory of Chemical Valency*," in *Proceedings of the Royal Society (London) A*, 205(1951)541. ★ The physical interpretation of the orbital energies in the Hartree–Fock method was given by Tjalling C. Koopmans in his *only* quantum chemical paper "*On the Assignment of Wave Functions and Eigenvalues to the Individual Electron of an Atom*," published in *Physica*, 1(1933/1934)104. ★ The first localized orbitals (for the methane molecule) were computed by Charles A. Coulson despite the difficulties of war time (*Transactions of the Faraday Society*, 38(1942)433). ★ Hideo Fukutome, first in *Progress in Theoretical Physics*, 40(1968)998, and then in several following papers, analyzed general solutions for the Hartree–Fock equations from the symmetry viewpoint, and showed exactly eight classes of such solutions.

* * *

In the previous chapter the motion of nuclei was considered. In the Born–Oppenheimer approximation (Chapter 6) the motion of the nuclei takes place in the potential, which is the electronic energy of a system (being a function of the nuclei position, **R**, in the configurational space). The electronic energy $E_k^0(\mathbf{R})$ is an eigenvalue given in Eq. (6.8) (adapted to the polyatomic case, hence $R \rightarrow \mathbf{R}$): $\hat{H}_0\psi_k(\mathbf{r};\mathbf{R}) = E_k^0(\mathbf{R})\psi_k(\mathbf{r};\mathbf{R})$. We will now deal exclusively with this equation, i.e., we will consider the electronic motion at fixed positions of the nuclei (clamped nuclei). Thus, our goal is two-fold: we are interested in what the electronic structure looks like and in how the electronic energy depends on the positions of the nuclei.[3]

Any theoretical method applicable to molecules may be also used for atoms, although very accurate wave functions, even for simple atoms, are not easy to calculate.[4] In fact for atoms we know the solutions quite well only in the mean-field approximation, i.e., the atomic orbitals (AOs). Such orbitals play an important role as building blocks of many-electron wave functions.

---

[3] Due to tradition in the previous chapter the ground-state electronic energy $E_0^0(\mathbf{R})$ was denoted as $V(\mathbf{R})$.

[4] If an atom is considered in the Born–Oppenheimer approximation, the problem is even simpler, the electronic equation also holds; we can then take, e.g., $\mathbf{R} = \mathbf{0}$. People still try to compute correlated wave functions (i.e., beyond the mean-field approximation, see Chapter V2-2) for heavier atoms. Besides, relativistic effects (see Chapter 3) play increasingly important roles for such atoms. Starting with magnesium, they are larger than the correlation corrections. Fortunately, the relativistic corrections for atoms are largest for the inner electronic shells, which are least important for chemists.

CHAPTER 1

Electronic Orbital Interactions in Periodic Systems

Beauty of style and harmony and grace and good rhythm depend on simplicity.
Plato

Where are we?

We are on the upper left branch of the TREE.

An example

Polyacetylene[1] represents a *practically* infinite polymeric chain: ⋯–CH=CH–CH=CH–CH=CH–CH=CH–⋯. There is no such a thing in Nature as a truly infinite system.[2] Yet, if we examine larger and larger portions of a homogeneous material, we come to the idea that such quantities as energy per stoichiometric unit, electron excitation energy, vibrational frequencies, etc., depend less and less on system size. This means that a boundary region (polymer ends, crystal surface) contribution to these quantities becomes negligible. Therefore, these (known as *intensive*) quantities attain limit values identical to those for an infinite system. *It pays to investigate the infinite system, because we can use its translational symmetry to simplify its description.* Well, this is what this chapter is all about.

---

[1] The discovery of conducting polymers (like polyacetylene) was highlighted by the Nobel Prize 2000 for Hideki Shirakawa, who synthesized a crystalline form of polyacetylene, as well as Allan G. MacDiarmid and Allan J. Heeger, who increased its electric conductivity by 18 orders of magnitude by doping the crystal with some electron acceptors and donors. This incredible increase is probably the largest known to humanity in any domain of experimental sciences (H. Shirakawa, E.J. Louis, A.G. MacDiarmid, C.K. Chiang, A.J. Heeger, *Chem. Soc. Chem. Commun.*, 578(1977)).

[2] That is, a macromolecule. The concept of polymer was introduced to chemistry by Herman Staudinger.

100th Anniversary
of the Nobel Prizes
Hermann Staudinger (Germany)
Chemistry, 1953
UGANDA 300/-

Herman Staudinger (1881–1965), German polymer chemist, professor at the University of Freiburg, received the Nobel Prize in 1953 "*for his discoveries in the field of macromolecular chemistry*." However strange it may sound now, as late as in 1926 the concept of polymers was unthinkable in chemistry. It will be encouraging for PhD students to read that a professor advised Staudinger in the late 1920s: "*Dear colleague, leave the concept of large molecules well alone: organic molecules with a molecular weight above 5000 do not exist. Purify your products, such as rubber, then they will crystallize and prove to be lower molecular substances.*"

- The symmetry of subsystem choice

If a motif (e.g., a cluster of atoms) associated with a unit cell is *regularly translated along three different directions in space*, we obtain an infinite three-dimensional periodic structure (translational symmetry). In 2D (Fig. 1.1a) this means that having a single (special) type of tiles (unit cells) we have been successful in tiling the *complete* two-dimensional space. One of the consequences is that the five-fold symmetry axes have to be absent in the atomic arrangements in such crystals. *It turned out that a vast majority of real crystals can be reliably modeled using this idea.* There were efforts in mathematics to design some nontranslational complete tilings. In 1963 it was first shown that for a number $N = 20\,000$ of square tiles such a nontranslational tiling is possible. This number has been gradually reduced and in 1976 Roger Penrose proposed covering by $N = 2$ kinds of tiles (see Fig. 1.1b). Then, Daniel Shechtman discovered[3] that there are substances (known now as quasicrystals) that indeed show five-fold symmetry axes (also other translationally forbidden symmetry axes). The reason why quasicrystals exist in Nature is quite simple: some strong short-range interactions force unusual five-ligand complexes. It is remarkable that the discovery of quasicrystals has been preceded by ancient artists (Fig. 1.1c).

When applying the Hartree–Fock method to such periodic infinite objects one exploits the translational symmetry of the system, e.g., in calculating integrals. It would be indeed prodigal to compute the integrals many times, the equality of which is *guaranteed* by translational symmetry. When translational symmetry is taken into account, the problem reduces to the calculation of the interaction of a single unit

---

[3] He received the 2011 chemistry Nobel Prize for “the discovery of quasicrystals.”

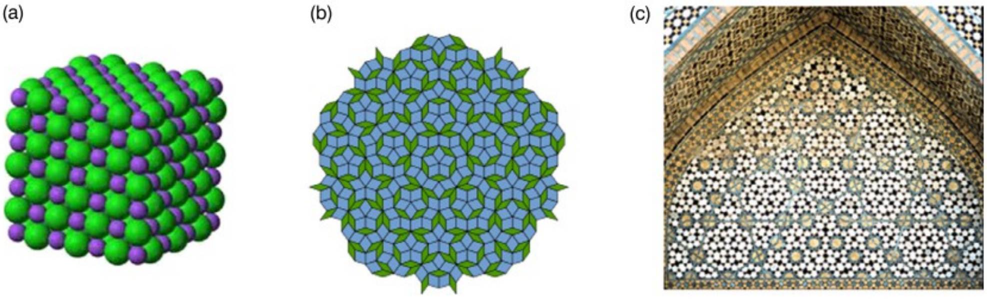

Fig. 1.1. Translational symmetry in crystals and its lack in the quasicrystals despite a perfect long-range order. (a) Translational symmetry in the NaCl crystal build of Na^+ and Cl^- ions. (b) The Penrose tiling as an example of a quasicrystal, no translational symmetry. (c) A medieval Arabian mosaic as an example of a long-range nontranslational order.

cell (reference, labeled by 0) with all other unit cells, the nearest neighbor cells being most important. The infinite size of the system is hidden in the plethora of points (to be taken into account) in what is known as the first Brillouin zone (FBZ). The FBZ represents a unit cell in what is called inverse lattice (associated with a given lattice reflecting the translational symmetry).

The electronic orbital energy becomes a function of the FBZ points and we obtain what is known as a band structure of energy levels. This band structure decides the electronic properties of the system (insulator, semiconductor, metal). We will also show how to carry out the mean-field (Hartree–Fock) computations on infinite periodic systems. The calculations require infinite summations (interaction of the reference unit cell with the infinite crystal) to be made. This creates some mathematical problems, which will be also described in the present chapter.

Why is this important?

The present chapter is particularly important for those readers who are interested in solid state physics and chemistry. Others may treat it as exotic and, if they decide they do not like exotic matter, may go directly to other chapters.

The properties of a polymer or a crystal sometimes differ very widely from those of the atoms or molecules of which they are built. *The same substance* may form *different* periodic structures, which have *different* properties (e.g., graphite and diamond). The properties of periodic structures could be computed by extrapolation of the results obtained for larger and larger clusters of the atoms from which the substance is composed. This avenue is however noneconomic. It is easier to carry out quantum mechanical calculations for an infinite system[4] than for a large cluster.[5]

---

[4] The surface effects can be neglected and the units the system is composed of are treated as equivalent.

[5] Sometimes we may be interested in a particular cluster, not in an infinite system. Then it may turn out that it is more economic to perform the calculations for the infinite system, and use the results in computations for the clusters (e.g., R.A. Wheeler, L. Piela, R. Hoffmann, *J. Am. Chem. Soc.*, 110(1988)7302).

What is needed?

- Operator algebra (Appendix V1-B, p. V1-595, necessary),
- translation operator (Appendix V1-C, p. V1-605, necessary),
- Hartree–Fock method (Chapter V1-8, necessary),
- multipole expansion (Appendix G, p. 613, advised),
- matrix diagonalization (Appendix V1-L, p. V1-703, advised).

Classical works

At the age of 23, Felix Bloch published an article "*Über die Quantenmechanik der Elektronen in Kristallgittern*" in *Zeitschrift für Physik*, 52(1928)555 (only two years after Schrödinger's historic publication) on the translational symmetry of the wave function. This has also been the first application of LCAO expansion. ★ A book appeared in 1931 by Leon Brillouin entitled *Quantenstatistik* (Springer Verlag, Berlin, 1931), in which the author introduced some of the fundamental notions of band theory. ★ The first *ab initio* calculations for a polymer were carried out by Jean-Marie André in the paper "*Self-Consistent Field Theory for the Electronic Structure of Polymers*," published in the *Journal of the Chemical Physics*, 50(1969)1536.

* * *

1.1 Primitive lattice

Let us imagine an *infinite crystal*, e.g., a system that exhibits the 3D *translational symmetry* of the charge distribution (nuclei and electrons). The translational symmetry will be fully determined by three (linearly independent) basis vectors[6]: $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, and $\boldsymbol{a}_3$, having the property that $\boldsymbol{a}_i$ beginning at any atom extends to the corresponding nearest-neighbor identical atom located in the crystal. The lengths of the basis vectors $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, and $\boldsymbol{a}_3$ are called the *lattice constants* along the three periodicity axes.[7]

A lot of such basis sets are possible. Any choice of basis vectors is acceptable from the point of view of mathematics. For economic reasons we choose one of the possible vector sets that give the *least volume parallelepiped*[8] with sides $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, and $\boldsymbol{a}_3$. This parallelepiped (arbitrarily

---

[6] Not necessarily perpendicular though; they determine the periodicity axes.

[7] As shown on p. V1-514, a symmetry of the nuclear framework does not guarantee the same symmetry of the electronic charge distribution computed using a mean-field method. We may cope with the period doubling as compared to the period of the nuclear framework (cf. BOAS, p. V1-514). If this happens, then we should choose such lattice constants that ensure the periodicity of both nuclear and electron distributions.

[8] We are, however, interested in the smallest unit cell.

Alexandr Alexandrovitch Friedmann (1888–1925), Russian mathematician and physicist, in his article in *Zeit. Phys.*, 10(1922)377 proved on the basis of Einstein's general theory of relativity that the curvature of the Universe must change, which became the basis of cosmological models of the expanding Universe. During the First World War, Friedman was a pilot in the Russian army and made bombing raids over my beloved Przemyśl.

In one of his letters he asked his friend cheerfully, the eminent Russian mathematician Steklov, for advice about the integration of equations he derived to describe the trajectories of his bombs. Later, in a letter to Steklov of February 28, 1915 he wrote: "*Recently I had an opportunity to verify my theory during a flight over Przemyśl, the bombs fell exactly in the places predicted by the theory. To get the final proof of my theory I intend to test it in flights during the next few days*."

More information can be found on http://www-groups.dcs.st-and.ac.uk/~history/Mathematicians/Friedmann.html.

2.4 Exponentially correlated Gaussian functions

In 1960, Boys[28] and Singer[29] noticed that the functions which are products of Gaussian orbitals and correlational factors of Gaussian type, $\exp(-br_{ij}^2)$, where r_{ij} is the distance between electron i and electron j, generate relatively simple integrals in quantum chemical calculations. A product of two Gaussian orbitals with positions shown by the vectors $\mathbf{A}, \mathbf{B}$ and of an exponential correlation factor is called *an exponentially correlated Gaussian geminal*,[30] i.e.,

$$g\left(\mathbf{r}_i, \mathbf{r}_j; \mathbf{A}, \mathbf{B}, a_1, a_2, b\right) = N e^{-a_1(\mathbf{r}_i-\mathbf{A})^2} e^{-a_2\left(\mathbf{r}_j-\mathbf{B}\right)^2} e^{-br_{ij}^2}.$$

A geminal represents a generalization of an orbital – there we have a one-electron function, here we have a two-electron one. A single geminal is very rarely used in computations[31]; we apply hundreds or even thousands of Gaussian geminals. When we want to find out what the optimal positions $\mathbf{A}, \mathbf{B}$ and the optimal exponents a and b are in these thousands of geminals, it turns out that nothing sure is known about them; the $\mathbf{A}, \mathbf{B}$ positions are scattered chaotically,[32] and in the $a > 0$ and $b > 0$ exponents there is no regularity either.

---

[28] S.F. Boys, *Proc. Royal Soc. A*, 258(1960)402.

[29] K. Singer, *Proc. Royal Soc. A*, 258(1960)412.

[30] This is an attempt to go beyond the two-electron systems with the characteristic for these systems approach of James, Coolidge, Hylleraas, Kołos, Wolniewicz, and others.

[31] Ludwik Adamowicz introduced an idea of the minimal basis of the Gaussian geminals (equal to the number of the electron pairs) and applied to the LiH and HF molecules; L. Adamowicz, A.J. Sadlej, *J. Chem. Phys.*, 69(1978)3992.

Edwin Powell Hubble (1889–1953), American astronomer, explorer of galaxies, found in 1929 that the distance between galaxies is proportional to the infrared shift in their spectrum caused by the Doppler effect, which is consequently interpreted as expansion of the Universe. A surprise from recent astronomical studies is that the expansion is faster and faster (for unknown reasons).

2.5 Electron holes

2.5.1 Coulomb hole ("correlation hole")

It is always good to count "on fingers" to make sure that everything is all right. Let us see how a *single* Gaussian geminal describes the correlation of the electronic motion. Let us begin with the helium atom with the nucleus in the position $\mathbf{A} = \mathbf{B} = \mathbf{0}$. The geminal takes the form

$$g_{He} = Ne^{-a_1 r_1^2} e^{-a_1 r_2^2} e^{-b r_{12}^2}, \tag{2.18}$$

where $N > 0$ is a normalization factor. Let us assume[33] that electron 1 is at $(x_1, y_1, z_1) = (1, 0, 0)$. Where does electron 2 prefer to be in such situation? We will find it out (Fig. 2.2) from the position of electron 2 for which g_{He} assumes the largest value.

Just to get an idea, let us try to restrict the motion of electron 2. For instance, let us demand that it moves only on the sphere of radius equal to 1 centered at the nucleus, so we insert $r_1 = r_2 = 1$. Then, $g_{He} = const \exp\left[-b r_{12}^2\right]$ and we will find out easily what electron 2 likes most. With $b > 0$ the latter factor tells us that what electron 2 likes best is just to sit on electron 1! Is it what the correlation is supposed to mean that one electron sits on the other? Here we have rather an anticorrelation. Something is going wrong. According to this analysis we should rather take the geminal of, e.g., the form

$$g_{He} = Ne^{-a_1 r_1^2} e^{-a_1 r_2^2} \left[1 - e^{-b r_{12}^2}\right].$$

---

[32] The methods in which those positions are selected at random scored great success.

[33] We use atomic units.

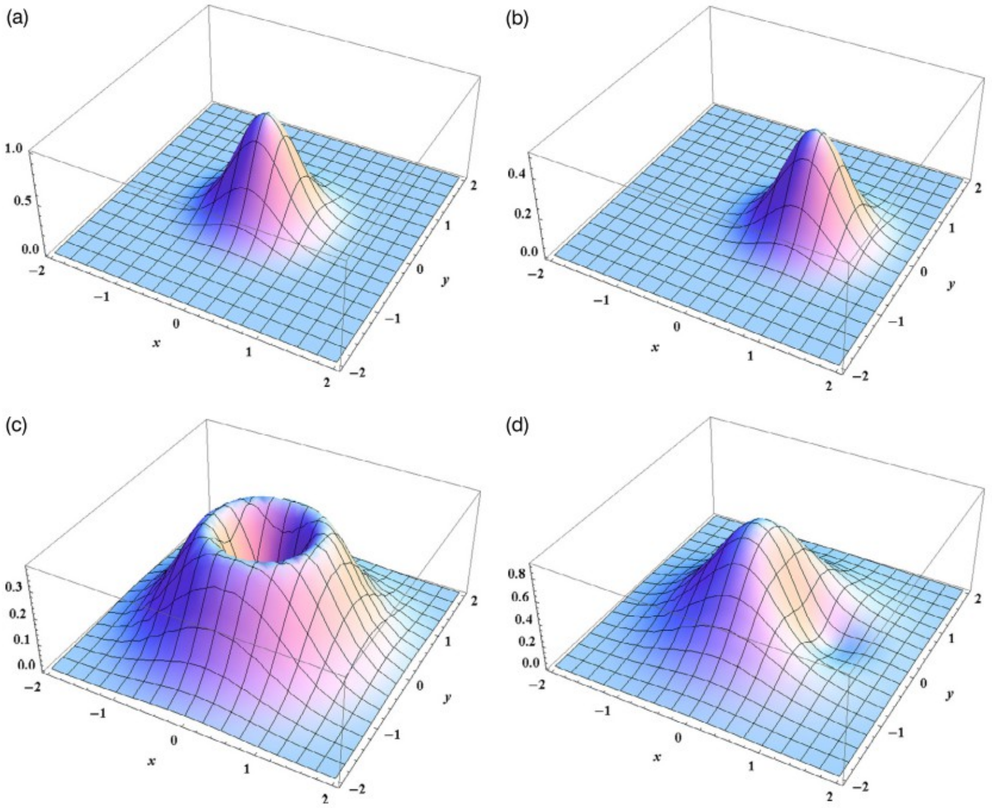

Fig. 2.2. Illustration of the correlation and anticorrelation of the electrons in a model helium atom. The machinery of the "anticorrelation" connected with the (not normalized) geminal $g_{He} = \exp\left[-r_1^2\right]\exp\left[-r_2^2\right]\exp\left[-2r_{12}^2\right]$. (a) Electron 1 has position $(0,0,0)$. (b) Electron 1 is at point $(1,0,0)$. It can be seen that electron 2 *holds on to electron 1*, i.e., it behaves in a completely unphysical manner (since the electrons repel each other). (c,d) Electron 2 responds to such two positions of electron 1 in case the wave function represents the geminal $g_{He} = \exp\left[-r_1^2\right]\exp\left[-r_2^2\right]\left[1-\exp\left[-2r_{12}^2\right]\right]$. (c) Electron 2 runs away (the hollow in the middle) from electron 1 placed at $(0,0,0)$, and we have correlation. (d) Similarly, if electron 1 is in point $(1,0,0)$, then it causes a slight depression for electron 2 in this position, and we have correlation. However, the graph is different from the one in (c). This is understandable since the nucleus is all the time in the point $(0,0,0)$. (e,f) The same displacements of electron 1, but this time the wave function is equal to $\psi\left(\mathbf{r}_1,\mathbf{r}_2\right) = \left(1+\frac{1}{2}r_{12}\right)\exp[-\left(r_1^2+r_2^2\right)]$, i.e., is similar to the wave function of the harmonic helium atom. It can be seen (particularly in (e)) that there *is* a correlation, although much less visible than in the previous examples. (g,h) The same as in (e,f), but (to amplify [artificially] the correlation effect) for the function $\psi\left(\mathbf{r}_1,\mathbf{r}_2\right) = (1+25r_{12})\exp[-\left(r_1^2+r_2^2\right)]$, which (unlike (e,f)) does not satisfy the correlation cusp condition.

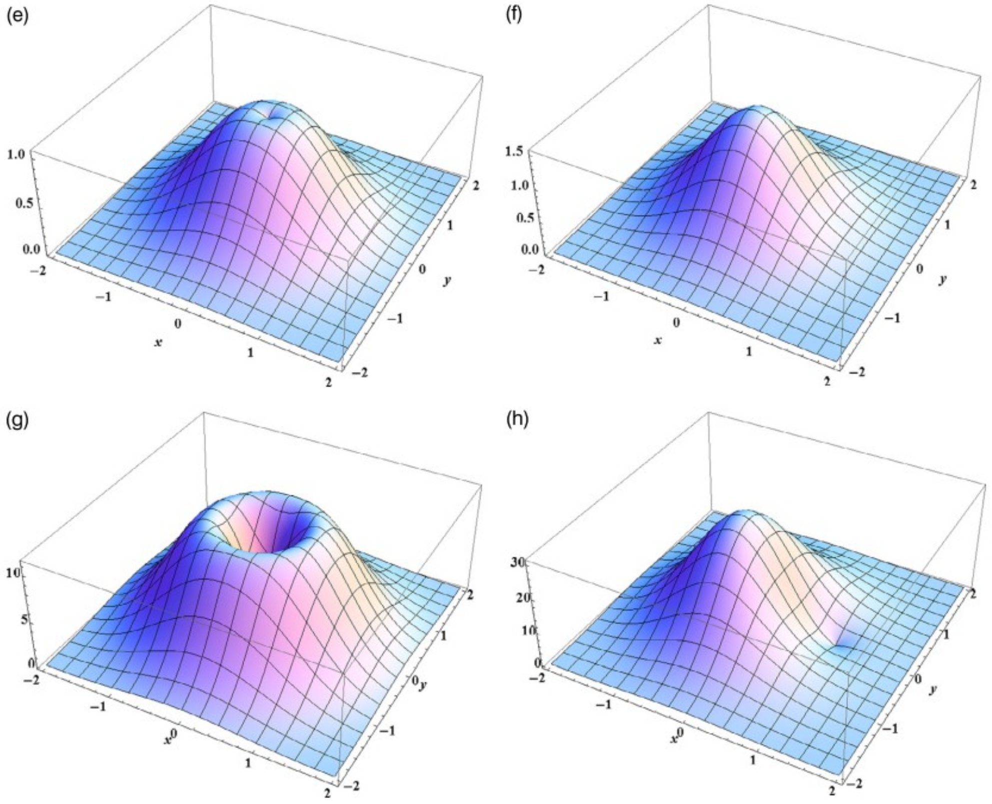

Fig. 2.2. (*continued*)

Now everything is qualitatively in order. When the interelectronic distance increases, the value of the g_{He} function also increases, which means that such a situation is *more* probable than that corresponding to a short distance. If the electrons become too agitated and begin to think that it would be better when their distance gets very large, they would be called to order by the factors $\exp\left[-a_1 r_1^2\right]\exp\left[-a_1 r_2^2\right]$. Indeed, in such a case, the distance between the nucleus and at least one of the electrons is long and the probability of such a situation is quenched by one or both exponential factors. For large r_{12} distances, the factor $\left[1-\exp\left[-b r_{12}^2\right]\right]$ is practically equal to 1. This means that for large interelectronic distances g_{He} is practically equal to $N\exp\left[-a_1 r_1^2\right]\exp\left[-a_1 r_2^2\right]$, i.e., to the product of the orbitals (no correlation of motions at long interelectronic distances and rightly so).

Around electron 1 there is a region of low probability of finding electron 2. This region is called the Coulomb hole.

The Gaussian geminals do not satisfy the correlation cusp condition (p. 92), because of the factor $\exp(-br_{ij}^2)$. It is required (for simplicity we write $r_{ij} = r$) that $(\frac{\partial g}{\partial r})_{r=0} = \frac{1}{2} g(r = 0)$, whereas the left-hand side is equal to 0, while the right-hand side $\frac{1}{2} N \exp\left[-a_1 \left(\mathbf{r}_i - \mathbf{A}\right)^2\right]$ $\exp\left[-a_2 \left(\mathbf{r}_j - \mathbf{B}\right)^2\right]$ is not equal to zero. This is not a disqualifying feature, since the region of space in which this condition should be fulfilled is very small.

The method of Gaussian geminals has been applied in extremely accurate calculations but for three- and four-electron systems only.[34]

2.5.2 Exchange hole ("Fermi hole")

The mutual avoidance of electrons in a helium atom or in a hydrogen molecule is caused by Coulombic repulsion of electrons ("Coulomb hole," see above). As we have shown in this chapter, in the Hartree–Fock method the Coulomb hole is absent, whereas methods which account for electron correlation generate such a hole. However, electrons avoid each other not only because of their charge. The Pauli principle is additional reason. One of the consequences is the fact that electrons with the same spin coordinate cannot reside in the same place (see p. V1-40). The continuity of the wave function implies that the probability density of them staying *in the vicinity* of each other is small, i.e.,

around the electron there is a NO PARKING area for other electrons with the same spin coordinate ("exchange hole" or "Fermi hole").

Let us see how such exchange holes arise. We will try to make the calculations as simple as possible.

We have shown above that the Hartree–Fock function does not include any electron correlation. We must admit, however, that we have come to this conclusion on the basis of the two-electron closed shell case. This is a special situation, since both electrons have *different* spin coordinates ($\sigma = \frac{1}{2}$ and $\sigma = -\frac{1}{2}$). Is it really true that the Hartree–Fock function does not include any correlation of electronic motion?

---

[34] W. Cencek, PhD Thesis, Adam Mickiewicz University, Poznań, 1993; also J. Rychlewski, W. Cencek, J. Komasa, *Chem. Phys. Letters*, 229(1994)657; W. Cencek, J. Rychlewski, *Chem. Phys. Letters*, 320(2000)549.

For each point on the IRC, i.e., on the curve $\mathbf{x}_{\mathrm{IRC}}(s)$, we may read the mass-weighted coordinates, and use them to calculate the coordinates of each atom. Therefore, each point on the IRC corresponds to a certain spatial and electronic structure of the system.

6.5 Reaction path Hamiltonian method

6.5.1 Energy close to IRC

A hypersurface of the potential energy represents an expensive product. We first have to calculate the potential energy for a grid of points. If we assume that ten points per coordinate is a sufficient number, then we have to perform 10^{3N-6} advanced quantum mechanical calculations; for $N = 10$ atoms this gives 10^{24} calculations, which is an impossible task. Now you see why specialists like three-atomic systems so much.

Are all the points necessary? For example, if we assume low energies, the system will in practice stay close to the IRC. Why, therefore, worry about other points? This idea was exploited by Miller, Handy, and Adams.[26] They decided to introduce the coordinates that are natural for the problem of motion in the reaction "drain-pipe." The approach corresponds to point 4 on p. 447.

The authors derived the

REACTION PATH HAMILTONIAN

an approximate expression for the energy of the reacting system in the form that stresses the existence of the IRC and of deviations from it.

This formula (*Hamilton function of the reaction path*) has the following form:

$$H(s, p_s, \{Q_k, P_k\}) = T(s, p_s, \{Q_k, P_k\}) + V(s, \{Q_k\}), \tag{6.26}$$

where T is the kinetic energy, V stands for the potential energy, s denotes the reaction coordinate along the IRC, $p_s = \frac{ds}{dt}$ represents the momentum coupled with s (mass = 1), and $\{Q_k\}$, $k = 1, 2, ...3N-7$, stand for other coordinates orthogonal to the reaction path $\mathbf{x}_{IRC}(s)$ (this is why Q_k will depend on s) and the momenta $\{P_k\}$ conjugated with them.

We obtain the coordinates Q_k in the following way. At point s of the reaction path we diagonalize the Hessian, i.e., the matrix of the second derivatives of the potential energy, and consider all the resulting normal modes ($\omega_k(s)$ are the corresponding frequencies, cf. Chapter V1-7)

---

[26] W.H. Miller, N.C. Handy, J.E. Adams, *J. Chem. Phys.,* 72(1980)99.

other than that which corresponds to the reaction coordinate s (the latter corresponds to the "imaginary"[27] frequency ω_k). The diagonalization also gives the orthonormal vectors $\mathbf{L}_k(s)$, each having a direction in the $(3N-6)$-dimensional configurational space (the mass-weighted coordinate system). The coordinate $Q_k \in (-\infty, +\infty)$ measures the displacement along the direction of $\mathbf{L}_k(s)$. The coordinates s and $\{Q_k\}$ are called the *natural coordinates*. To stress that Q_k is related to $\mathbf{L}_k(s)$, we will write it as $Q_k(s)$.

The potential energy close to the IRC can be approximated (*harmonic approximation*, cf. p. V1-218) by

$$V(s, \{Q_k\}) \cong V_0(s) + \frac{1}{2}\sum_{k=1}^{3N-7} \omega_k(s)^2 Q_k(s)^2, \tag{6.27}$$

where the term $V_0(s)$ represents the potential energy that corresponds to the bottom of the reaction "drain-pipe" at a point s along the IRC, while the second term tells us what will happen to the potential energy if we displace the point (i.e., the system) perpendicular to $\mathbf{x}_{IRC}(s)$ along all the normal oscillator coordinates. In the *harmonic approximation* for the oscillator k, the energy goes up by half the force constant × the square of the normal coordinate Q_k^2. The force constant is equal to ω_k^2, because the mass is equal to 1.

The kinetic energy turns out to be more complicated. We have

$$T(s, p_s, \{Q_k, P_k\}) = \frac{1}{2}\frac{[p_s - \sum_{k=1}^{3N-7}\sum_{k'=1}^{3N-7} B_{kk'} Q_{k'} P_k]^2}{[1 + \sum_{k=1}^{3N-7} B_{ks} Q_k]^2} + \sum_{k=1}^{3N-7} \frac{P_k^2}{2}. \tag{6.28}$$

The last term is recognized as the vibrational kinetic energy for the independent oscillations perpendicular to the reaction path (recall that the mass is treated as equal to 1). If in the first term we insert $B_{kk'} = 0$ and $B_{ks} = 0$, the term would be equal to $\frac{1}{2}p_s^2$ and, therefore, would describe the kinetic energy of a point moving as if the reaction coordinate were a straight line.

---

[27] For large $|s|$ the corresponding ω^2 is close to zero. When $|s|$ decreases (we approach the saddle point), ω^2 becomes negative (i.e., ω is imaginary). For simplicity we will call this the "imaginary frequency" for any s.

> CORIOLIS AND CURVATURE COUPLINGS
>
> - $B_{kk'}$ are called the Coriolis coupling constants. They couple the normal modes perpendicular to the IRC.
> - The B_{ks} are called the *curvature coupling constants*, because they would be equal to zero if the IRC was a straight line. They couple the translational motion along the reaction coordinate with the vibrational modes orthogonal to it.
> - All the above coupling constants B depend on s.

Therefore, in the reaction path Hamiltonian we have the following quantities that characterize the reaction "drain-pipe":

- the reaction coordinate s that measures the progress of the reaction along the "drain-pipe,"
- the value $V_0(s) \equiv V_0(\mathbf{x}_{IRC}(s))$ represents the energy that corresponds to the bottom of the "drain-pipe"[28] at the reaction coordinate s,
- the width of the "drain-pipe" is characterized[29] by a set $\{\omega_k(s)\}$,
- the curvature of the "drain-pipe" is hidden in constants B; their definition will be given later in this chapter. Coefficient $B_{kk'}(s)$ tells us how normal modes k and k' are coupled together, while $B_{ks}(s)$ is responsible for a similar coupling between reaction path $\mathbf{x}_{\mathrm{IRC}}(s)$ and vibration k perpendicular to it.

6.5.2 Vibrational adiabatic approximation

Most often when moving along the bottom of the "drain-pipe," potential energy $V_0(s)$ only changes moderately when compared to the potential energy changes the molecule undergoes when oscillating perpendicularly[30] to $\mathbf{x}_{IRC}(s)$. Simply, the valley bottom profile results from the fact that the molecule hardly holds together when moving along the reaction coordinate s, *a chemical bond breaks*, while *other bonds remain strong* and it is not so easy to stretch their strings. This suggests that there is *slow* motion along s and *fast* oscillatory motion along the coordinates Q_k.

> Since we are mostly interested in the slow motion along s, we may average over the fast motion.

---

[28] That is, the classical potential energy corresponding to the point of the IRC given by s (this gives an idea of how the potential energy changes when walking along the IRC).

[29] A small ω corresponds to a wide valley when measured along a given normal mode coordinate ("soft" vibration), a large ω means a narrow valley ("hard" vibration).

[30] That is, when moving along the coordinates Q_k, $k = 1, 2, ...3N - 7$.

-1 " ? 6

The philosophy behind the idea is that while the system moves slowly along s, it undergoes a large number of oscillations along Q_k. After such vibrational averaging the only information that remains about the oscillations are the vibrational quantum energy levels for each of the oscillators (of course, the levels will depend on s).

VIBRATIONAL ADIABATIC APPROXIMATION

The fast vibrational motions will be treated quantum mechanically and their total energy will enter the potential energy for the classical motion along s.

This approximation parallels the adiabatic approximation made in Chapter V1-6, where fast motion of electrons was separated from the slow motion of nuclei in a similar way. There after averaging over fast electronic motion, the total electronic energy became the potential energy for motion of nuclei, here after averaging over fast vibrational motion perpendicular to IRC the total vibrational energy (the energy of the corresponding harmonic oscillators in their quantum states) becomes the potential energy for the slow motion along s. This concept is called the *vibrational adiabatic approximation*.

In this approximation, to determine the stage of the reaction we give two *classical* quantities, i.e., *where* the system is on the reaction path (s) and *how fast* the system moves along the reaction path (p_s), as well as what the *quantum states* of the oscillators vibrating perpendicularly to the reaction path are (vibrational quantum number $v_k = 0, 1, 2, \ldots$ for each of the oscillators). Therefore, the potential energy for the (slow) motion along the reaction coordinate s is[31]

$$V_{adiab}(s; v_1, v_2, \ldots, v_{3N-7}) = V_0(s) + \sum_{k=1}^{3N-7} (v_k + \frac{1}{2})\hbar[\omega_k(s) - \omega_k(-\infty)], \quad (6.29)$$

where we have chosen an arbitrary additive constant in the potential as equal to the vibrational energy of the reactants (with minus sign), $-\sum_{k=1}^{3N-7}(v_k + \frac{1}{2})\hbar\omega_k(-\infty)$. Note that even though $v_k = 0$ for each of the oscillators, there is a nonzero vibrational correction to the classical potential energy $V_0(s)$, because the zero-vibrational energy changes if s changes.

---

[31] Even if (according to the vibrational adiabatic approximation) the vibrational quantum numbers were kept constant during the reaction, their energies as depending on s through ω would change.

The vibrational adiabatic potential V_{adiab} was created for a given set of the vibrational quantum numbers υ_k, fixed during the reaction process. Therefore, it is impossible to exchange energy between the vibrational modes (we assume therefore the Coriolis coupling constants $B_{kk'} = 0$), as well as between the vibrational modes and the reaction path (we assume the curvature coupling constants $B_{ks} = 0$). This would mean a change of υ_k's.

From Eq. (6.29) we may draw the following conclusion.

When during the reaction the frequency of a normal mode decreases dramatically (which corresponds to breaking of a chemical bond), the square bracket becomes negative. This means that an excitation of the bond before the reaction decreases the (vibrational adiabatic) reaction barrier and the reaction rate will increase.

As a matter of fact, this is quite obvious; a vibrational excitation that engages the chemical bond to be broken already weakens the bond before the reaction.

Why do chemical reactions proceed?

Exothermic reactions

When the reactants (products) have kinetic energy higher than the barrier and the corresponding momentum p_s is large enough, with a high probability the barrier will be overcome (cf. p. V1-205). Even if the energy is lower than the barrier there is still a nonzero probability of passing to the other side because of the tunneling effect. In both cases (passing over and under the barrier) it is easier when the kinetic energy is large.

The barrier *height* is usually different for the reactions reactants → products and products → reactants (Fig. 6.1). If the barrier height is smaller for the reactants, this *may* result in an excess of the product concentration over the reactant concentration.[32] Since the reactants have higher energy than the products, the potential energy excess will change into kinetic energy[33] of the products (which is observed as a temperature increase – the reaction is exothermic). This may happen if the system has the possibility to pump the potential (i.e., electronic) energy excess into the translational and rotational degrees of freedom or to a "third body or bodies" (through collisions, e.g., with the solvent molecules) or has the possibility to emit light quanta. If the system has no such possibilities the reaction will not take place.

---

[32] Because a lower barrier is easier to overcome.

[33] Most often rotational energy.

Endothermic reactions

The barrier height does not always decide.

> Besides the barrier height the *widths* of the entrance and exit channels also count.

For the time being let us take an example with $V_0(-\infty) = V_0(\infty)$, i.e., the barrier calculated from IRC is *the same* in both directions. Imagine a narrow entrance channel, i.e., large force constants for the oscillators, and a wide exit channel, i.e., low force constants (Figs. 6.2g,h and 6.7).

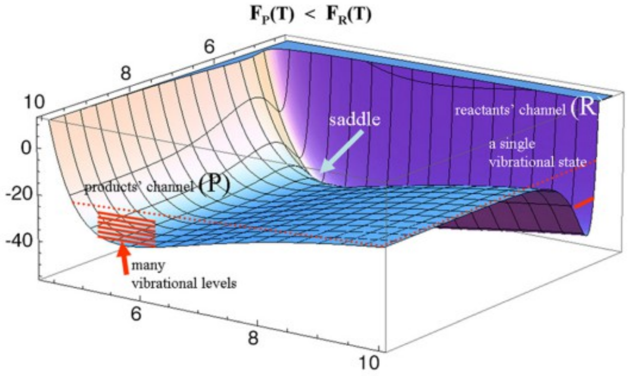

Fig. 6.7. Why do some endothermic reactions proceed spontaneously? The figure shows the reaction "drain-pipe" V. As we can see, the reactants have lower energy than the products. Yet it is not V that decides the reaction to proceed, but the free energy $F = E - TS$, where T is the temperature and S the entropy. The free energy depends on the density of the vibrational states of the reactants and products. The more numerous the low-energy vibrational levels, the larger the entropy and the lower the free energy, if $T > 0$. As we can see, the reactant vibrational levels are scarce (only one is shown), while on the product side they are densely distributed. When the energy gain related to the entropy overcomes the potential energy loss, the (endothermic) reaction will proceed spontaneously.

Note that, if the entrance channel is narrow while the exit channel is wide, the density of the vibrational states will be small in the entrance channel and large in the exit channel. Therefore, for $T > 0$ there will be a lot of possibilities to occupy the low-energy vibrational levels for the products, and only a few possibilities for the reactants. This means a high entropy of the products and a small entropy of the reactants, i.e., the products will be more stabilized by the entropy than the reactants.[34] Once again we can see that while the energy in a spontaneous endothermic reaction increases, the decisive factor is the free energy which *decreases*. The reactants → products reaction occurs “uphill” the potential energy, but “downhill” the free energy.

---

[34] It pertains to the term $-TS$ in the free energy. In such a chemistry masterpiece as biology the endothermic reactions which are not spontaneous, are often coupled with exothermic ones. In such a way the whole process may go spontaneously.

Kinetic and thermodynamic pictures

- In a macroscopic reaction carried out in a chemist’s flask we have a statistical ensemble of the systems that are in different microscopic stages of the reaction.
- The ensemble may be modeled by a reaction “drain-pipe” (we assume the barrier) with a lot of points, each representing one of the reacting systems.
- When the macroscopic reaction begins (e.g., we mix two reactants) a huge number of points appear in the entrance channel, i.e., we have the reactants only. As the reactant molecules assemble or dissociate the points appear or disappear.
- If the barrier were high (no tunneling) and temperature $T = 0$, all the reactants would be in their zero-vibrational states[35] and in their ground rotational states. This state would be stable even when the product valley corresponded to a lower energy (this would be a metastable state).
- Raising the temperature causes some of the ensemble elements in the entrance channel to acquire energy comparable to the barrier height. Those elements might have a chance to pass the barrier either by tunneling (for energy smaller than the barrier) or by going over the barrier. Not all of the elements with sufficient energies would pass the barrier, but only those with reactive trajectories (corresponding to a proper orientation and kinetic energy).
- After passing the barrier the energy is conserved, but in case of exothermic reactions the excess of energy changes into the translational, vibrational, and rotational energy of products or may be transferred to a “third body” (e.g., the solvent molecules) or changed into electromagnetic radiation. The latter if in the infrared region means a hot testtube – typical for the exotermic reactions. On the other hand, a spontaneous endotermic reaction takes the necessary energy from the neighborhood, which means cooling or even freezing (like when producing icecream).
- The probability of the reactive trajectories might be calculated in a way similar to that described in Chapter V1-4 (tunneling[36]), with additionally taking into account the initial vibrational and rotational states of the reactants as well as averaging over the energy level populations.
- The products would also have a chance to pass the barrier back to the reactant side (Nature does not know what we call reactants), but at the beginning the number of the elements

---

[35] Please note that even in this case ($T = 0$) the energy of these states would not only depend on the bottom of the valley, $V_0(s)$, but also on the valley’s width through $\omega_k(s)$, according to Eq. (6.29).

[36] See also H. Eyring, J. Walter, G.E. Kimball, “*Quantum Chemistry*,” John Wiley, New York, 1967.

passing the barrier in the reactant-to-product direction would be larger (nonequilibrium state).

- However, the higher the product concentration, the more often the products transform into the reactants. As an outcome we arrive at the *thermodynamic equilibrium state*, in which the average numbers of the elements passing the barrier per unit time in either direction are equal.
- If the barrier is high and the energies considered are low, then the stationary states of the system could be divided into those (of energy $E_{i,R}$) which have high amplitudes in the entrance channel (the reactant states) and those (of energy $E_{i,P}$) with high amplitudes in the exit channel (product states). In such a case we may calculate the partition function for the reactants as (we choose the same reference energy)

$$Z_R(T) = \sum_i g_i \exp\left(-\frac{E_{i,R} - E_{0,R}}{k_B T}\right)$$

and for the products as

$$Z_P(T) = \sum_i g_i \exp\left(-\frac{E_{i,P} - E_{0,R}}{k_B T}\right) = \sum_i g_i \exp\left(-\frac{E_{i,P} - E_{0,P} + \Delta E}{k_B T}\right),$$

where g_i stands for the degeneracy of the i-th energy level and the difference of the ground-state levels is $\Delta E = E_{0,P} - E_{0,R}$.

- Having the partition functions, we may calculate (at a given temperature and volume and a fixed number of particles[37]) the free or Helmholtz energy (F) corresponding to the entrance and exit channels (in thermodynamic equilibrium) as follows:

$$F_R(T) = -k_B T \frac{\partial}{\partial T} \ln Z_R(T), \tag{6.30}$$

$$F_P(T) = -k_B T \frac{\partial}{\partial T} \ln Z_P(T). \tag{6.31}$$

- The reaction goes in such a direction as to attain the minimum free energy F.
- The higher the density of states in a given channel (this corresponds to higher entropy), the lower F. The density of the vibrational states is higher for wider channels (see Fig. V1-4.16).

---

[37] Similar considerations may be performed for a constant pressure (instead of volume). The quantity that then attains the minimum at the equilibrium state is the Gibbs potential G.

Schrödinger, Heisenberg, and Interaction Pictures

The terms **Schrödinger picture**, **Heisenberg picture**, and **interaction picture** are given to three particular frames of reference. The pictures are distinguished from one another by the specific time-dependent unitary transformations involved in defining the different reference frames.

In the Schrödinger picture, state vectors evolve in time under the action of the Hamiltonian according to the Schrödinger equation and postulate 3 on page 11. If a time evolution operator $\hat{\mathbb{U}}(t, t_0)$ and an initial state vector $|\Psi_S(t_0)\rangle$ are known for a given system, then the state vector dynamics in the Schrödinger picture are found via $|\Psi_S(t)\rangle = \hat{\mathbb{U}}(t, t_0)|\Psi_S(t_0)\rangle$. The state vectors are labeled with the subscript S here to identify that the state vectors correspond to the Schrödinger picture. Also in the Schrödinger picture, position and momentum operators have no time dependence. If not explicitly stated otherwise, the state vectors and operators of this *Field Guide* are given in the Schrödinger picture. The Schrödinger picture is the frame of reference on which the transformations to the other two pictures are based.

The Heisenberg picture (page 45) is defined by a unitary transformation operator $\hat{\mathbb{F}}(t) = \hat{\mathbb{U}}^\dagger(t, t_0)$ (see page 42) that is the adjoint of the time evolution operator of the Schrödinger picture. When this unitary transformation is applied to a Schrödinger-picture state vector $|\Psi_S(t)\rangle$, time dependence vanishes: $|\Psi_H\rangle \equiv \hat{\mathbb{U}}^\dagger(t, t_0)|\Psi_S(t)\rangle = |\Psi_S(t_0)\rangle$, where $|\Psi_H\rangle$ is the transformed ket of the Heisenberg picture. The Heisenberg picture is therefore the specific time-dependent reference frame in which the transformed state vectors are constant in time, while operators (such as the position and momentum operators) that have no time dependence in the Schrödinger picture may depend on time in the Heisenberg picture.

The interaction picture (page 46) is used when the Schrödinger-picture Hamiltonian is time dependent. In this picture, operators and state vectors generally evolve in time.

Schrödinger Picture: Expectation Value Dynamics

Position and momentum operators have no explicit time dependence in the Schrödinger picture. Nevertheless, other operators that do have explicit time dependence can be constructed. Let $\hat{A}_S(t)$ be an arbitrary operator in the Schrödinger picture that may have explicit time dependence.

For a given Schrödinger-picture state vector $|\Psi_S(t)\rangle$ evolving under a Hamiltonian $\hat{H}_S(t)$, the expectation value of $\hat{A}_S(t)$ will generally have time dependence that results from both the time dependence of $|\Psi_S(t)\rangle$ and any time dependence in $\hat{A}_S(t)$. This time-dependent expectation value may be calculated as

$$\langle \hat{A}_S(t)\rangle(t) = \langle \Psi_S(t)|\hat{A}_S(t)|\Psi_S(t)\rangle$$

Differentiating the equation above with respect to time produces the following differential equation for the dynamics of expectation values in the Schrödinger picture, noting that $\hat{A}_S$, $\hat{H}_S$ and the expectation values are generally time dependent.

Schrödinger-picture expectation values:

$$\frac{d}{dt}\langle \hat{A}_S\rangle = \frac{1}{i\hbar}\left\langle [\hat{A}_S, \hat{H}_S]\right\rangle + \left\langle \frac{\partial \hat{A}_S}{\partial t}\right\rangle$$

Ehrenfest's equations (or Ehrenfest's theorem) are obtained by replacing $\hat{A}_S(t)$ in the equation above with the position operator $\hat{\mathbf{R}} = (\hat{X}, \hat{Y}, \hat{Z})$, and also with the momentum operator $\hat{\mathbf{P}} = (\hat{P}_x, \hat{P}_y, \hat{P}_z)$. Noting that $\frac{\partial \hat{\mathbf{R}}}{\partial t} = 0$ and $\frac{\partial \hat{\mathbf{P}}}{\partial t} = 0$, and that the expectation value of the gradient of the potential energy operator $V(\hat{\mathbf{R}})$ is $\langle \nabla V(\hat{\mathbf{R}})\rangle \equiv \left(\left\langle \frac{\partial V(\hat{\mathbf{R}})}{\partial \hat{X}}\right\rangle, \left\langle \frac{\partial V(\hat{\mathbf{R}})}{\partial \hat{Y}}\right\rangle, \left\langle \frac{\partial V(\hat{\mathbf{R}})}{\partial \hat{Z}}\right\rangle\right)$, the pair of Ehrenfest's equations can be solved to determine how expectation values of position and momentum evolve for any state of a system.

Ehrenfest's equations (Ehrenfest's theorem):

$$\frac{d}{dt}\langle \hat{\mathbf{R}}\rangle = \frac{1}{m}\langle \hat{\mathbf{P}}\rangle$$

$$\frac{d}{dt}\langle \hat{\mathbf{P}}\rangle = -\langle \nabla V(\hat{\mathbf{R}})\rangle$$

Heisenberg Picture: Operators and Dynamics

The adjoint $\hat{\mathbb{U}}^{\dagger}(t, t_0)$ of the time evolution operator $\hat{\mathbb{U}}(t, t_0)$ defines a unitary transformation that transforms state vectors of the Schrödinger picture into time-independent state vectors within the Heisenberg picture. An arbitrary operator $\hat{A}_S(t)$ in the Schrödinger picture is transformed into the Heisenberg operator

$$\hat{A}_H(t) = \hat{\mathbb{U}}^{\dagger}(t, t_0)\hat{A}_S(t)\hat{\mathbb{U}}(t, t_0)$$

The expectation value of an observable is a physically meaningful quantity and must be the same in any picture, since transforming between pictures is only of mathematical utility for performing calculations. As shown below, the time-dependent expectation value of $\hat{A}_H(t)$ calculated in the Heisenberg picture is equivalent to that of $\hat{A}_S(t)$. In the table, $\hat{H}_S$ and $|\Psi_S(t)\rangle$ are the Schrödinger-picture Hamiltonian and state vector.

Heisenberg Picture Quantities and Dynamics	
$\lvert\Psi_H\rangle$	$\equiv \hat{\mathbb{U}}^{\dagger}(t, t_0)\lvert\Psi_S(t)\rangle = \lvert\Psi_S(t_0)\rangle$
$\hat{A}_H(t)$	$\equiv \hat{\mathbb{U}}^{\dagger}(t, t_0)\hat{A}_S(t)\hat{\mathbb{U}}(t, t_0)$
$\hat{H}_H$	$= \hat{H}_S$, for time-independent H_S
$\hat{H}_H(t)$	$= \hat{H}_S(t)$, for $[\hat{H}_S(t), \hat{H}_S(t')] = 0$
$\langle\hat{A}_H(t)\rangle(t)$	$= \langle\Psi_H\lvert\hat{A}_H(t)\rvert\Psi_H\rangle$
	$= \langle\Psi_S(t_0)\lvert\hat{\mathbb{U}}^{\dagger}(t, t_0)\hat{A}_S(t)\hat{\mathbb{U}}(t, t_0)\rvert\Psi_S(t_0)\rangle$
	$= \langle\Psi_S(t)\lvert\hat{A}_S(t)\rvert\Psi_S(t)\rangle = \langle\hat{A}_S(t)\rangle(t)$
$i\hbar\frac{d}{dt}\hat{A}_H(t)$	$= [\hat{A}_H(t), \hat{H}_H(t)]$
	$+ i\hbar\hat{\mathbb{U}}^{\dagger}(t, t_0)\left(\frac{d}{dt}\hat{A}_S(t)\right)\hat{\mathbb{U}}(t, t_0)$

The effective Hamiltonian of the Heisenberg picture is $\hat{H}_E = 0$, which is not identical to the transformed Hamiltonian $\hat{H}_H(t)$ (see page 42). Since $\hat{H}_E = 0$ in the Heisenberg picture, the effective Schrödinger equation $i\hbar\frac{\partial}{\partial t}|\Psi_H\rangle = 0$ is solved by $|\Psi_H\rangle = |\Psi_S(t_0)\rangle$. In the Heisenberg picture, only operators evolve in time, satisfying the differential equation in the last line of the table above. These operators are then used with $|\Psi_H\rangle$ in calculations of physically meaningful quantities.

Interaction Picture

The interaction picture is obtained with a unitary transformation of the state vectors and operators of the Schrödinger picture. This transformation removes some of the time dependence of the Schrödinger-picture state vectors, while also altering the time dependence of operators. The interaction picture is typically used with a time-dependent Schrödinger-picture Hamiltonian $\hat{H}_S(t) = \hat{H}_0 + \hat{W}(t)$, where the eigenstates of the time-independent term $\hat{H}_0$ are known, and $\hat{W}(t)$ is a time-dependent **perturbation**. $\hat{W}(t)$ can induce time-dependent dynamics and **transitions** between the eigenstates of $\hat{H}_0$, which are not stationary states of the system. These dynamics are often of primary interest when the interaction picture is used.

To transform into the interaction picture, an evolution operator $\hat{\mathbb{U}}_0(t, t_0) \equiv e^{-\frac{i}{\hbar}(t-t_0)\hat{H}_0}$ is associated with $\hat{H}_0$. Note that $\hat{\mathbb{U}}_0$ is not the time evolution operator associated with $\hat{H}_S(t)$. If $|\Psi_S(t)\rangle$ is a state vector and $\hat{A}_S(t)$ is an arbitrary operator, both specified in the Schrödinger picture, then the transformed state vector and arbitrary operator expressed in the interaction picture are

$$|\Psi_I(t)\rangle \equiv \hat{\mathbb{U}}_0^\dagger(t, t_0)|\Psi_S(t)\rangle$$
$$\hat{A}_I(t) \equiv \hat{\mathbb{U}}_0^\dagger(t, t_0)\hat{A}_S(t)\hat{\mathbb{U}}_0(t, t_0)$$

The effective Schrödinger equation in the interaction picture is

$$i\hbar\frac{\partial}{\partial t}|\Psi_I(t)\rangle = \hat{H}_E(t)|\Psi_I(t)\rangle$$

where $\hat{H}_E(t)$ is an effective Hamiltonian given by

$$\hat{H}_E(t) = \hat{\mathbb{U}}_0^\dagger(t, t_0)\hat{W}(t)\hat{\mathbb{U}}_0(t, t_0)$$

and is not identical to the transformed Hamiltonian $\hat{H}_I(t) \equiv \hat{\mathbb{U}}_0^\dagger(t, t_0)\hat{H}_S(t)\hat{\mathbb{U}}_0(t, t_0)$ (see the boxes at the bottom of pages 42 and 45). In the interaction picture, calculation of state vector dynamics that are due entirely to $\hat{W}(t)$ are emphasized, since the dynamics due to $\hat{H}_0$ are removed in the transformation. If $\hat{W}(t) = 0$, then the interaction picture reduces to the Heisenberg picture; in that case, $\hat{H}_E(t) = 0$ and $|\Psi_I(t)\rangle = |\Psi_S(t_0)\rangle$.

Exactly Solvable Problems in One Dimension

There are a few common **exactly solvable problems** consisting of a particle of mass m in a 1D time-independent potential well $V(x)$. A "problem" in this context means the identification of a specific state space and a Hamiltonian. A "solution" usually involves determining the energy eigenvalues and energy eigenstates, the relationships between these quantities, and the expression of energy eigenstates in representations that are meaningful for the given problem. Exactly solvable problems are ones for which solutions can be found analytically and without approximation methods.

For each of the exactly solvable 1D problems described on the following pages, the Hamiltonian has the form

$$\hat{H} = \frac{1}{2m}\hat{P}_x^2 + V(\hat{X})$$

In the 1D position representation, $\hat{H}$ takes the form

$$H_{\{x\}} = -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + V(x)$$

If a constant energy term is added to $\hat{H}$, all energy eigenvalues will be shifted by that amount. However, the physical dynamics of the system depend only on differences between energy eigenvalues, so the dynamics remain unchanged. Energy is therefore measured and specified with respect to some implicit or specified reference value for every problem.

The examples on the following pages utilize the position representation. The problems and solutions include

- The potential $V(x)$, which defines the problem
- The energy eigenvalue equation, which defines the notation used to specify energy eigenvalues, quantum numbers, and the energy eigenkets and eigenfunctions
- Solutions to the energy eigenvalue equation
- Explanatory or illustrative notes, plots, and special features about the specific problem

Free Particle and Delta Function Potential Well

Free particle:

$$V(x) = 0$$

$$H_{\{x\}}\, \varphi_{p'}(x) = E_{p'}\, \varphi_{p'}(x)$$

Solutions:

$$E_{p'} = \frac{p'^2}{2m}; \quad \left\{ p' \in \mathbb{R} \,|\, p' : \left[\frac{\mathrm{kg} \cdot \mathrm{m}}{\mathrm{s}}\right] \right\}$$

$$\varphi_{p'}(x) = \frac{1}{\sqrt{2\pi\hbar}} e^{ixp'/\hbar}$$

The functions $\varphi_{p'}(x)$ are **plane waves**, each indexed by a precise particle momentum p'. These solutions are non-degenerate eigenkets of the momentum operator, expressed in the position representation; they are non-normalizable and are not physically realizable wavefunctions. In the momentum representation, $\varphi_{p'}(x)$ transforms (page 24) into a Dirac delta function $\tilde{\varphi}_{p'}(p) = \delta(p - p')$.

For any $p' \neq 0$, $\varphi_{p'}(x)$ and $\varphi_{-p'}(x)$ have the same energy eigenvalue $E_{p'}$, so that for scalars c_+ and c_-, the superposition

$$\psi(x) = c_+ \varphi_{p'}(x) + c_- \varphi_{-p'}(x)$$

is also an energy eigenfunction with eigenvalue $E_{p'}$.

Dirac delta function potential well:

$$V(x) = -\alpha\delta(x); \qquad \{\alpha \in \mathbb{R}^+ \,|\, \alpha : [\mathrm{J} \cdot \mathrm{m}]\}$$

$$H_{\{x\}}\, \varphi_\alpha(x) = E_\alpha\, \varphi_\alpha(x)$$

Solutions:

$$E_\alpha = -\frac{m\alpha^2}{2\hbar^2}$$

$$\varphi_\alpha(x) = \sqrt{m\alpha/\hbar^2}\, e^{-m\alpha|x|/\hbar^2}$$

$\varphi_\alpha(x)$ is the wavefunction for the ground state, which is also the system's only bound state (i.e., localized about $x = 0$).

Chapter 36

Analytical Solid Geometry

36.1 INTRODUCTION

In 1637, Rene Descartes[*] represented geometrical figures (configurations) by equations and vice versa. Analytical Geometry involves algebraic or analytic methods in geometry. Analytical geometry in three dimensions also known as Analytical solid[**] geometry or solid analytical geometry, studies geometrical objects in space involving three dimensions, which is an extension of coordinate geometry in plane (two dimensions).

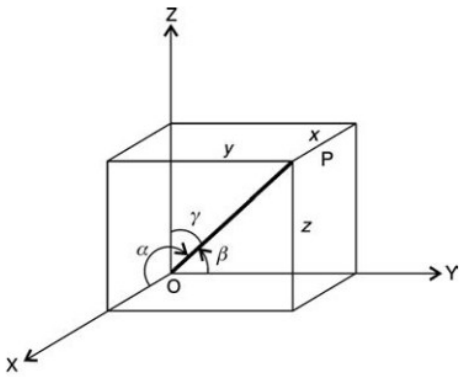

Fig. 36.1

Rectangular Cartesian Coordinates

The position (location) of a point in space can be determined in terms of its perpendicular distances (known as rectangular cartesian coordinates or simply *rectangular coordinates*) from three mutually perpendicular planes (known as **coordinate planes**). The lines of intersection of these three coordinate planes are known as *coordinate axes* and their point of intersection the *origin*.

The three axes called x-axis, y-axis and z-axis are marked positive on one side of the origin. The positive sides of axes OX, OY, OZ form a right handed system. The coordinate planes divide entire space into eight parts called *octants*. Thus a point P with coordinates x, y, z is denoted as $P(x, y, z)$. Here x, y, z are respectively the perpendicular distances of P from the YZ, ZX and XY planes. Note that a line perpendicular to a plane is perpendicular to every line in the plane.

Distance between two points $P_1(x_1, y_1, z_1)$ and $P_2(x_2, y_2, z_2)$ is $\sqrt{(x_2-x_1)^2+(y_2-y_1)^2+(z_2-z_1)^2}$. *Distance* from origin $O(0, 0, 0)$ is $\sqrt{x_2^2 + y_2^2 + z_2^2}$. Divisions of the line joining two points P_1, P_2: The coordinates of $Q(x, y, z)$, the point on P_1P_2 dividing the line segment P_1P_2 in the ratio $m : n$ are $\left(\frac{nx_1+mx_2}{m+n}, \frac{ny_1+my_2}{m+n}, \frac{nz_1+mz_2}{m+n}\right)$ or putting k for $\frac{m}{n}$, $\left(\frac{x_1+kx_2}{1+k}, \frac{y_1+ky_2}{1+k}, \frac{z_1+kz_2}{1+k}\right); k \neq -1$. Coordinates of mid point are $\left(\frac{x_1+x_2}{2}, \frac{y_1+y_2}{2}, \frac{z_1+z_2}{2}\right)$.

---

[*] Rene Descartes (1596–1650) French philosopher and mathematician, latinized name for Renatus Cartesius.

[**] *Not* used in the sense of "non-hollowness". By a sphere or cylinder we mean a hollow sphere or cylinder.

Direction of a line: A line in space is said to be directed if it is taken in a definite sense from one extreme (end) to the other (end).

Angle between Two Lines

Two straight lines in space may or may not intersect. If they intersect, they form a plane and are said to be coplanar. If they do not intersect, they are called *skew lines*.

Angle between two intersecting (coplanar) lines is the angle between their positive directions.

Angle between two non-intersecting (non-coplanar or skew) lines is the angle between two intersecting lines whose directions are same as those of given two lines.

36.2 DIRECTION COSINES AND DIRECTION RATIOS

Direction Cosines of a Line

Let L be a directed line OP from the origin $O(0, 0, 0)$ to a point $P(x, y, z)$ and of length r (Fig. 36.2). Suppose OP makes angles α, β, γ with the positive directions of the coordinate axes. Then α, β, γ are known as the *direction angles* of L. The cosines of these angles $\cos\alpha$, $\cos\beta$, $\cos\gamma$ are known as the *direction cosines* of the line $L(OP)$ and are in general denoted by l, m, n respectively.

Thus

$$l = \cos\alpha = \frac{x}{r}, \quad m = \cos\beta = \frac{y}{r}, \quad n = \cos\gamma = \frac{z}{r}.$$

where $\qquad r = \sqrt{x^2 + y^2 + z^2}.$

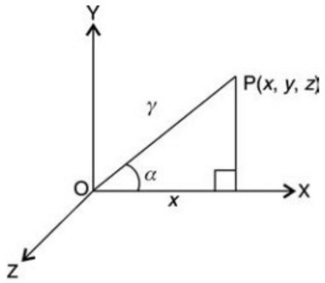

Fig. 36.2

Corollary 1: Lagrange's identity: $l^2+m^2+n^2 = 1$ i.e., sum of the squares of the direction cosines of any line is one, since $l^2 + m^2 + n^2 = \cos^2\alpha + \cos^2\beta + \cos^2\gamma = \frac{x^2}{r^2} + \frac{y^2}{r^2} + \frac{z^2}{r^2} = 1$.

Corollary 2: Direction cosines of the coordinate axes *OX*, *OY*, *OZ* are (1, 0, 0), (0, 1, 0), (0, 0, 1) respectively.

Corollary 3: The coordinates of P are (lr, mr, nr) where l, m, n are the direction cosines of OP and r is the length of OP.

Note: Direction cosines is abbreviated as DC's.

Direction Ratios

(abbreviated as DR's:) of a line L are any set of three numbers a, b, c which are proportional to l, m, n the DC's of the line L. DR's are also known as direction numbers of L. Thus $\frac{l}{a} = \frac{m}{b} = \frac{n}{c} = k$ (proportionality constant) or $l = ak, m = bk, n = ck$. Since $l^2 + m^2 + n^2 = 1$ or $(ak)^2 + (bk)^2 + (ck)^2 = 1$ or $k = \frac{\pm 1}{\sqrt{a^2+b^2+c^2}}$. Then the actual direction cosines are $\cos\alpha = l = ak = \pm\frac{a}{\sqrt{a^2+b^2+c^2}}$, $\cos\beta = m = bk = \pm\frac{b}{\sqrt{a^2+b^2+c^2}}$, $\cos\gamma = m = ck = \pm\frac{c}{\sqrt{a^2+b^2+c^2}}$ with $a^2 + b^2 + c^2 \neq 0$. Here +ve sign corresponds to positive direction and −ve sign to negative direction.

Note 1: Sum of the squares of DR's need not be one.

Note 2: Direction of line is $[a, b, c]$ where a, b, c are DR's.

Direction cosines of the line joining two points $P_1(x_1, y_1, z_1)$ and $P_2(x_2, y_2, z_2)$:

$$l = \cos\alpha = \frac{PQ}{r} = \frac{LM}{r} = \frac{OM - OL}{r} = \frac{x_2 - x_1}{r}.$$

Similarly, $m = \cos\beta = \frac{y_2 - y_1}{r}$ and $n = \cos\gamma = \frac{z^2 - z_1}{r}$. Then the DR's of P_1P_2 are $x_2 - x_1$, $y_2 - y_1$, $z_2 - z_1$

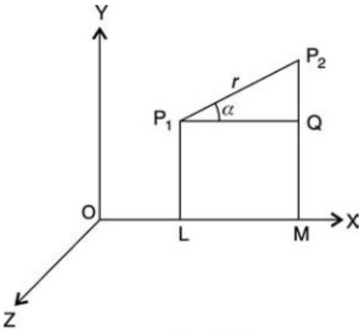

Fig. 36.3

Projections

Projection of a point P on line L is Q, the foot of the perpendicular from P to L.

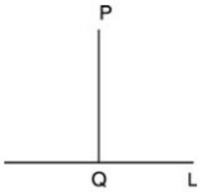

Fig. 36.4

Projection of line segment

P_1P_2 on a line L is the line segment MN where M and N are the feet of the perpendiculars from P and Q on to L. If θ is the angle between P_1P_2 and line L, then projection of P_1P_2 on $L = MN = PR = P_1P_2\cos\theta$. Projection of line segment P_1P_2 on line L with (whose) DC's l, m, n is

$$l(x_2 - x_1) + m(y_2 - y_1) + n(z_2 - z_1)$$

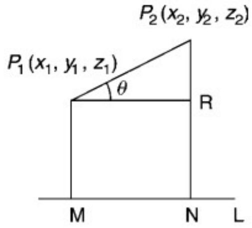

Fig. 36.5

Angle between Two Lines

Let θ be the angle between the two lines OP_1 and OP_2. Let $OP_1 = r_1, OP_2 = r_2$. Let l_1, m_1, n_1 be DC's of OP_1 and l_2, m_2, n_2 are DC's of OP_2. Then the coordinates of P_1 are l_1r_1, m_1r_1, n_1r_1 and of P_2 and l_2r_2, m_2r_2, n_2r_2.

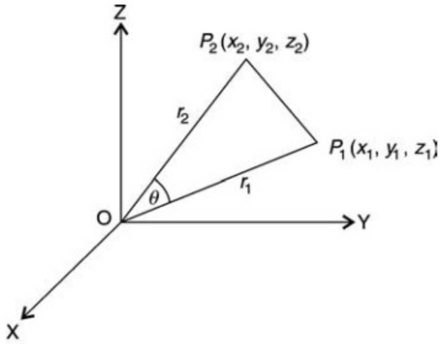

Fig. 36.6

From ΔOP_1P_2, we have

$$P_1P_2^2 = OP_1^2 + OP_2^2 - 2OP_1 \cdot OP_2 \cdot \cos\theta$$

$$(l_2r_2 - l_1r_1)^2 + (m_2r_2 - m_1r_1)^2 + (n_2r_2 - n_1r_1)^2$$
$$= \left[(l_1r_1)^2 + (m_1r_1)^2 + (n_1r_1)^2\right]$$
$$+ \left[(l_2r_2)^2 + (m_2r_2)^2 + (n_2r_2)^2\right] - 2 \cdot r_1r_2\cos\theta.$$

Using $l_1^2 + m_1^2 + n_1^2 = 1$ and $l_2^2 + m_2^2 + n_2^2 = 1$,

$$r_1^2 + r_2^2 - 2r_1r_2(l_1l_2 + m_1m_2 + n_1n_2)$$
$$= r_1^2 + r_2^2 - 2r_1r_2\cos\theta.$$

Then $\boxed{\cos\theta = l_1l_2 + m_1m_2 + n_1n_2}$

Corollary 1:

$$\sin^2\theta = 1 - \cos^2\theta = 1 - (l_1l_2 + m_1m_2 + n_1n_2)^2$$
$$= (l_1^2 + m_1^2 + n_1^2)(l_2^2 + m_2^2 + n_2^2)$$
$$-(l_1l_2 + m_1m_2 + n_1n_2)^2$$
$$= (l_1m_2 - m_1l_2)^2 + (m_1n_2 - n_1m_2)^2$$
$$+(n_1l_2 - n_2l_1)^2$$

using the Lagrange's identity. Then

$$(l_1^2+m_1^2+n_1^2)(l_2^2+m_2^2+n_2^2)-(l_1l_2+m_1m_2+n_1n_2)^2)$$
$$= (l_1m_2-l_2m_1)^2+(m_1n_2-m_2n_1)^2+(n_1l_2-n_2l_1)^2.$$

Thus $\sin\theta = \sqrt{\sum(l_1m_2 - m_1l_2)^2}$

Corollary 2: $\tan\theta = \frac{\sin\theta}{\cos\theta} = \frac{\sqrt{\sum(l_1m_2-m_1l_2)^2}}{l_1l_2+m_1m_2+n_1n_2}$.

Corollary 3: If a_1, b_1, c_1 and a_2, b_2, c_2 are DR's of OP_1 and OP_2

Then $l_1 = \frac{a_1}{\sqrt{a_1^2+b_1^2+c_1^2}}$, $m_1 = \frac{b_1}{\sqrt{a_1^2+b_1^2+c_1^2}}$, $n_1 = \frac{c_1}{\sqrt{a_1^2+b_1^2+c_1^2}}$ etc.

Then $\cos\theta = \frac{a_1a_2+b_1b_2+c_1c_2}{\sqrt{a_1^2+b_1^2+c_1^2}\sqrt{a_2^2+b_2^2+c_2^2}}$,

$$\sin\theta = \frac{\sqrt{(a_1b_2-a_2b_1)^2+(b_1c_2-b_2c_1)^2+(c_1a_2-c_2a_1)^2}}{\sqrt{a_1^2+b_1^2+c_1^2}\sqrt{a_2^2+b_2^2+c_2^2}}.$$

Corollary: Condition for perpendicularity:

The two lines are perpendicular if $\theta = 90°$. Then

$$\cos\theta = \cos 90 = 0$$

Thus $\boxed{l_1l_2 + m_1m_2 + n_1n_2 = 0}$

or $\boxed{a_1a_2 + b_1b_2 + c_1c_2 = 0}$

Corollary: Condition for parallelism:

If the two lines are parallel then $\theta = 0$. So $\sin\theta = 0$.

$$(l_1m_2 - m_1l_2)^2 + (m_1n_2 - m_2n_1)^2 + (n_1l_2 - n_2l_1)^2 = 0$$

or $$\frac{l_1}{l_2} = \frac{m_1}{m_2} = \frac{n_1}{n_2} = \frac{\sqrt{l_1^2+m_1^2+n_1^2}}{\sqrt{l_2^2+m_2^2+n_2^2}} = \frac{1}{1}.$$

Thus $\boxed{l_1 = l_2, \quad m_1 = m_2, \quad n_1 = n_2}$

or $$\frac{a_1}{a_2} = \frac{b_1}{b_2} = \frac{c_1}{c_2}.$$

WORKED OUT EXAMPLES

Example 1: Find the angle between the lines $A(-3, 2, 4)$, $B(2, 5, -2)$ and $C(1, -2, 2)$, $D(4, 2, 3)$.

Solution: DR's of AB: $2 - (-3), 5 - 2, -2 - 4 = 5, 3, -6$
DR's of CD: 3, 4, 1. Then DC's of AB are $l_1 = \cos\alpha_1 = \frac{5}{\sqrt{5^2+3^2+6^2}} = \frac{5}{\sqrt{25+9+36}} = \frac{5}{\sqrt{70}}$ and $m_1 = \cos\beta_1 = \frac{3}{70}$, $n_1 = \cos\gamma_1 = \frac{-6}{\sqrt{70}}$. Similarly, $l_2 = \cos\alpha_2 = \frac{3}{\sqrt{3^2+4^2+1^2}} = \frac{3}{\sqrt{9+16+1}} = \frac{3}{\sqrt{26}}$, and $m_2 = \cos\beta_2 = \frac{4}{\sqrt{26}}$, $n_2 = \cos\gamma_2 = \frac{1}{\sqrt{26}}$. Now

$$\begin{aligned}\cos\theta &= \cos\alpha_1\cdot\cos\alpha_2 + \cos\beta_1\cdot\cos\beta_2 + \cos\gamma_1\cdot\cos\gamma_2\\ &= l_1l_2 + m_1m_2 + n_1n_2\\ \cos\theta &= \frac{5}{\sqrt{70}}\cdot\frac{3}{\sqrt{26}} + \frac{3}{\sqrt{70}}\cdot\frac{4}{\sqrt{26}} - \frac{6}{\sqrt{70}}\cdot\frac{1}{\sqrt{26}}\\ &= 0.49225\end{aligned}$$

$$\therefore\quad \theta = \cos^{-1}(0.49225) = 60°30.7'$$

Example 2: Find the DC's of the line that is $\perp^r$ to each of the two lines whose directions are $[2, -1, 2]$ and $[3, 0, 1]$.

Solution: Let $[a, b, c]$ be the direction of the line. Since this line is $\perp^r$ to the line with direction $[2, -1, 2]$, by orthogonality

$$2a - b + 2c = 0$$

Similarly, direction $[a, b, c]$ is $\perp^r$ to direction $[3, 0, 1]$. So

$$3a + 0 + c = 0.$$

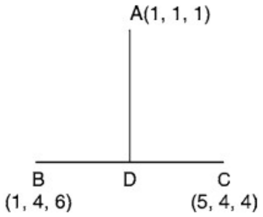
Solving $c = -3a$, $b = -4a$ or
direction $[a, b, c] = [a, -4a, -3a] = [1, -4, -3]$.
$\therefore$ DC's of the line: $\frac{1}{\sqrt{1^2+4^2+3^2}} = \frac{1}{\sqrt{26}}, \frac{-4}{\sqrt{26}}, \frac{-3}{\sqrt{26}}$.

Example 3: Show that the points $A(1, 0, -2)$, $B(3, -1, 1)$ and $C(7, -3, 7)$ are collinear.

Solution: DR's of AB: $[2, -1, 3]$, DR's of AC: $[6, -3, 9]$, DR's of BC: $[4, -2, 6]$. Thus DR's of AB, AC, BC are same. Hence A, B, C are collinear.

Example 4: Find the coordinates of the foot of the perpendicular from $A(1, 1, 1)$ on the line joining $B(1, 4, 6)$ and $C(5, 4, 4)$.

Solution: Suppose D divides BC in the ratio $k : 1$. Then the coordinates of D are $\left(\frac{5k+1}{k+1}, \frac{4k+4}{k+1}, \frac{4k+6}{k+1}\right)$. DR's of AD: $\frac{4k}{k+1}, 3, \frac{3K+5}{k+1}$, DR's of BC: $4, 0, -2$ AD is $\perp^r$ BC: $16k - 6k - 10 = 0$, or $k = 1$.



Coordinates of the foot of perpendicular are (3, 4, 5).

Example 5: Show that the points $A(1, 0, 2)$, $B(3, -1, 3)$, $C(2, 2, 2)$, $D(0, 3, 1)$ are the vertices of a parallelogram.

Fig. 36.7

Solution: DR's of AB are $[3 - 1, -1 - 0, 3 - 2] = [2, -1, 1]$. Similarly, DR's of BC are $[-1, 3, -1]$, of $CD[-2, 1, -1]$ of $DA[-1, 3, -1]$. Since DR's of AB and CD are same, they are parallel. Similarly BC and DA are parallel since DR's are same. Further AB is not $\perp^r$ to AD because

$$2(+1) + (-1)(-3) + 1(+1) = 6 \neq 0$$

Similarly, AD is not $\perp^r$ to BC because

$$2(-1) + (-1)3 + 1(-1) = -6 \neq 0.$$

Hence $ABCD$ is a parallelogram.

EXERCISE

1. Show that the points $A(7, 0, 10)$, $B(6, -1, 6)$, $C(9, -4, 6)$ form an isoscales right angled triangle.

   Hint: $AB^2 = BC^2 = 18$, $CA^2 = 36$, $AB^2 + BC^2 = CA^2$

2. Prove that the points $A(3, -1, 1)$, $B(5, -4, 2)$, $C(11, -13, 5)$ are collinear.

   Hint 1: $AB^2 = 14$, $BC^2 = 126$, $CA^2 = 224$, $AB + BC = 4\sqrt{14} = CA$

   Hint 2: DR's of $AB = 2, -3, 1$; BC: $6, -9, 3$; $AB \|^l$ to BC

3. Determine the internal angles of the triangle ABC where $A(2, 3, 5)$, $B(-1, 3, 2)$, $C(3, 5, -2)$.

   Hint: $AB^2 = 18, BC^2 = 36, AC^2 = 54$. DC's AB: $-\frac{1}{\sqrt{2}}, 0, -\frac{1}{\sqrt{2}}$; BC: $\frac{2}{3}, \frac{1}{3}, \frac{-2}{3}$; AC: $\frac{1}{3\sqrt{6}}, \frac{2}{3\sqrt{6}}, \frac{-7}{3\sqrt{6}}$.

Ans. $\cos A = \frac{1}{\sqrt{3}}$, $\cos B = 0$ i.e., $B = 90^\circ$, $\cos C = \frac{\sqrt{6}}{3}$.

4. Show that the foot of the perpendicular from $A(0, 9, 6)$ on the line joining $B(1, 2, 3)$ and $C(7, -2, 5)$ is $D(-2, 4, 2)$.

   Hint: D divides BC in $k : 1$, $D\left(\frac{7k+1}{k+1}, \frac{-2k+2}{k+1}, \frac{5k+3}{k+1}\right)$. DR's AD: $(7k + 1, -11k - 7, -k - 3)$, DR's BC: $6, -4, 2$. $AD \perp^r BC$: $k = -\frac{1}{3}$.

5. Find the condition that three lines with DC's $l_1, m_1, n_1; l_2, m_2, n_2; l_3, m_3, n_3$ are concurrent.

   Hint: Line with DC's l, m, n through point of concurrency will be $\perp^r$ to all three lines, $ll_i + mm_i + nn_i = 0$, $i = 1, 2, 3$.

Ans.
$$\begin{vmatrix} l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \\ l_3 & m_3 & n_3 \end{vmatrix} = 0$$

6. Show that $\cos^2\alpha + \cos^2\beta + \cos^2\gamma + \cos^2\delta = \frac{4}{3}$ where $\alpha, \beta, \gamma, \delta$ are the angles which a line makes with the four diagonals of a cube.

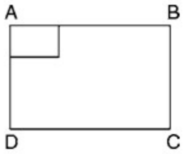
   Hint: DC's of four diagonals are (k, k, k), $(-k, k, k)$, $(k, -k, k)$, $(k, k, -k)$ where $k = \frac{1}{\sqrt{3}}$; l, m, n are DC's of line. $\cos\alpha = l.k. + mk + nk$, $\cos\beta = (-l + m + n)k$, $\cos\gamma = (l - m + n)k$, $\cos\delta = (l + m - n)k$.

7. Show that the points $A(-1, 1, 3)$, $B(1, -2, 4)$, $C(4, -1, 1)$ are vertices of a right triangle.

   Hint: DR's $AB : [2, -3, 1]$, $BC : [3, 1, -3]$, $CA : [5, -2, -2]$. AB is $\perp^r$ BC.

8. Prove that $A(3, 1, -2)$, $B(3, 0, 1)$, $C(5, 3, 2)$, $D(5, 4, -1)$ form a rectangle.

   Hint: DR's: AB: $[0, -1, 3]$; AC: $[2, 2, 4]$, $CD[0, 1, -3]$; $AD[2, 3, 1]$; $BC[2, 3, 1]$; $AB \| CD$, $AD \| BC$, $AD \perp AB: 0 - 3 + 3 = 0$, $BC \perp DC: 0 + 3 - 3 = 0$.



9. Find the interior angles of the triangle

   $A(3, -1, 4)$, $B(1, 2, -4)$, $C(-3, 2, 1)$.

   Hint: DC's of AB: $(-2, 3, -8)k_1$, BC: $(-4, 0, 5)k_2$, AC: $(-6, 3, -3)k_3$ where $k_1 = \frac{1}{\sqrt{77}}$, $k_2 = \frac{1}{\sqrt{41}}$, $k_3 = \frac{1}{\sqrt{54}}$.

Ans. $\cos A = \frac{15}{\sqrt{462}}$, $\cos B = \frac{32}{\sqrt{3157}}$, $\cos C = \frac{3}{\sqrt{246}}$.

10. Determine the DC's of a line $\perp^r$ to a triangle formed by $A(2, 3, 1)$, $B(6, -3, 2)$, $C(4, 0, 3)$.

Ans. $(3, 2, 0)k$ where $k = \frac{1}{\sqrt{13}}$.

   Hint: DR: AB: $[4, -6, 1]$, BC: $[-2, 3, 1]$, CA: $[2, -3, 2]$. $[a, b, c]$ of $\perp^r$ line: $4a - 6b + c = 0$, $-2a + 3b + c = 0$, $2a - 3b + 2c = 0$.

36.3 THE PLANE

Surface is the locus of a point moving in space satisfying a single condition.

Example: Surface of a sphere is the locus of a point that moves at a constant distance from a fixed point.

Surfaces are either plane or curved. Equation of the locus of a point is the analytical expression of the given condition(s) in terms of the coordinates of the point.

Exceptional cases: Equations may have locus other than a surface. Examples: (i) $x^2 + y^2 = 0$ is z-axis (ii) $x^2 + y^2 + z^2 = 0$ is origin (iii) $y^2 + 4 = 0$ has no locus.

Plane is a surface such that the straight line PQ, joining any two points P and Q on the plane, lies completely on the plane.

General equation of first degree in x, y, z is of the form

$$Ax + By + Cz + D = 0$$

Here A, B, C, D are given real numbers and A, B, C are not all zero (i.e., $A^2 + B^2 + C^2 \neq 0$)

Book Work: Show that every equation of the first degree in x, y, z represents a plane.

Proof: Let

$$Ax + By + Cz + D = 0 \tag{1}$$

be the equation of first degree in x, y, z with the condition that not all A, B, C are zero (i.e., $A^2 + B^2 + C^2 \neq 0$). Let $P(x_1, y_1, z_1)$ and $Q(x_2, y_2, z_2)$ be any two points on the surface represented by (1). Then

$$Ax_1 + By_1 + Cz_1 + D_1 = 0 \tag{2}$$

$$Ax_2 + By_2 + Cz_2 + D_2 = 0 \tag{3}$$

Multiplying (3) by k and adding to (2), we get

$$A(x_1 + kx_2) + B(y_1 + ky_2) + C(z_1 + kz_2) + D(1 + k) = 0 \tag{4}$$

Assuming that $1 + k \neq 0$, divide (4) by $(1 + k)$.

$$A\left(\frac{x_1 + kx_2}{1 + k}\right) + B\left(\frac{y_1 + ky_2}{1 + k}\right) + C\left(\frac{z_1 + kz_2}{1 + k}\right) + D = 0$$

i.e., the point $R\left(\frac{x_1+kx_2}{1+k}, \frac{y_1+ky_2}{1+k}, \frac{z_1+kz_2}{1+k}\right)$ which is point dividing the line PQ in the ratio $k : 1$, also lies on the surface (1). Thus any point on the line joining P and Q lies on the surface i.e., line PQ completely lies on the surface. Therefore the surface by definition must be a plane.

General form of the equation of a plane is

$$Ax + By + Cz + D = 0$$

Special cases:

(i) Equation of plane passing through origin is

$$Ax + By + Cz = 0 \tag{5}$$

(ii) Equations of the coordinate planes XOY, YOZ and ZOX are respectively $z = 0, x = 0$ and y=0

(iii) $Ax + By + D = 0$ plane $\perp^r$ to xy-plane
$Ax + Cz + D = 0$ plane $\perp^r$ to xz-plane
$Ay + Cz + D = 0$ plane $\perp^r$ to yz-plane.

Similarly, $Ax + D = 0$ is $\|^l$ to yz-plane, $By + D = 0$ is $\|^l$ to zx-plane, $cz + D = 0$ is $\|^l$ to xy-plane.

One point form

Equation of a plane through a fixed point $P_1(x_1, y_1, z_1)$ and whose normal CD has DC's proportional to (A, B, C): For any point $P(x, y, z)$ on the given plane, the DR's of the line P_1P are $(x - x_1, y - y_1, z - z_1)$. Since a line perpendicular to a plane is perpendicular to every line in the plane, so ML is perpendicular to P_1, P. Thus

$$A(x - x_1) + B(y - y_1) + C(z - z_1) = 0 \qquad (6)$$

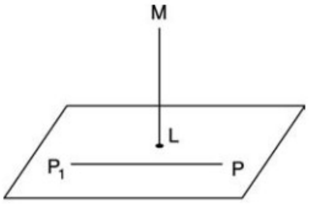


Fig. 36.8

Note 1: Rewriting (6), we get the general form of plane

$$Ax + By + Cz + D = 0 \qquad (1)$$

where $D = -ax_1 - by_1 - cz_1$

Note 2: The real numbers A, B, C which are the coefficients of x, y, z respectively in (1) are proportional to DC's of the normal ot the plane (1).

Note 3: Equation of a plane parallel to plane (1) is

$$Ax + By + Cz + D^* = 0 \qquad (7)$$

x-intercept of a plane is the point where the plane cuts the x-axis. This is obtained by putting $y = 0$, $z = 0$. Similarly, y-, z-intercepts. Traces of a plane are the lines of intersection of plane with coordinate axis.

Example: xy-trace is obtained by putting $z = 0$ in equation of plane.

Intercept form

Suppose $P(a, 0, 0)$, $Q(0, b, 0)$, $R(0, 0, c)$ are the x-, y-, z-intercepts of the plane. Then P, Q, R lies on the plane. From (1)

$$Aa + 0 + 0 + D = 0$$

or
$$A = -\frac{D}{a}.$$

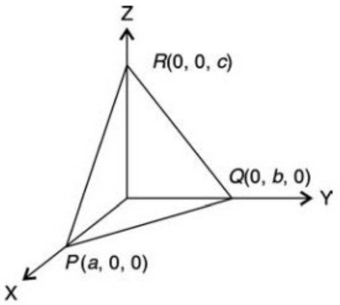

Fig. 36.9

similarly, $0 + bB + 0 + D = 0$ or $B = -\frac{D}{b}$ and $C = -\frac{D}{c}$.

Eliminating A, B, C the equation of the plane in the intercept form is

$$-\frac{D}{a}x - \frac{D}{b} - \frac{D}{c}z + D = 0$$

or
$$\frac{x}{a} + \frac{y}{b} + \frac{z}{c} = 1 \qquad (8)$$

Normal form

Let $P(x, y, z)$ be any point on the plane. Let ON be the perpendicular from origin O to the given plane. Let $ON = p$. (i.e., length of the perpendicular ON is p). Suppose l, m, n are the DC's of ON. Now ON is perpendicular to PN. Projection of OP on ON is ON itself i.e., p.

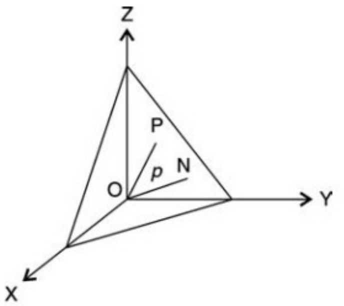

Fig. 36.10

Also the projection OP joining origin (0, 0, 0) to $P(x, y, z)$ on the line ON with DC's l, m, n is

$$l(x-0)+m(y-0)+n(z-0)$$

or
$$lx+my+nz \tag{9}$$

Equating the two projection values from (8) & (9)

$$lx+my+nz=p \tag{10}$$

Note 1: p is always positive, since p is the perpendicular distance from origin to the plane.

Note 2: Reduction from general form.

Transpose constant term to R.H.S. and make it positive (if necessary by multiplying throughout by -1). Then divide throughout by $\pm\sqrt{A^2+B^2+C^2}$. Thus the general form $Ax+By+Cz+D=0$ takes the following normal form

$$\frac{Ax}{\pm\sqrt{A^2+B^2+C^2}}+\frac{By}{\pm\sqrt{A^2+B^2+C^2}}+\frac{Cz}{\pm\sqrt{A^2+B^2+C^2}}$$
$$=\frac{-D}{\pm\sqrt{A^2+B^2+C^2}} \tag{11}$$

The sign before the radical is so chosen to make the R.H.S. in (11) positive.

Three point form

Equation of a plane passing through three given points $P_1(x_1, y_1, z_1)$, $P_2(x_2, y_2, z_2)$, $P_3(x_3, y_3, z_3)$:

Since the three points P_1, P_2, P_3 lie on the plane

$$Ax+By+Cz+D=0 \tag{1}$$

we have
$$Ax_1+By_1+Cz_1+D=0 \tag{12}$$
$$Ax_2+By_2+Cz_2+D=0 \tag{13}$$
$$Ax_3+By_3+Cz_3+D=0 \tag{14}$$

Eliminating A, B, C, D from (1), (12), (13), (14) (i.e., a non trivial solution A, B, C, D for the homogeneous system of 4 equations exist if the determinant coefficient is zero)

$$\begin{vmatrix} x & y & z & 1 \\ x_1 & y_1 & z_1 & 1 \\ x_2 & y_2 & z_2 & 1 \\ x_3 & y_3 & z_3 & 1 \end{vmatrix}=0 \tag{15}$$

Equation (15) is the required equation of the plane through the 3 points P_1, P_2, P_3.

Corollary 1: Coplanarity of four given points: The four points $P_1(x_1, y_1, z_1)$, $P_2(x_2, y_2, z_2)$, $P_3(x_3, y_3, z_3)$, $P_4(x_4, y_4, z_4)$ are coplanar (lie in a plane) if

$$\begin{vmatrix} x_1 & y_1 & z_1 & 1 \\ x_2 & y_2 & z_2 & 1 \\ x_3 & y_3 & z_3 & 1 \\ x_4 & y_4 & z_4 & 1 \end{vmatrix}=0 \tag{16}$$

Angle between Two Given Planes

The angle between two planes

$$A_1x+B_1y+C_1z+D_1=0 \tag{17}$$
$$A_2x+B_2y+C_2z+D_2=0 \tag{18}$$

is the angle θ between their normals. Here A_1, B_1, C_1 and A_2, B_2, C_2 are the DR's of the normals respectively to the planes (17) and (18). Then

$$\cos\theta=\frac{A_1A_2+B_1B_2+C_1C_2}{\sqrt{A_1^2+B_1^2+C_1^2}\sqrt{A_2^2+B_2^2+C_2^2}}$$

Condition for perpendicularity

If $\theta=0$ then the two planes are $\perp^r$ to each other. Then

$$A_1A_2+B_1B_2+C_1C_2=0 \tag{19}$$

Condition for parallelism

If $\theta=0$, the two planes are $\|^l$ to each other. Then

$$\frac{A_1}{A_2}=\frac{B_1}{B_2}=\frac{C_1}{C_2} \tag{20}$$

Note: Thus parallel planes differ by a constant.

Although there are four constants A, B, C, D in the equation of plane, essentially three conditions are required to determine the three ratios of A, B, C, D, for example plane passing through:

a. three non-collinear points

b. two given points and $\perp^r$ to a given plane

c. a given point and $\perp^r$ to two given planes etc.

Coordinate of the Foot of the Perpendicular from a Point to a Given Plane

Let $Ax + By + Cz + D = 0$ be the given plane and $P(x_1, y_1, z_1)$ be a given point. Let PN be the perpendicular from P to the plane. Let the coordinates of the foot of the perpendicular PN be $N(\alpha, \beta, \gamma)$. Then DR's of $PN(x_1 - \alpha, y_1 - \beta, z_1 - \gamma)$ are proportional to the coefficients A, B, C i.e.,

$$x_1 - \alpha = kA, \quad y_1 - B = kB, \quad z_1 - \gamma = kC$$

or $$\alpha = x_1 - kA, \quad y_1 = \beta - kB, \quad z_1 = \gamma - kC$$

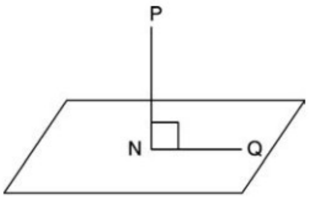

Fig. 36.11

Since N lies in the plane

$$A\alpha + B\beta + C\gamma + D = 0$$

Substituting α, β, γ,

$$A(x_1 - kA) + b(y_1 - kB) + c(z_1 - kC) + D = 0$$

Solving $$k = \frac{Ax_1 + By_1 + CZ_1 + D}{A^2 + B^2 + C^2}$$

Thus the coordinates of $N(\alpha, \beta, \gamma)$ the foot of the perpendicular from $P(x_1, y_1, z_1)$ to the plane are

$$\alpha = x_1 - \frac{A(Ax_1 + By_1 + Cz_1 + D)}{A^2 + B^2 + C^2},$$

$$\beta = y_1 - \frac{B(Ax_1 + By_1 + Cz_1 + D)}{A^2 + B^2 + C^2},$$

$$\gamma = z_1 - \frac{C(Ax_1 + By_1 + Cz_1 + D)}{A^2 + B^2 + C^2} \tag{21}$$

Corollary 1: Length of the perpendicular from a given point to a given plane:

$$PN^2 = (x_1 - \alpha)^2 + (y_1 - \beta)^2 + (z_1 - \gamma)^2$$
$$= (kA)^2 + (kB)^2 + (kC)^2$$
$$= k^2(A^2 + B^2 + C^2)$$
$$= \left[\frac{Ax_1 + By_1 + Cz_1 + D}{A^2 + B^2 + C^2}\right]^2 (A^2 + B^2 + C^2)$$
$$= \frac{(Ax_1 + By_1 + Cz_1 + D)^2}{A^2 + B^2 + C^2}$$

or $$PN = \frac{Ax_1 + By_1 + Cz_1 + D}{\pm\sqrt{A^2 + B^2 + C^2}}.$$

The sign before the radical is chosen as positive or negative according as *D* is positive or negative. Thus the numerical values of the length of the perpendicular *PN* is

$$PN = \left|\frac{Ax_1 + By_1 + Cz_1 + D}{\sqrt{A^2 + B^2 + C^2}}\right| \tag{22}$$

Note: PN is obtained by substituting the coordinates (x_1, y_1, z_1) in the L.H.S. of the Equation (1) and dividing it by $\sqrt{A^2 + B^2 + C^2}$.

Equation of a plane passing through the line of intersection of two given planes $u \equiv A_1x + B_1y + C_1z + D_1 = 0$ and $v \equiv A_2x + B_2y + C_2z + D_2 = 0$ is $u + kv = 0$ where k is any constant.

Equations of the two planes bisecting the angles between two planes are

$$\frac{A_1x + B_1y + C_1z + D_1}{\sqrt{A_1^2 + B_1^2 + C_1^2}} = \pm\frac{A_2x + B_2y + C_2z + D_2}{\sqrt{A_2^2 + B_2^2 + C_2^2}}.$$

Worked Out Examples

Example 1: Find the equation of the plane which passes through the point $(2, 1, 4)$ and is

a. Parallel to plane $2x + 3y + 5z + 6 = 0$

b. Perpendicular to the line joining $(3, 2, 5)$ and $(1, 6, 4)$

c. Perpendicular to the two planes $7x + y + 2z = 6$ and $3x + 5y - 6z = 8$

d. Find intercept points and traces of the plane in case c.

Solution:

a. Any plane parallel to the plane

$$2x + 3y + 5z + 6 = 0$$

is given by $2x+3y+5z+k=0$ (1) (differs by a constant). Since the point $(2,1,4)$ lies on the plane (1), $2(2)+3(1)+5(4)+k=0$, $k=-27$. Required equation of plane is $2x+3y+5z-27=0$.

b. Any plane through the point $(2,1,4)$ is (one point form)

$$A(x-2)+B(y-1)+C(z-4)=0 \qquad (2)$$

DC's of the line joining $M(3,2,5)$ and $N(1,6,4)$ are proportional to $2,-4,1$. Since MN is perpendicular to (2), A,B,C are proportional to $2,-4,1$. Then $2(x-2)-4(y-1)+1(z-4)=0$. The required equation of plane is $2x-4y+z-4=0$.

c. The plane through $(2,1,4)$ is

$$A(x-2)+B(y-1)+C(z-4)=0. \qquad (2)$$

This plane (2) is perpendicular to the two planes $7x+y+2z=6$ and $3x+5y-6z=8$.
Using $A_1A_2+B_1B_2+C_1C_2=0$, we have

$$7a+b+2c=0$$

$$3a+5b-6c=0$$

Solving $\frac{a}{-6-10}=\frac{-b}{-42-8}=\frac{c}{35-3}$ or $\frac{a}{1}=\frac{b}{-3}=\frac{c}{-2}$.

Required equation of plane is

$$1(x-4)-3(y-1)-2(z-4)=0$$

or
$$x-3y-2z+7=0$$

d. x-intercept: Put $y=z=0$, $\therefore x=-7$ or $(-7,0,0)$ is the x-intercept. Similarly, y-intercept is $(0,\frac{7}{3},0)$ and z-intercept is $\left(0,0,\frac{7}{2}\right)$. xy-trace is obtained by putting $z=0$. It is $x-3y+7=0$. Similarly, yz-trace is $3y+2z-7=0$ and zx-trace is $x-2z+7=0$.

Example 2: Find the equation of the plane containing the points $P(3,-1,-4)$, $Q(-2,2,1)$, $R(0,4,-1)$.

Solution: Equation of plane through the point $P(3,-1,-4)$ is

$$A(x+3)+B(y+1)+C(z+4)=0. \qquad (1)$$

DR's of PQ: $-5,3,5$; DR's of PR: $-3,5,3$. Since line PQ and PR completely lies in the plane (1), normal to (1) is perpendicular to PQ and PR. Then

$$-5A+3B+5C=0$$

$$-3A+5B+3C=0$$

Solving $A=C=1, \qquad B=0$

$$(x-3)+0+(z+4)=0$$

Equation of the plane is

$$x+z+1=0$$

Aliter: Equation of the plane by 3-point form is

$$\begin{vmatrix} x & y & z & 1 \\ 3 & -1 & -4 & 1 \\ -2 & 2 & 1 & 1 \\ 0 & 4 & -1 & 1 \end{vmatrix}=0$$

Expanding $D_1x-D_2y+D_3z-1.D_4=0$ where

$$D_1=\begin{vmatrix} -1 & -4 & 1 \\ 2 & 1 & 1 \\ 4 & -1 & 1 \end{vmatrix}=-16, \quad D_2=\begin{vmatrix} 3 & -4 & 1 \\ -2 & 1 & 1 \\ 0 & -1 & 1 \end{vmatrix}0=0$$

$$D_3=\begin{vmatrix} 3 & -1 & 1 \\ -2 & 2 & 1 \\ 0 & 4 & 1 \end{vmatrix}=-16, \quad D_4=\begin{vmatrix} 3 & -1 & -4 \\ -2 & 2 & 1 \\ 0 & 4 & -1 \end{vmatrix}=16$$

or required equation is $x+z+1=0$.

Example 3: Find the perpendicular distance between (a) The Point $(3,2,-1)$ and the plane $7x-6y+6z+8=0$ (b) between the parallel planes $x-2y+2z-8=0$ and $x-2y+2z+19=0$ (c) find the foot of the perpendicular in case (a).

Solution:
Perpendicular distance $=\left(\frac{Ax_1+By_1+Cz_1+D}{\sqrt{A^2+B^2+C^2}}\right)$

a. Point $(3,2,-1)$, plane is $7x-6y+6z+8=0$. So perpendicular distance from $(3,2,-1)$ to plane is

$$=\frac{7(3)-6(2)+6(-1)+8}{\sqrt{7^2+6^2+6^2}}=\frac{11}{-11}=|-1|=1$$

b. x-intercept point of plane $x-2y+2z-8=0$ is $(8,0,0)$ (obtained by putting $y=0, z=0$ in the equation). Then perpendicular distance from the point $(8, 0, 0)$ to the second plane $x - 2y + 2z + 19 = 0$ is $\frac{1.8-2.0+2.0+19}{\sqrt{1^2+2^2+2^2}} = \frac{27}{3} = 9$

c. Let $N(\alpha, \beta, \gamma)$ be the foot of the perpendicular from $P(3, 2, -1)$. DR's of PN: $3 - \alpha, 2 - \beta, -1 - \gamma$. DR's of normal to plane are $7, -6, 6$. These are proportional. $\frac{3-\alpha}{7} = \frac{2-\beta}{-6} = \frac{-1-\gamma}{6}$ or $\alpha = 3 - 7k, \beta = 2 + 6k, \gamma = -1 - 6k$. Now (α, β, γ) lies on the plane. $7(3 - 7k) - 6(2 + 6k) + 6(-1 - 6k) + 8 = 0$ or $k = \frac{1}{11}$.
$\therefore$ the coordinates of the foot of perpendicular are $\left(\frac{26}{11}, \frac{28}{11}, \frac{-17}{11}\right)$.

Example 4: Are the points $(2, 3, -5)$ and $(3, 4, 7)$ on the same side of the plane $x + 2y - 2z = 9$?

Solution: Perpendicular distance of the point $(2, 3, -5)$ from the plane $x + 2y - 2z - 9 = 0$ or $-x - 2y + 2z + 9 = 0$ is $\frac{-1.2-2(3)-2(-5)+9}{\sqrt{1^2+2^2+2^2}} = -\frac{9}{3} = -3$.

$\perp^r$ distance of $(3, 4, 7)$ is $\frac{-1.3-2.4+2.7+9}{\sqrt{1^2+2^2+2^2}} = \frac{12}{3} = 6$

$\perp^r$ distance from origin $(0, 0, 0)$ is $\frac{0+0+0+9}{3} = 3$

So points $(2, 3, -5)$ and $(3, 4, 7)$ are on opposite sides of the given plane.

Example 5: Find the angle between the planes $4x - y + 8z = 9$ and $x + 3y + z = 4$.

Solution: DR's of the planes are $[4, -1, 8]$ and $[1, 3, 1]$. Now

$$\cos\theta = \frac{A_1A_2 + B_1B_2 + C_1C_2}{\sqrt{A_1^2 + B_1^2 + C_1^2}\sqrt{A_2^2 + B_2^2 + C_2^2}}$$
$$= \frac{4.1 + 3\cdot(-1) + 1.8}{\sqrt{16 + 1 + 64}\sqrt{1 + 9 + 1}}$$
$$= \frac{9}{\sqrt{81}\sqrt{11}} = \frac{1}{\sqrt{11}} \quad \text{or} \quad \theta = \cos^{-1}\frac{1}{\sqrt{11}}.$$

Example 6: Find the equation of a plane passing through the line of intersection of the planes.

a. $3x + y - 5z + 7 = 0$ and $x - 2y + 4z - 3 = 0$ and passing through the point $(-3, 2, -4)$

b. $2x - 5y + z = 3$ and $x + y + 4z = 5$ and parallel to the plane $x + 3y + 6z = 1$.

Solution:

a. Equation of plane is $u + kv = 0$ i.e.,

$$(3x + y - 5z + 7) + k(x - 2y + 4z - 3) = 0.$$

Since point $(-3, 2, -4)$ lies on the intersection plane

$$[3(-3) + 1.(2) - 5(-4) + 7]$$
$$+k[1(-3) - 2(2) + 4(-4) - 3] = 0.$$

So $k = \frac{10}{13}$. Then the required plane is

$$49x - 7y - 25z + 61 = 0.$$

b. Equation of plane is $u + kv = 0$ i.e.,

$$(2x - 5y + z - 3) + k(x + y + 4z - 5) = 0$$

or $$(2+k)x+(-5+k)y+(1+4k)z+(-3-5k) = 0.$$

Since this intersection plane is parallel to $x + 3y + 6z - 1 = 0$

So $$\frac{2+k}{1} = \frac{-5+k}{3} = \frac{1+4k}{6} \quad \text{or} \quad k = -\frac{11}{2}.$$

Required equation of plane is $7x + 21y + 42z - 49 = 0$.

Example 7: Find the planes bisecting the angles between the planes $x + 2y + 2z = 9$ and $4x - 3y + 12z + 13 = 0$. Specify the angle θ between them.

Solution: Equations of the bisecting planes are

$$\frac{x + 2y + 2z - 9}{\sqrt{1 + 2^2 + 2^2}} = \pm\frac{4x - 3y + 12z + 13}{\sqrt{4^2 + 3^2 + 12^2}}$$
$$\frac{x + 2y + 2z - 9}{3} = \pm\frac{4x - 3y + 12z + 13}{13}$$

or $$25x + 17y + 62z - 78 = 0 \quad \text{and}$$
$$x + 35y - 10z - 156 = 0.$$

$$\cos\theta = \frac{25\cdot 1 + 17\cdot 35 - 62 \times 10}{\sqrt{25^2 + 17^2 + 62^2}\sqrt{1 + 35^2 + 10^2}} = 0$$

$$\therefore \quad \theta = \frac{\pi}{2}$$

i.e, angle between the bisecting planes is $\frac{\pi}{2}$.

Example 8: Show that the planes

$$7x + 4y - 4z + 30 = 0 \qquad (1)$$

$$36x - 51y + 12z + 17 = 0 \qquad (2)$$

$$14x + 8y - 8z - 12 = 0 \qquad (3)$$

$$12x - 17y + 4z - 3 = 0 \qquad (4)$$

form four faces of a rectangular parallelopiped.

Solution: (1) and (3) are parallel since $\frac{7}{14} = \frac{4}{8} = \frac{-4}{-8} = \frac{1}{2}$. (2) and (4) are parallel since $\frac{36}{12} = \frac{-51}{-17} = \frac{12}{4} = 3$. Further (1) and (2) are $\perp^r$ since

$$7 \cdot 36 + 4(-51) - 4(12) = 252 - 204 - 48 = 0.$$

EXERCISE

1. Find the equation of the plane through $P(4, 3, 6)$ and perpendicular to the line joining $P(4, 3, 6)$ to the point $Q(2, 3, 1)$.

   Hint: DR's PQ: $[2, 0, 5]$, DR of plane through $(4, 3, 6) : x - 4, y - 3, z - 6; \perp^r$: $2(x - 4) + 0(y - 3) + 5(z - 6) = 0$

Ans. $2x + 5z - 38 = 0$

2. Find the equation of the plane through the point $P(1, 2, -1)$ and parallel to the plane $2x - 3y + 4z + 6 = 0$.

   Hint: Eq. $2x - 3y + 4z + k = 0$, $(1, 2, -1)$ lies, $k = 8$.

Ans. $2x - 3y + 4z + 8 = 0$

3. Find the equation of the plane that contains the three points $P(1, -2, 4)$, $Q(4, 1, 7)$, $R(-1, 5, 1)$.

   Hint: $A(x - 1) + B(y + 2) + C(z - 4) = 0$, DR: PQ: $[3, 3, 3]$, PR: $[-2, 7, -3]$. $\perp^r$ $3A + 3B + 3C = 0$, $-2A + 7B - 3C = 0$, $A = -10B$, $C = 9B$.

   Aliter: $$\begin{vmatrix} x & y & z & 1 \\ 1 & -2 & 4 & 1 \\ 4 & 1 & 7 & 1 \\ -1 & 5 & 1 & 1 \end{vmatrix} = 0,$$

   $$D_1 x - D_2 y + D_3 z - D_4 = 0$$

   where $$D_1 = \begin{vmatrix} -2 & 4 & 1 \\ 1 & 7 & 1 \\ 5 & 1 & 1 \end{vmatrix} \text{ etc.}$$

Ans. $10x - y - 9z + 24 = 0$

4. Find the equation of the plane
   - **a.** passing through $(1, -1, 2)$ and $\perp^r$ to each of the planes $2x + 3y - 2z = 5$ and $x + 2y - 3z = 8$
   - **b.** passing through $(-1, 3, -5)$ and parallel to the plane $6x - 3y - 2z + 9 = 0$
   - **c.** passing through $(2, 0, 1)$ and $(-1, 2, 0)$ and $\perp^r$ to the plane $2x - 4y - z = 7$.

Ans. **a.** $5x - 4y - z = 7$
b. $6x - 3y - 2z + 5 = 0$
c. $6x + 5y - 8z = 4$

5. Find the perpendicular distance between
   - **a.** the point $(-2, 8, -3)$ and plane $9x - y - 4z = 0$
   - **b.** the two planes $x - 2y + 2z = 6$, $3x - 6y + 6z = 2$
   - **c.** the point $(1, -2, 3)$ and plane $2x - 3y + 2z - 14 = 0$.

Ans. (a) $\sqrt{2}$ (b) $\frac{-16}{9}$ (c) 0 i.e., lies on the plane.

6. Find the angle between the two planes
   - **a.** $x + 4y - z = 5$, $y + z = 2$
   - **b.** $x - 2y + 3z + 4 = 0$, $2x + y - 3z + 7 = 0$

Ans. (a) $\cos\theta = \frac{1}{2}$, $\theta = 60^\circ$ (b) $\cos\theta = \frac{-9}{14}$.

7. Prove that the planes $5x - 3y + 4z = 1$, $8x + 3y + 5z = 4$, $18x - 3y + 13z = 6$ contain a common line.

   Hint: $u + kv = 0$ substitute in $w = 0$, $k = \frac{1}{2}$

8. Find the coordinates of N, the foot of the perpendicular from the point $P(-3, 0, 1)$ on the plane $4x - 3y + 2z = 19$. Find the length of this perpendicular. Find also the image of P in the plane.

   Hint: $PN = NQ$ i.e., N is the mid point.

Ans. $N(1, -3, 3)$, $\sqrt{29}$, image of P is $Q(5, -6, 5)$

9. Find the equation of the plane through the line of intersection of the two planes $x - 3y + 5z - 7 = 0$ and $2x + y - 4z + 1 = 0$ and $\perp^r$ to the plane $x + y - 2z + 4 = 0$.

Ans. $3x - 2y + z - 6 = 0$

10. A variable plane passes through the fixed point (a, b, c) and meets the coordinate axes in P, Q, R. Prove that the locus of the point common to the planes through P, Q, R parallel to the coordinate plane is $\frac{a}{x} + \frac{b}{y} + \frac{c}{z} = 1$.

    Hint: $OP = x_1,\ OQ = y_1,\ OR = z_1,\ \frac{x}{x_1} + \frac{y}{y_1} + \frac{z}{z_1} = 1$, (a, b, c) lies, $\frac{a}{x_1} + \frac{b}{y_1} + \frac{c}{z_1} = 1$.

36.4 THE STRAIGHT LINE

Two surfaces will in general intersect in a curve. In particular two planes, which are not parallel, intersect in a straight line.

Example: The coordinate planes ZOX and XOY, whose equations are $y = 0$ and $z = 0$ respectively, intersect in a line the x-axis.

Straight line

The locus of two simultaneous equations of first degree in x, y, z

$$\begin{aligned} A_1x + B_1y + C_1z + D_1 = 0 \\ A_2x + B_2y + C_2z + D_2 = 0 \end{aligned} \tag{1}$$

is a straight line, provided $A_1 : B_1 : C_1 \neq A_2 : B_2 : C_2$ (i.e., not parallel). Equation (1) is known as the **general form** of the equation of a straight line. Thus the equation of a straight line or simply line is the pair of equations taken together i.e., equations of two planes together represent the equation of a line. However this representation is not unique, because many planes can pass through a given line. Thus a given line can be represented by different pairs of first degree equations.

Projecting planes

Of the many planes passing through a given line, those that are perpendicular to the coordinate planes are known as projecting planes and their traces give the **projections** of the line on the coordinate planes.

Symmetrical Form

The equation of line passing through a given point $P_1(x_1, y_1, z_1)$ and having direction cosines l, m, n is given by

$$\frac{x - x_1}{l} = \frac{y - y_1}{m} = \frac{z - z_1}{n} \tag{2}$$

since for any point $P(x, y, z)$ on the line, the DR's of PP_1: $x - x_1, y - y_1, z - z_1$ be proportional to l, m, n. Equation (2) represent two independent linear equations and are called the symmetrical (or symmetric) form of the equation of a line.

Corollary: Any point P on the line (2) is given by

$$x = x_1 + lr, \qquad y = y_1 + mr, \qquad z = z_1 + nr \tag{3}$$

for different values of r, where $r = PP_1$.

Corollary: Lines perpendicular to one of the coordinate axes:

a. $x = x_1, \frac{y-y_1}{m} = \frac{z-z_1}{n}$, ($\perp^r$ to x-axis i.e., $\|^l$ to yz-plane)

b. $y = y_1, \frac{x-x_1}{l} = \frac{z-z_1}{n}$, ($\perp^r$ to y-axis i.e., $\|^l$ to xz-plane)

c. $z = z_1, \frac{x-x_1}{l} = \frac{y-y_1}{m}$, ($\perp^r$ to z-axis i.e., $\|^l$ to xy-plane)

Corollary: Lines perpendicular to two axes

a. $x = x_1, y = y_1$ ($\perp^r$ to x- & y-axis i.e., $\|^l$ to z-axis):

b. $x = x_1, z = z_1$ ($\perp^r$ to x- & z-axis i.e., $\|^l$ to y-axis)

c. $y = y_1, z = z_1$ ($\perp^r$ to y- & z-axis i.e., $\|^l$ to x-axis)

Corollary: Projecting planes: (containing the given line)

(a) $\frac{x-x_1}{l} = \frac{y-y_1}{m}$ (b) $\frac{x-x_1}{l} = \frac{z-z_1}{n}$ (c) $\frac{y-y_1}{m} = \frac{z-z_1}{n}$.

Note: When any of the constants l, m, n are zero, the Equation (2) are equivalent to equations

$$\frac{l}{x - x_1} = \frac{m}{y - y_1} = \frac{n}{z - z_1}.$$

Example: $\frac{x}{0}=\frac{y}{2}=\frac{z}{0}$ means $\frac{0}{x}=\frac{2}{y}=\frac{0}{z}$.

Corollary: If a, b, c are the DR's of the line, then (2) takes the form $\frac{x-x_1}{a}=\frac{y-y_1}{b}=\frac{z-z_1}{c}$.

Corollary: **Two point form** of a line passing through two given points $P_1(x_1, y_1, z_1)$ and $P_2(x_2, y_2, z_2)$ is

$$\frac{x-x_1}{x_2-x_1}=\frac{y-y_1}{y_2-y_1}=\frac{z-z_1}{z_2-z_1} \tag{4}$$

since the DR's of P_1P_2 are $x_2-x_1, y_2-y_1, z_2-z_1$.

Transformation of General Form to Symmetrical Form

The general form also known as unsymmetrical form of the equation of a line can be transformed to symmetrical form by determining

(a) one point on the line, by putting say $z=0$ and solving the simultaneous equations in x and y.

(b) the DC's of the line from the fact that this line is $\perp^r$ to both normals of the given planes.

For example,

(a) by putting $z=0$ in the general form

$$\begin{aligned} A_1x+B_1y+C_1z+D_1&=0\\ A_2x+B_2y+C_2z+D_2&=0 \end{aligned} \tag{2}$$

and solving the resulting equations

$$A_1x+B_1y+D_1=0$$

$$A_2x+B_2y+D_2=0,$$

we get a point on the line as

$$\left(\frac{B_1D_2-B_2D_1}{A_1B_2-A_2B_1}, \frac{A_2D_1-A_1D_2}{A_1B_2-A_2B_1}, 0\right) \tag{5}$$

(b) Using the orthogonality of the line with the two normals of the two planes, we get

$$lA_1+mB_1+nC_1=0$$

$$lA_2+mB_2+nC_2=0$$

where $(l, m, n), (A_1, B_1, C_1)$ and (A_2, B_2, C_2) are DR's of the line, normal to first plane, normal to second plane respectively. Solving, we get the DR's l, m, n of the line as

$$\frac{l}{B_1C_2-B_2C_1}=\frac{m}{C_1A_2-C_2A_1}=\frac{n}{A_1B_2-A_2B_1} \tag{6}$$

Using (5) and (6), thus the given general form (2) of the line reduces to the symmetrical form

$$\frac{x-\frac{(B_2D_1-B_1D_2)}{A_1B_2-A_2B_1}}{B_1C_2-B_2C_1}=\frac{y-\frac{(A_2D_1-A_1D_2)}{A_1B_2-A_2B_1}}{C_1A_2-C_2A_1}= =\frac{z-0}{A_1B_2-A_2B_1} \tag{7}$$

Note 1: In finding a point on the line, one can put $x=0$ or $y=0$ instead of $z=0$ and get similar results.

Note 2: General form (2) can also be reduced to the two point form (4) (special case of symmetric form) by determining two points on the line.

Angle between a Line and a Plane

Let π be the plane whose equation is

$$Ax+By+Cz+D=0 \tag{8}$$

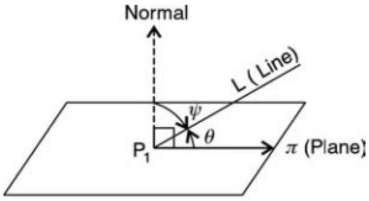

Fig. 36.12

and L be the straight line whose symmetrical form is

$$\frac{x-x_1}{l}=\frac{y-y_1}{m}=\frac{z-z_1}{n} \tag{2}$$

Let θ be the angle between the line L and the plane π. Let ψ be the angle between L and the normal to the plane π. Then

$$\cos\psi=\frac{lA+mB+nC}{\sqrt{l^2+m^2+n^2}\sqrt{A^2+B^2+C^2}}$$

$$=\cos(90-\theta)=\sin\theta \tag{9}$$

since $\psi=90-\theta$. The angle between a line L and plane π is the complement of the angle between the line L and the normal to the plane). Thus θ is determined from (9).

Corollary: Line is $\|^l$ to the plane if $\theta = 0$ then $\sin\theta = 0$ i.e.,

$$\boxed{lA + mB + nC = 0} \tag{10}$$

Corollary: Line is $\perp^r$ to the plane if $\theta = \frac{\pi}{2}$, then $\sin\theta = 1$ i.e.,

$$\boxed{\frac{l}{A} = \frac{m}{B} = \frac{n}{C}} \tag{11}$$

(i.e., DR's of normal and the line are same).

Conditions for a Line L to Lie in a Plane π

If every point of line L is a point of plane π, then line L lies in plane π. Substituting any point of the line $L : (x_1 + lr, y_1 + mr, z_1 + nr)$ in the equation of the plane (8), we get

$$A(x_1 + lr) + B(y_1 + mr) + C(z_1 + nr) + D = 0$$

or $$(Al + Bm + Cn)r + (Ax_1 + By_1 + Cz_1 + D) = 0 \tag{12}$$

This Equation (12) is satisfied for all values of r if the coefficient of r and constant term in (12) are both zero i.e.,

$$\boxed{\begin{array}{ll} Al + Bm + Cn = 0 & \text{and} \\ Ax_1 + By_1 + Cz_1 + D = 0 & \end{array}} \tag{13}$$

Thus the two conditions for a line L to lie in a plane π are given by (13) which geometrically mean that (i) line L is $\perp^r$ to the nomal ot the plne and (ii) a (any one) point of line L lies on the plane.

Corollary: General equation of a plane containing line L (2) is

$$A(x - x_1) + B(y - y_1) + C(z - z_1) = 0 \tag{14}$$

subject to

$$Al + Bm + Cn = 0$$

Corollary: Equation of any plane through the line of intersection of the two planes

$$u \equiv A_1x + B_1y + C_1z + D_1 = 0 \quad \text{and}$$
$$v \equiv A_2x + B_2y + C_2z + D_2 = 0$$

is $u + kv = 0$ or $(A_1x + B_1y + C_1z + D_1) + k(A_2x + B_2y + C_2z + D_2) = 0$ where k is a constant.

Coplanar Lines

Consider two given straight lines L_1

$$\frac{x - x_1}{l_1} = \frac{y - y_1}{m_1} = \frac{z - z_1}{n_1} \tag{15}$$

and line L_2

$$\frac{x - x_2}{l_2} = \frac{y - y_2}{m_2} = \frac{z - z_2}{n_2} \tag{16}$$

From (14), equation of any plane containing line L_1 is

$$A(x - x_1) + B(y - y_1) + C(z - z_1) = 0 \tag{17}$$

subject to

$$Al_1 + Bm_1 + Cn_1 = 0 \tag{18}$$

If the plane (17) contains line L_2 also, then the point (x_2, y_2, z_2) of L_2 should also lie in the plane (17). Then

$$A(x_2 - x_1) + B(y_2 - y_1) + C(z_2 - z_1) = 0 \tag{19}$$

But the line L_2 is $\perp^r$ to the normal to the plane (17). Thus

$$Al_2 + Bm_2 + Cn_2 = 0 \tag{20}$$

Therefore the two lines L_1 and L_2 will lie in the same plane if (17), (18), (20) are simultaneously satisfied. Eliminating A, B, C from (19), (18), (20)(i.e., homogeneous system consistent if coefficient determinant is zero), we have

$$\begin{vmatrix} x_2 - x_1 & y_2 - y_1 & z_2 - z_1 \\ l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \end{vmatrix} = 0 \tag{21}$$

Thus (21) is the condition for coplanarity of the two lines L_1 and L_2. Now the equation of the plane containing lines L_1 and L_2 is

$$\begin{vmatrix} x - x_1 & y - y_1 & z - z_1 \\ l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \end{vmatrix} = 0 \tag{22}$$

which is obtained by eliminating A, B, C from (17), (18), (20).

Corollary: Condition for the two lines L_1

$$\begin{aligned} & u_1 \equiv A_1x + B_1y + C_1z + D_1 = 0, \\ & u_2 \equiv A_2x + B_2y + C_2z + D_2 = 0 \\ \text{and Line } L_2 \quad & u_3 \equiv A_3x + B_3y + C_3z + D_3 = 0, \\ & u_4 \equiv A_4x + B_4y + C_4z + D_4 = 0 \end{aligned} \tag{23}$$

to be coplanar is

$$\begin{vmatrix} A_1 & B_1 & C_1 & D_1 \\ A_2 & B_2 & C_2 & D_2 \\ A_3 & B_3 & C_3 & D_3 \\ A_4 & B_4 & C_4 & D_4 \end{vmatrix} = 0 \tag{24}$$

If $P(\alpha, \beta, \gamma)$ is the point of intersection of the two lies, then P should satisfy the four Equations (23): $u_i|$ at $(\alpha, \beta, \gamma) = 0$ for $i = 1, 2, 3, 4$. Elimination of (α, β, γ) from these four equations leads to (24).

Corollary: The general form of equations of a line L_3 intersecting the lines L_1 and L_2 given by (23) are

$$u_1 + k_1u_2 = 0 \quad \text{and} \quad u_3 + k_2u_4 = 0 \tag{25}$$

where k_1 and k_2 are any two numbers.

Foot and length of the perpendicular from a point $P_1(\alpha, \beta, \gamma)$ to a given line L: $\frac{x-x_1}{l} = \frac{y-y_1}{m} = \frac{z-z_1}{n}$

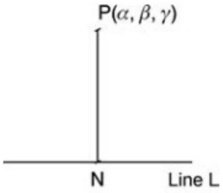

Fig. 36.13

Any point on the line L be $(x_1 + lr, y_1 + mr, z_1 + nr)$. The DR's of PN are $x_1 + lr - \alpha, y_1 + mr - \beta, z_1 + nr - \gamma$. Since PN is $\perp^r$ to line L, then

$$l(x_1+lr-\alpha)+m(y_1+mr-\beta)+n(z_1+nr-\gamma) = 0.$$

Solving

$$r = \frac{l(\alpha - x_1) + m(\beta - y_1) + n(\gamma - z_1)}{l^2 + m^2 + n^2} \tag{26}$$

The coordinates of N, the foot of the perpendicular PN is $(x_1 + lr - \alpha, y_1 + mr - \beta, z_1 + nr - \gamma)$ where r is given by (26).

The length of the perpendicular PN is obtained by distance formula between P (given) and N (found).

Line of greatest slope in a plane

Let ML be the line of intersection of a horizontal plane I with slant plane II. Let P be any point on plane II. Draw PN $\perp^r$ to the line ML. Then the line of greatest slope in plane II is the line PN, because no other line in plane II through P is inclined to the horizontal plane I more steeply than PN.

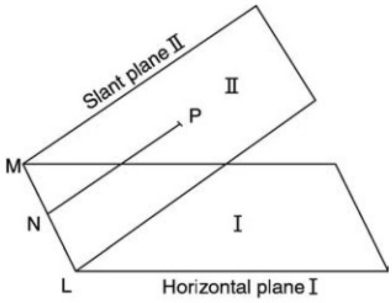

Fig. 36.14

WORKED OUT EXAMPLES

Example 1: Find the points where the line $x - y + 2z = 2$, $2x - 3y + 4z = 0$ pierces the coordinate planes.

Solution: Put $z = 0$ to find the point at which the line pierces the xy-plane: $x - y = 2$ and $2x - 3y = 0$ or $x = 6$, $y = 4$. $\therefore$ $(6, 4, 0)$.
Put $x = 0$, $-y + 2z = 2$, $-3y + 4z = 0$ or $y = 4$, $z = 3$ $\therefore$ $(0, 4, 3)$ is piercing point.
Put $y = 0$, $x + 2z = 2$, $2x + 4z = 0$ no unique solution.
Note that DR's of the line are $[2, 0, -1]$. So this line is $\perp^r$ to y-axis whose DR's are $[0, 1, 0]$ (i.e., $2 \cdot 0 + 0 \cdot 1 + (-1) \cdot 0 = 0$). Hence the given line does not pierce the xz-plane.

Example 2: Transfer the general (unsymmetrical) form $x + 2y + 3z = 1$ and $x + y + 2z = 0$ to the symmetrical form.

Solution: Put $x = 0$, $2y + 3z = 1$, $y + 2z = 0$. Solving $z = -1$, $y = 2$. So $(0, 2, -1)$ is a point on the line. Let l, m, n be the DR's of the line. Since this line is $\perp^r$ to both normals of the given two planes, we have

$$1 \cdot l + 2 \cdot m + 3 \cdot n = 0$$

$$1 \cdot l + 1 \cdot m + 2 \cdot n = 0$$

Solving $\dfrac{l}{4-3} = -\dfrac{m}{2-3} = \dfrac{n}{1-2}$ or $\dfrac{l}{1} = \dfrac{m}{1} = -\dfrac{n}{1}$

Equation of the line passing through the point $(0, 2, -1)$ and having DR's $1, 1, -1$ is

$$\frac{x-0}{1} = \frac{y-2}{2} = \frac{z+1}{-1}$$

Aliter: Two point form.

Put $y = 0$, $x + 3z = 1$, $x + 27 = 0$. Solving $z = 1$, $x = -2$ or $(-2, 0, 1)$ is another point on the line. Now DR's of the line joining the two points $(0, 2, -1)$ and $(-2, 0, 1)$ are $-2, -2, 2$. Hence the equation of the line in the two point form is

$$\frac{x-0}{-2} = \frac{y-2}{-2} = \frac{z+1}{2} \quad \text{or} \quad \frac{x}{1} = \frac{y-2}{1} = \frac{z+1}{-1}.$$

Example 3: Find the acute angle between the lines $\frac{x}{2} = \frac{y}{2} = \frac{z}{1}$ and $\frac{x}{5} = \frac{y}{4} = \frac{z}{-3}$.

Solution: DR's are $[2, 2, 1]$ and $[5, 4, -3]$. If θ is the angle between the two lines, then

$$\cos\theta = \frac{l_1 l_2 + m_1 m_2 + n_1 n_2}{\sqrt{l_1^2 + m_1^2 + n_1^2}\sqrt{l_2^2 + m_2^2 + n_2^2}}$$

$$= \frac{2 \cdot 5 + 2 \cdot 4 + 1 \cdot (-3)}{\sqrt{4+4+1}\sqrt{25+16+9}} = \frac{15}{3\sqrt{50}} = \frac{1}{\sqrt{2}}$$

$$\therefore \quad \theta = 45^\circ$$

Example 4: Find the equation of the plane containing the line $x = y = z$ and passing through the point $(1, 2, 3)$.

Solution: General form of the given line is

$$x - y = 0 \quad \text{and} \quad x - z = 0.$$

Equation of a plane containing this line is

$$(x - y) + k(x - z) = 0$$

Since point $(1, 2, 3)$ lies on this line, it also lies on the above plane. Then

$$(1 - 2) + k(1 - 3) = 0 \quad \text{or} \quad k = -\frac{1}{2}$$

Equation of required plane is

$$(x - y) - \frac{1}{2}(x - z) = 0$$

or
$$x - 2y + z = 0.$$

Example 5: Show that the lines $\frac{x}{1} = \frac{y+3}{2} = \frac{z+1}{3}$ and $\frac{x-3}{2} = \frac{y}{1} = \frac{z-1}{-1}$ intersect. Find the point of intersection.

Solution: Rewriting the equation in general form, we have

$$2x - y = 3, \qquad 3x - z = 1$$

and
$$x - 2y = 3, \qquad x + 2z = 5$$

If these four equations have a common solution, then the given two lines intersect. Solving, $y = -1$, then $x = 1$, $z = 2$. So the point of intersection is $(1, -1, 2)$.

Example 6: Find the acute angle between the lines $\frac{x}{3} = \frac{y}{1} = \frac{z}{0}$ and the plane $x + 2y - 7 = 0$.

Solution: DR's of the line: $[3, 1, 0]$. DR's of normal to the plane is $[1, 2, 0]$. If ψ is the angle between the line and the normal, then

$$\cos\psi = \frac{3 \cdot 1 + 1 \cdot 2 + 0 \cdot 0}{\sqrt{3^2 + 1^2 + 0^2}\sqrt{1^2 + 2^2 + 0^2}}$$

$$= \frac{5}{\sqrt{10}\sqrt{5}} = \frac{1}{\sqrt{2}} \qquad \text{so} \qquad \psi = 45^\circ.$$

Angle θ between the line and the plane is the complement of the angle ψ i.e., $\theta = 90 - \psi = 90 - 45 = 45^\circ$.

Example 7: Show that the lines $x + y - 3z = 0$, $2x + 3y - 8z = 1$ and $3x - y - z = 3$, $x + y - 3z = 5$ are parallel.

Solution: DR's of the first line are

$$\begin{array}{ccc} l_1 & m_1 & n_1 \\ 1 & 1 & -3 \\ 2 & 3 & -8 \end{array} \quad \text{or} \quad \frac{l_1}{1} = \frac{m_1}{2} = \frac{n_1}{1}$$

Similarly, DR's of the second line are

$$\begin{array}{ccc} l_2 & m_2 & n_2 \\ 3 & -1 & -1 \\ 1 & 1 & -3 \end{array} \quad \text{or} \quad \frac{l_2}{4}=\frac{m_2}{8}=\frac{n_2}{4} \quad \text{i.e.,} \quad \frac{l_2}{1}=\frac{m_2}{2}=\frac{n_2}{1}$$

Since the DR's of the two lines are same, they are parallel.

Example 8: Find the acute angle between the lines $2x - y + 3z - 4 = 0$, $3x + 2y - z + 7 = 0$ and $x + y - 2z + 3 = 0$, $4x - y + 3z + 7 = 0$.

Solution: The line represented by the two planes is perpendicular to both the normals of the two planes. If l_1, m_1, n_1 are the DR's of this line, then

$$\begin{array}{ccc} l_1 & m_1 & n_1 \\ 2 & -1 & 3 \\ 3 & 2 & -1 \end{array} \quad \text{or} \quad \frac{l_1}{-5} = \frac{m_1}{11} = \frac{n_1}{7}$$

Similarly, DR's of the 2nd line are

$$\begin{array}{ccc} l_2 & m_2 & n_2 \\ 1 & +1 & -2 \\ 4 & -1 & -3 \end{array} \quad \text{or} \quad \frac{l_2}{-1} = \frac{m_2}{11} = \frac{n_2}{5}$$

If θ is the angle between the lines, then

$$\cos\theta = \frac{l_1 l_2 + m_1 m_2 + n_1 n_2}{\sqrt{l_1^2 + m_1^2 + n_1^2}\sqrt{l_2^2 + m_2^2 + n_2^2}}$$

$$= \frac{5 + 121 + 35}{\sqrt{195}\sqrt{147}} = \frac{23}{3\sqrt{65}}$$

$$\therefore \qquad \text{So} \qquad \theta = 180^\circ 1.4'$$

Example 9: Prove that the line $\frac{x-4}{2} = \frac{y-2}{3} = \frac{z-3}{6}$ lies in the plane $3x - 4y + z = 7$.

Solution: The point of the line $(4, 2, 3)$ should also lie in the plane. So $3 \cdot 4 - 4 \cdot 2 + 1 \cdot 3 = 7$ satisfied. The line and normal to the plane are perpendicular. So $2 \cdot 3 + 3 \cdot (-4) + 6 \cdot 1 = 6 - 12 + 6 = 0$. Thus the given line completely lies in the given plane.

Example 10: Show that the lines $\frac{x-2}{2} = \frac{y-3}{-1} = \frac{z+4}{3}$ and $\frac{x-3}{1} = \frac{y+1}{3} = \frac{z-1}{-2}$ are coplanar. Find their common point and determine the equation of the plane containing the two given lines.

Solution: Here first line passes through $(2, 3, -4)$ and has DR's $l_1, m_1, n_1 : 2, -1, 3$. The second line passes through $(3, -1, 1)$ and has DR's $l_2, m_2, n_2 :$ $1, 3, -2$. Condition for coplanarity:

$$\begin{vmatrix} x_2-x_1 & y_2-y_1 & z_2-z_1 \\ l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \end{vmatrix} = \begin{vmatrix} 3-2 & -1-3 & 1+4 \\ 2 & -1 & 3 \\ 1 & 3 & 2 \end{vmatrix}$$

$$= \begin{array}{c} 7+28-35 = 0 \\ \text{satisfied.} \end{array}$$

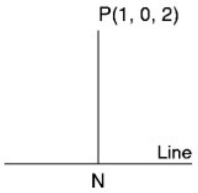
Point of intersection: Any point on the first line is $(2 + 2r_1, 3 - r_1 - 4 + 3r_1)$ and any point on the second line is $(3 + r_2, -1 + 3r_2, 1 - 2r_2)$. When the two lines intersect in a common point then coordinates on line (1) and line (2) must be equal, i.e., $2 + 2r_1 = 3 + r_2, 3 - r_1 = -1 + 3r_2$ and $-4 + 3r_1 = 1 - 2r_2$. Solving $r_1 = r_2 = 1$. Therefore the point of intersection is $(2 + 2 \cdot 1, 3 - 1, -4 + 3 \cdot 1)$ $= (4, 2, -1)$.
Equation of plane containing the two lines:

$$\begin{vmatrix} x-x_1 & y-y_1, & z-z_1 \\ l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \end{vmatrix} = \begin{vmatrix} x-2 & y-3 & z+4 \\ 2 & -1 & 3 \\ 1 & 3 & -2 \end{vmatrix} = 0$$

Expanding $\quad -7(x-2) - (-7)(y-3) + 7(z+4) = 0$ or $x - y - z + 3 = 0$.

Example 11: Find the coordinates of the foot of the perpendicular from $P(1, 0, 2)$ to the line $\frac{x+1}{3} = \frac{y-2}{-2} = \frac{z+1}{-1}$. Find the length of the perpendicular and its equation.

Solution: Any point N on the given line is $(3r - 1, 2 - 2r, -1 - r)$. DR's of PN are $(3r - 2, 2 - 2r, -3 - r)$. Now PN is normal to line if $3(3r - 2) + (-2)(2 - 2r) + (-1)(-3 - r) = 0$ or $r = \frac{1}{2}$. So the coordinates of N the foot of the perpendicular from P to the line are $\left(3 \cdot \frac{1}{2} - 1, 2 - 2 \cdot \frac{1}{2}, -1 - \frac{1}{2}\right)$ or $\left(\frac{1}{2}, 1, -\frac{3}{2}\right)$.



Length of the perpendicular

$$PN = \sqrt{\left(\frac{1}{2}-1\right)^2 + (1-0)^2 + \left(-\frac{3}{2}-2\right)^2}$$

$$= \sqrt{\frac{1}{4}+1+\frac{49}{4}} = \sqrt{\frac{54}{4}} = \frac{3}{2}\sqrt{6}.$$

DR's of *PM* with $r = \frac{1}{2}$ are $[3 \cdot \frac{1}{2} - 2, 2 - 2 \cdot \frac{1}{2}, -3 - \frac{1}{2}]$ i.e., DR's of *PM* are $\frac{1}{2}, -1, \frac{7}{2}$. And *PM* passes through $P(1, 0, 2)$. Therefore the equation of the perpendicular *PM*

$$\frac{x-1}{\frac{1}{2}} = \frac{y-0}{-1} = \frac{z-2}{\frac{7}{2}} \quad \text{or} \quad x - 1 = \frac{y}{-2} = \frac{z-2}{7}.$$

Example 12: Find the equation of the line of the greatest slope through the point (2, 1, 1) in the slant plane $2x + y - 5z = 0$ to the horizontal plane $4x - 3y + 7z = 0$.

Solution: Let l_1, m_1, n_1 be the DR's of the line of intersection *ML* of the two given planes. Since *ML* is $\perp^r$ to both normals,

$$2l_1 + m_1 - 5n_1 = 0, \qquad 4l_1 - 3m_1 + 7n_1 = 0.$$

Solving $\frac{l_1}{4} = \frac{m_1}{17} = \frac{n_1}{5}$. Let *PN* be the line of greatest slope and let l_2, m_2, n_2 be its DR's. Since *PN* and *ML* are perpendicular

$$4l_2 + 17m_2 + 5n_2 = 0$$

Also *PN* is perpendicular to normal of the slant plane $2x + y - 5z = 0$. So

$$2l_2 + m_2 - 5n_2 = 0$$

Solving $\frac{l_2}{3} = \frac{m_2}{-1} = \frac{n_2}{1}$.
Therefore the equation of the line of greatest slope *PN* having DR's $3, -1, 1$ and passing through $P(2, 1, 1)$ is

$$\frac{x-2}{3} = \frac{y-1}{-1} = \frac{z-1}{1}.$$

EXERCISE

1. Find the points where the line $x + y + 4z = 6$, $2x - 3y - 2z = 2$ pierce the coordinate planes.

Ans. $(0, -2, 2), (4, 2, 0), (2, 0, 1)$

2. Transform the general form $3x + y - 2z = 7$, $6x - 5y - 4z = 7$ to symmetrical form and two point form.

   Hint: $(0, 1, -3), (2, 1, 0)$ are two points on the line.

Ans. $\frac{x-2}{2} = \frac{y-1}{0} = \frac{z-0}{3}$

3. Show that the lines $x = y = z + 2$ and $\frac{x-1}{1} = \frac{y}{0} = \frac{z}{2}$ intersect and find the point of intersection.

   Hint: Solve $x - y = 0$, $y - z = 2$, $y = 0$, $2x - z = 2$ simultaneously.

Ans. $(0, 0, -2)$

4. Find the equation plane containing the line $x = y = z$ and

   a. Passing through the line $x + 1 = y + 1 = z$

   b. Parallel to the line $\frac{x+1}{3} = \frac{y}{2} = \frac{z}{-1}$.

Ans. (a) $x - y = 0$; (b) $3x - 4y + z = 0$

5. Show that the line $\frac{x+1}{1} = \frac{y}{-1} = \frac{z-2}{2}$ is in the plane $2x + 4y + z = 0$.

   Hint: $2(1) + 4(-1) + 1(2) = 0$,
   $2(-1) + 4(0) + 2 = 0$

6. Find the equation of the plane containing line $\frac{x-1}{3} = \frac{y-1}{4} = \frac{z-2}{2}$ and parallel to the line $x - 2y + 3z = 4$, $2x - 3y + 4z = 5$.

   Hint: Eq. of 2nd line $\frac{x-0}{\frac{1}{2}} = \frac{y-1}{1} = \frac{z-2}{\frac{1}{2}}$, contains 1st line: $3A + 4B + 2C = 0$. Parallel to 2nd line $A + 2B + C = 0$, $A = 0$, $B = -\frac{1}{2}C$, $D = -\frac{3}{2}C$.

Ans. $y - 2z + 3 = 0$

7. Show that the lines $x + 2y - z = 3$, $3x - y + 2z = 1$ and $2x - 2y + 3z = 2$, $x - y + z + 1 = 0$ are coplanar. Find the equation of the plane containing the two lines.

   Hint: $\frac{x-0}{3} = \frac{y-\frac{7}{3}}{-5} = \frac{z-\frac{5}{3}}{-7}$, $\frac{x-0}{1} = \frac{y-5}{+1} = \frac{z-4}{0}$.

$$\begin{vmatrix} x-0 & y-5 & z-4 \\ 3 & -5 & -7 \\ 1 & 1 & 0 \end{vmatrix} = 0, \quad \text{Expand.}$$

Ans. $7x - 7y + 8z + 3 = 0$

8. Prove that the equation of the plane through the origin containing the line $\frac{x-1}{5} = \frac{y-2}{4} = \frac{z-3}{5}$ is $x - 5y + 3z = 0$.

   Hint: $A(x-1) + B(y-2) + C(z-3) = 0$, $5A + 2B + 3C = 0$, $A + 2B + 3C = 0$,

   $$\text{Expand} \begin{vmatrix} x-1 & y-2 & z-3 \\ 5 & 4 & 5 \\ 1 & 2 & 3 \end{vmatrix} = 0$$

9. Find the image of the point $P(1, 3, 4)$ in the plane $2x - y + z + 3 = 0$.

   Hint: Line through P and $\perp^r$ to plane: $\frac{x-1}{2} = \frac{y-3}{-1} = \frac{z-4}{1}$. Image Q: $(2r + 1, -r + 3, r+4)$. Mid point L of PQ is $(r + 1, -\frac{1}{2}r + 3, \frac{1}{2}r + 4)$. L lies on plane, $r = -2$.

Ans. $(-3, 5, 2)$

10. Determine the point of intersection of the lines

    $$\frac{x-4}{1} = \frac{y+3}{-4} = \frac{z+1}{7}, \frac{x-1}{2} = \frac{y+1}{-3} = \frac{z+10}{8}$$

    Hint: General points: $(r_1 + 4, -4r_1 - 3, 7r_1 - 1)$, $(2r_2 + 1, -3r_2 - 1, 8r_2 - 10)$, Equating $r_1 + 4 = 2r_2 + 1$, $-4r_1 - 3 = -3r_2 - 1$, solving $r_1 = 1, r_2 = 2$.

Ans. $(5, -7, 6)$

11. Show that the lines $\frac{x+3}{2} = \frac{y+5}{3} = \frac{z-7}{-3}$, $\frac{x+1}{4} = \frac{y+1}{5} = \frac{z+1}{-1}$ are coplanar. Find the equation of the plane containing them.

Ans. $6x - 5y - z = 0$

12. Find the equation of the line which passes through the point $(2, -1, 1)$ and intersect the lines $2x + y = 4$, $y + 2z = 0$, and $x + 3z = 4$, $2x + 5z = 8$.

Ans. $x + y + z = 2, x + 2z = 4$

13. Find the coordinates of the foot of the perpendicular from $P(5, 9, 3)$ to the line $\frac{x-1}{2} = \frac{y-2}{3} = \frac{z-3}{4}$. Find the length of the perpendicular and its equations.

Ans. $(3, 5, 7)$, Length: 6, Equation $\frac{x-5}{-2} = \frac{y-9}{-4} = \frac{z-3}{4}$.

14. Find the equation of the line of greatest slope in the slant plane $2x + y - 5z = 12$ and passing through the point $(2, 3, -1)$ given that the line $\frac{x}{4} = \frac{y}{-3} = \frac{z}{7}$ is vertical.

Ans.

15. Find the angle between the line $\frac{x+1}{2} = \frac{y}{3} = \frac{z-3}{6}$ and the plane $3x + y + z = 7$.

    Hint: DR's of line: 2, 3, 6; DR's of normal to plane 3, 1, 1

    $$\cos(90 - \theta) = \sin\theta = \frac{2 \cdot 3 + 3 \cdot 1 + 6 \cdot 1}{\sqrt{4 + 9 + 36}\sqrt{9 + 1 + 1}}.$$

Ans. $\sin\theta = \frac{15}{7\sqrt{11}}$

16. Find the angle between the line $x + y - z = 1$, $2x - 3y + z = 2$ and the plane $3x + y - z + 5 = 0$.

    Hint: DR's of line 2, 3, 5, DR's of normal: $3, 1, -1$

    $$\cos(90 - \theta) = \sin\theta = \frac{2 \cdot 3 + 3 \cdot 1 + 5 \cdot (-1)}{\sqrt{4 + 9 + 25}\sqrt{9 + 1 + 1}}.$$

Ans. $\sin\theta = \frac{4}{\sqrt{38}\sqrt{11}}$

36.5 SHORTEST DISTANCE BETWEEN SKEW LINES

Skew lines: Any two straight lines which do not lie in the same plane are known as skew lines (or non-planar lines). Such lines neither intersect nor are parallel. **Shortest distance between two skew lines:**

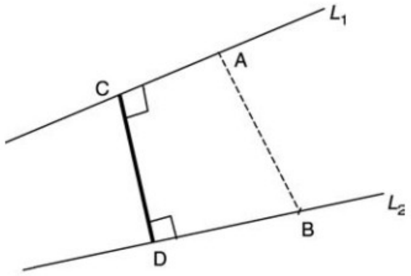


Fig. 36.15

Let L_1 and L_2 be two skew lines; L_1 passing through a given point A and L_2 through a given point

B. Shortest distance between the two skew lines L_1 and L_2 is the length of the line segment CD which is perpendicular to **both** L_1 and L_2. The equation of the shortest distance line CD can be uniquely determined since it intersects both lines L_1 and L_2 at right angles. Now $CD =$ projection of AB on $CD = AB \cos\theta$ where θ is the angle between AB and CD. Since $\cos\theta < 1$, $CD < AB$, thus CD is the shortest distance between the lines L_1 and L_2.

Magnitude (length) and the equations of the line of shortest distance between two lines L_1 and L_2:

Suppose the equation of given line L_1 be

$$\frac{x-x_1}{l_1} = \frac{y-y_1}{m_1} = \frac{z-z_1}{n_1} \tag{1}$$

and of line L_2 be

$$\frac{x-x_2}{l_2} = \frac{y-y_2}{m_2} = \frac{z-z_2}{n_2} \tag{2}$$

Assume the equation of shortest distance line CD as

$$\frac{x-\alpha}{l} = \frac{y-\beta}{m} = \frac{z-\gamma}{n} \tag{3}$$

where (α, β, γ) and (l, m, n) are to be determined. Since CD is perpendicular to both L_1 and L_2,

$$ll_1 + mm_1 + nn_1 = 0$$

$$ll_2 + mm_2 + nn_2 = 0$$

Solving

$$\frac{l}{m_1n_2 - m_2n_1} = \frac{m}{n_1l_2 - n_2l_1} = \frac{n}{l_1m_2 - l_2m_1}$$

$$= \frac{\sqrt{l^2+m^2+n^2}}{\sqrt{(m_1n_2-m_2n_1)^2+(n_1l_2-n_2l_1)^2+(l_1m_2-l_2m_1)^2}}$$

$$= \frac{1}{\sqrt{\sum(m_1n_2-m_2n_1)^2}} = \frac{1}{k}$$

where $k = \sqrt{\sum(m_1n_2 - m_2n_1)^2}$

or $l = \dfrac{m_1n_2 - m_2n_1}{k}, \quad m = \dfrac{n_1l_2 - n_2l_1}{k},$

$$n = \frac{l_1m_2 - l_2m_1}{k} \tag{4}$$

Thus the DC's l, m, n of the shortest distance line CD are determined by (4).

Magnitude of shortest distance $CD =$ projection of AB on CD where $A(x_1, y_1, z_1)$ is a point on L_1 and $B(x_2, y_2, z_2)$ is a point on L_2.

$\therefore$ shortest distance $CD =$

$$= l(x_2 - x_1) + m(y_2 - y_1) + n(z_2 - z_1) \tag{5}$$

In the determinant form,

$$\text{Shortest distance } CD = \frac{1}{k}\begin{vmatrix} x_2 - x_1 & y_2 - y_1 & z_2 - z_1 \\ l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \end{vmatrix} \tag{5$'$}$$

Note: If shortest distance is zero, then the two lines L_1 and L_2 are coplanar.

Equation of the line of shortest distance CD: Observe that CD is coplanar with both L_1 and L_2. Let P_1 be the plane containing L_1 and CD. Equation of plane P_1 containing coplanar lines L_1 and CD is

$$\begin{vmatrix} x - x_1 & y - y_1 & z - z_1 \\ l_1 & m_1 & n_1 \\ l & m & n \end{vmatrix} = 0 \tag{6}$$

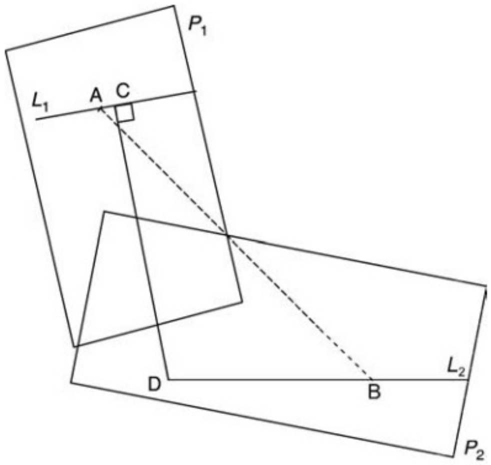

Fig. 36.16

Similarly, equation of plane P_2 containing L_2 and CD is

$$\begin{vmatrix} x - x_2 & y - y_2 & z - z_2 \\ l_2 & m_2 & n_2 \\ l & m & n \end{vmatrix} = 0 \tag{7}$$

Equations (6) and (7) together give the equation of the line of shortest distance.

Points of intersection C and D with L_1 and L_2: Any general point C^* on L_1 is

$$(x_1 + l_1 r_1, \quad y_1 + m_1 r_1, \quad z_1 + n_1 r_1)$$

and any general point D^* on L_2 is

$$(x_2 + l_2 r_2, \quad y_2 + m_2 r_2, \quad z_2 + n_2 r_2)$$

$$\text{DR's of } C^*D^*: (x_2 - x_1 + l_2 r_2 - l_1 r_1,\ y_2 - y_1 + m_2 r_2 - m_1 r_1,\ z_2 - z_1 + n_2 r_2 - n_1 r_1)$$
